The TREATMENT of hydro-peritoneum relates—*first*, to the dropsical effusion; and *second*, to the morbid conditions on which the effusion depends. As regards the dropsical effusion, the object is to effect its removal or diminution. For this object, medicinal and surgical measures may be employed. The medicinal means consist of remedies to eliminate water from the blood and thereby induce absorption of the effused liquid. The elimination of water from the blood is to be accomplished by diuretics and hydragogue cathartics. Diuretics in most cases effect but little. It is generally not easy to obtain much diuretic effect from any of the remedies of this class, the difficulty arising from the slowness with which the remedies enter the general circulation, owing to the fact that the morbid conditions giving rise to the dropsy usually involve obstruction to the portal circulation. Of 13 cases treated with diuretic remedies, in 8 no effect upon the dropsy was produced; in 5 more or less diminution of the dropsy followed; but in only 2 cases was the improvement marked and progressive. Little dependence, therefore, is to be placed on diuretics, but inasmuch as, if properly prescribed, they do not cause much disorder or prostration, they should be fairly tried. The saline and vegetable diuretics may be given in succession, and a diuretic effect is more likely to be produced if several be employed in combination.

Hydragogue cathartics act more efficiently than diuretics, but clinical observation does not furnish much evidence of success from their use. Of the different hydragogues, elaterium is the most reliable. I am accustomed

prescribe this remedy in doses of a quarter of a grain repeated at short intervals until abundant liquid evacuations are produced. Afterward doses may be repeated according to circumstances. Owing to the disturbance and prostration caused by the prolonged use of hydragogues, they are able to do harm and should not enter largely into the treatment.

The apocynum cannabinum, or the Indian hemp indigenous in this country, is considered by some as an efficient hydragogue in this form of dropsy. From some trial of this remedy in Bellevue Hospital I have been led to think it is less reliable than the elaterium. The decoction of the root or the extract may be employed.

It is important to bear in mind that in order to secure the desired effect of diuretics or hydragogue cathartics upon the dropsy the ingestion of liquids is to be restricted, the patient drinking no more than the wants of the body require.

The surgical method of effecting the removal of the liquid is tapping. With respect to this operation the views heretofore held are that it is to be resorted to only when the abdominal distension occasions great distress or danger, and not until the indirect means have been thoroughly tried; that the dropsy generally increases more rapidly after the operation; and that the operation involves danger if the system be much prostrated. These views are erroneous. Tapping effects promptly, without perturbation and without impairing the vital powers, the object for which diuretics and cathartics are employed, the latter being generally ineffectual, disturbing the digestive functions, and enfeebling the powers of life. The operation is a trivial one, involving little risk of accidents or of peritoneal inflammation. A patient under my observation had repeatedly tapped himself, using as a trocar a blade of a pair of scissors, and a piece of an ordinary clay pipe-stem as a canula. There is no danger from increased rapidity of effusion directly after the operation. The patient is spared not only the inconvenience and distress, but the permanent injury caused by the prolonged pressure of the liquid upon the abdominal and thoracic viscera, and he is in a condition more favorable for the action of remedies other than those which have special reference to the removal or diminution of the dropsy. Clinical experience shows that in some cases, even when the dropsy is dependent on cirrhosis, the liquid does not accumulate for weeks, months, and years afterward. In another work I have cited several instances in which, after a great number of tapplings, the dropsy ceased to return and recovery seemed to be complete.¹ It is judicious to resort to tapping as soon as the accumulation of liquid is sufficient to occasion much inconvenience, adopting this direct method in lieu of the indirect means, provided the latter do not prove immediately efficacious, and repeating the operation whenever the abdomen becomes again distended. These views were enunciated by me in a paper published in 1863, and were based on the results of tapping in 20 cases under my observation, the operation in these cases being performed but once in 11 cases, and in the remaining 9 cases being repeated from three to thirty times. The conclusions drawn from the facts contained in the histories of these cases are the following: 1. Tapping may be resorted to as a palliative measure when the condition of the patient is such that only temporary relief is to be expected. 2. In a certain proportion of cases the dropsy returns more or less quickly, and it may be necessary to repeat the operation many times. The repetitions, however, are innocuous. This was illustrated in one case in which it was performed thirty times within fifteen months. 3. In some cases the dropsy does not return for a considerable or even a long period, and in some cases it never returns. That it will prove a curative measure is not to be expected in the majority of cases.

¹ Vide *Clinical Medicine*.

Since the publication of that paper the correctness of these conclusions has been substantiated by a large number of cases under my observation. If it be deemed advisable to avoid a rapid withdrawal of the liquid, it may be removed by aspiration. An aspirating needle, however, should not be used. My adaptation of Davidson's syringe is the most convenient aspirator.¹

The dropsical collection is sometimes discharged spontaneously, the walls of the abdomen becoming attenuated by distension and rupture taking place. The perforation in these cases is most likely to occur at the umbilicus or at some point at the median line. In a case at Bellevue Hospital a protrusion of a cyst-like tumor took place at the umbilicus, which, after attaining a large size, burst, and the contents of the peritoneal sac were discharged through the opening. Four months after the spontaneous discharge took place the dropsical effusion had not returned.

The treatment relating to the morbid conditions on which the dropsy depends embraces, in the first place, measures to prevent an increase of the incurable lesion which exists in the majority of cases—namely, cirrhosis of the liver. It will be seen, when we come to consider this lesion, that it is caused by spirit-drinking. Change of habits as regards the use of spirits is therefore the most important of the measures coming under this head. In the second place, certain accessory or co-operative causative conditions may be removed—causes which act by impoverishing the blood and impairing the forces which carry on the circulation. This part of the treatment embraces tonic medication with nutritious diet and other measures to strengthen and invigorate the system. Well-directed treatment for this end, although not curative, will often do much to prolong life and to secure as much improvement of health as is compatible with existing structural lesions.

Mechanical compression of the abdomen after tapping, by means of a swathe or a laced supporter, is a measure of importance, as not only affording comfort, but tending to prevent a renewal of the dropsical effusion.

CHAPTER XI.

DISEASES OF THE LIVER.

Suppurative Hepatitis.—Chronic Interstitial Hepatitis (Cirrhosis).—Syphilitic Hepatitis.—Acute Yellow Atrophy of the Liver.

OF diseases affecting the solid abdominal viscera, the greater number and the more important are seated in the liver. These will be first considered, and afterward diseases of the spleen and pancreas. Acute diffuse hepatitis, considered as a disease distinct from acute yellow atrophy of the liver, has so little practical interest, except in certain tropical climates, that it is not considered in the present edition of this work. Suppurative hepatitis or hepatic abscess, chronic interstitial hepatitis, syphilitic hepatitis, and acute yellow atrophy of the liver will be treated of in this chapter, and the next chapter will embrace the different structural together with functional affections.

¹ Vide paper entitled "Early Tapping in Cases of Ascites," by the author, read at a meeting of the British Medical Association, in August, 1883, and published in the *British Med. Journal*, and in the *Journal of the Am. Med. Association*, Sept. 15, 1883.

Suppurative Hepatitis—Abscess of the Liver.

ANATOMICAL CHARACTERS.—Suppurative hepatitis is always circumscribed and leads to the formation of abscess. There may be only one abscess, which may attain a very large size, so as to occupy the greater part of the liver. Such large solitary abscesses are found especially when the disease is of traumatic origin or when it occurs in tropical climates. They are sometimes called tropical abscesses. There may be multiple abscesses, varying in number between three and forty or more. When very many the individual abscesses are usually of small size. In a case under the author's observation five and a half quarts of pus were at once evacuated by an opening made through the thoracic walls. The patient recovered. An abscess has been found to contain after death eighteen pints of pus, the entire organ except the left lobe being transformed into a mere sac. The abscess may be situated at any part of the gland. It is oftener seated in the right than in the left lobe, and oftenest at the posterior and superior portion of the right lobe.

We may assume that abscesses in the liver, as well as abscesses elsewhere, are caused by the invasion of micro-organisms. In most cases, and probably by proper methods in all, it is possible to demonstrate the presence of bacteria in hepatic abscess. In the majority of cases, at least in temperate climates, the bacteria enter the liver by the blood-current, either through the portal vein or the hepatic artery. They lodge within the capillaries of the liver, where they usually form zooglœa filling up a certain number of capillaries. The hepatic cells adjacent to these capillaries become cloudy, lose their nuclei, and disintegrate. In this way necrotic foci are produced which appear to the naked eye as grayish or yellowish-gray spots embracing one or more hepatic lobules. Around these areas of necrosis there is an emigration of white blood-corpuscles, which appear first in the interlobular connective tissue, rarely in the centre of the lobules. This accumulation of pus-cells is accompanied by the breaking down and liquefaction of the necrotic tissue. The result is the formation of an abscess-cavity. Small abscess-cavities so produced may coalesce and make larger cavities. As a rule, the longer the duration of the disease the smaller the number and the larger the size of the abscesses.

The purulent matter from an hepatic abscess often does not differ from ordinary pus, but it may contain liver-cells and shreds of necrotic tissue. It is not infrequently reddish or brownish in color from extravasated blood, or it may be stained with bile when the abscess communicates with one of the bile-ducts. Sometimes the abscess contains few or no recognizable pus-cells, but instead *débris* composed of fatty and albuminous granules, pigment-particles, bacteria, and perhaps shreds of dead tissue. The walls of the abscess at first consist of exposed hepatic tissue more or less discolored, ragged, and infiltrated with pus-cells; but after a time a wall of connective tissue is formed which increases in thickness and firmness with age. Sometimes the abscess-wall becomes gangrenous, especially when air enters the abscess or when the abscess is secondary to gangrene in some part of the body. An instance of this is reported in the author's *Clinical Medicine*.

If the contents of an abscess be discharged, its walls may cease to secrete pus and cicatrization may ensue. The pus in small abscesses may become thick and dry and remain innocuous, or an abscess may become enveloped with extremely firm fibrous tissue and cease to grow; but as a rule, if life continue, the pus makes its way, as in other abscesses, in the direction in which the pressure is least, and is at length discharged in some cavity, canal, or outlet.

When the abscess reaches the surface of the liver a circumscribed inflam-

mation of its serous covering takes place. This, as a rule, leads to adhesion between the surface of the liver and the diaphragm, the abdominal wall, or some neighboring viscus.

In the larger proportion of cases the evacuation is through the thoracic or the abdominal parietes. When it takes this direction a fluctuating tumor after a time makes its appearance, caused by the accumulation of the pus beneath the integument. The tumor, if left to itself, increases, becomes pointed, the skin becomes reddened, and finally the discharge is effected by ulceration. The most frequent situation of the tumor is below the ensiform cartilage, but it may appear at any point over the site of the liver. Sometimes the pus burrows beneath the integument, and the tumor is situated at a greater or less distance from the liver. It has been observed as high as the axilla, and below on the inner side of the thigh. In the latter case it is liable to be mistaken for lumbar abscess. Of course partial peritonitis and adhesion over the circumscribed space occupied by the abscess are essential in order that the pus may be discharged externally. This conservative provision does not always precede the opening of the abscess, and then the contents are discharged into the peritoneal cavity; peritonitis is at once developed, and under these circumstances death speedily follows. The direction next in frequency which the pus takes is through the diaphragm into the chest. Partial peritonitis precedes the perforation of the diaphragm, and partial pleuritis ensues, frequently limited to a small space, preventing evacuation into the pleural cavity. Occasionally, however, the latter conservative provision does not take place, and the pus, discharged into the pleural cavity, at once causes general pleuritis. If this be prevented by adhesion around the opening through the diaphragm, the lung becomes perforated, and the evacuation is into the bronchial tubes, the pus being discharged by expectoration. The abscess is sometimes evacuated into the pleural cavity, and afterward perforation of the lung takes place and the pus is expectorated. Other less frequent directions in which the pus is discharged are the following: Into the stomach or intestine, the pus being then discharged by vomiting or stool; into the pericardium, causing pyo-pericarditis, or if the quantity of pus be large speedy death; into the pelvis of the right kidney, the pus being discharged with the urine; into an hepatic vein or the vena cava, giving rise to purulent infection of the blood; into the gall-bladder or biliary ducts, and thus, if there be no obstruction, the pus finds its way into the duodenum. In a case which came under my observation an abscess pointed externally and was opened; subsequently perforation of the stomach took place and liquids ingested escaped through the external opening, the patient dying from inanition.

CLINICAL HISTORY.—The clinical history of hepatic abscess is obscure. The symptoms rarely point distinctly to this affection. Pain exists if the hepatitis be near the surface of the liver and whenever partial peritonitis ensues; but even then pain is not always a prominent symptom, and if the inflammation be deep-seated there may be no pain. Pain is felt in the right shoulder in a small number of cases. Rigidity of the abdominal walls over the liver or of the right rectus muscle is a sign to which much importance is attached by several observers. Febrile movement is rarely marked, and may be wanting. Chills usually occur during the suppurative process. These sometimes occur regularly, simulating intermittent fever, but generally they are irregular. Jaundice is rare. The appetite and digestion may be more or less disturbed or they may be unaffected. The nutrition may be but little or not at all affected. Reference is now had to symptoms prior to the discharge of the pus or its appearance beneath the integument. The affection is not

infrequently completely latent. It is not uncommon in tropical climates to find an abscess in the liver in bodies dead with various diseases when hepatic disease had not been suspected during life; and the first intimation of the existence of this affection during life in certain cases may be the discharge of pus from the stomach, bowels, or air-passages.

The clinical history after the discharge takes place will of course depend upon the direction in which the abscess is evacuated. In certain cases the phenomena of the affections caused by the presence of pus are superadded—namely, of peritonitis, pleuritis, pyæmia, etc. If the evacuation take place either externally or into the alimentary canal or through the bronchial tubes, symptoms are produced analogous to those connected with purulent discharges in other situations—namely, anæmia, debility, emaciation, and, in cases which pursue an unfavorable course, hectic fever, colliquative diarrhœa, and exhaustion, death taking place by asthenia.

CAUSATION.—Abscess of the liver may be produced by wounds of this organ. It sometimes, though rarely, follows injury over the region of the liver without wound of the latter or even of the integuments. Suppurative inflammation may invade the liver by extension of suppuration from adjoining parts. An abscess may be caused by perforation of a gastric ulcer.

Usually, however, the special agent which causes suppuration, and which probably consists of bacteria, is brought to the liver by the blood-current in the form of septic emboli, or it enters the organ from the intestine through the bile-ducts. In one group of cases the septic material is derived from some affection involving the rootlets of the portal vein in the stomach, the intestine, or the spleen. Ulcerative and necrotic processes in these parts, particularly dysenteric ulcers, are likely to give rise to secondary abscesses of the liver. As will be described in a subsequent article, suppurative pylephlebitis is usually accompanied with multiple abscesses of the liver. In another group of cases the primary focus of infection is in parts of the body other than those from which the portal vein derives its blood. Injuries and suppurations of the head, of the extremities, and of other parts may cause the entrance of the bacteria of suppuration into the blood, and these wherever they lodge and develop give rise to pyæmic abscesses. It is an interesting fact that although these bacteria must pass the pulmonary circulation before they are carried to the liver, nevertheless they not infrequently leave the lungs intact, although giving rise to hepatic abscesses. An explanation of the relatively frequent involvement of the liver by pyæmic abscesses is probably to be found in the slowness of the circulation in this organ in consequence of the diminished *vis a tergo*, so that bacteria more readily lodge in the hepatic than in the pulmonary capillaries.

Abscesses starting from the bile-ducts are rare, except in connection with the formation of biliary calculi within the hepatic ducts.

The causation of the large, single abscesses not uncommon in tropical countries is not understood. Such abscesses without evident causation are not uncommon in those countries. Cases apparently identical with tropical hepatic abscess sometimes occur in New York in those who have never visited a tropical country. There has been much discussion as to the relation between these abscesses and dysentery. In some cases tropical abscess appears to be secondary to dysentery; in other cases the dysentery follows the abscess, or both may develop simultaneously, as if dependent upon a common cause. Again, tropical hepatic abscess may develop without the appearance of dysentery at any time during the history of the case. A plausible supposition is that the bacteria of suppuration in these cases enter the liver from the intestine through the bile-ducts.

[That form of dysentery known as "amœbic" (see article on Dysentery) is peculiarly apt to be associated with hepatic abscess. This association has been carefully studied by Councilman and Lafleur, from whose article the following "conclusions" are quoted:

"Abscess of the liver, with or without involvement of the lung, is a frequent complication—much more so than in any other form of dysentery. The involvement of the lung may early follow hepatic involvement, and be detected by the occurrence of amœbæ in the sputum before there is evidence of liver-abscess. These abscesses differ in their anatomical features from those produced by other causes. The chief difference is found in the absence of purulent inflammation, the abscess being caused by necrosis, softening, and liquefaction of the tissue. In these liver-abscesses the amœbæ are not associated with any other organisms."—H.]

Abscess of the liver is called *primary* or *idiopathic* when not referable to some antecedent affection. The so-called tropical abscesses of the liver, at least many of them, in the present state of our knowledge are to be classified as *primary*. Hepatic abscesses resulting from pyæmia, pyelephlebitis, and affections involving the rootlets of the portal vein are called *secondary*, *pyæmic*, or *metastatic* abscesses. Pyæmic abscesses are generally small and multiple; primary abscesses are usually of large size, and are either single or few in number. It is probable that the large abscesses are due to coalescence of small abscesses.

Pyæmic abscesses of the liver are not uncommon in infants as a result of inflammation of the umbilical vein.

Primary abscess of the liver is more common in males than in females, and is rare in children.

DIAGNOSIS.—When abscess of the liver is considered clinically as an individual affection, reference is had not to the small, multiple pyæmic abscesses, which are not susceptible of diagnosis, but to cases in which the patient's life is sufficiently prolonged for the abscess to attain a certain size.

The diagnosis by means of symptoms cannot be made with any degree of positiveness prior to the discovery of the abscess by manual exploration or the discharge of pus into the alimentary canal or the bronchial tubes. The symptoms which have been named as belonging to its clinical history should suggest its existence as possible or perhaps probable, especially in a warm climate, but they are not sufficiently distinctive to render the diagnosis positive. Not infrequently grounds of even a suspicion of its existence are wanting. When a fluctuating enlargement or tumor is perceived over the site or in the neighborhood of the liver, it is to be discriminated from a subcutaneous, phlegmonous inflammation, carcinoma of the liver, a hyatid formation, and a distended gall-bladder. The first of these is distinguished by pain, hardness, and redness of the integument, preceding the sense of fluctuation. Carcinoma offers a resemblance only when the medullary variety exists. The duration of the tumor and the nodulated condition of the liver as felt through the abdominal walls will serve for the recognition of this affection. A hyatid cyst is of slower development, and is not attended with the pain, tenderness, chills, and febrile movement which usually accompany an abscess. A hyatid cyst, however, may be the seat of suppuration, becoming converted into an abscess, and then the discrimination is impossible. A distended gall-bladder, which is the tumor most likely to be confounded with an abscess, is to be distinguished by its situation, the pear-shaped form, and by the fact that in consequence of peritoneal adhesions rarely taking place it has a mobility which an hepatic abscess has not. The antecedent history is of course always to be taken into account. Enlargement of the liver frequently, but not invariably,

exists in cases of hepatic abscess, and the enlargement may be found to be limited to a particular direction, not affecting the whole organ—a point of some importance in the diagnosis. Exploration by means of a fine hollow needle attached to a hypodermic syringe is admissible whenever there is reason to suspect the existence of abscess, and by this method the differentiation of abscess from the other affections just named can be made demonstratively. There is no risk of injury in resorting to this procedure, and it should therefore not be omitted.

If the abscess discharge through the bronchial tubes the diagnosis is generally made without difficulty. The sudden expectoration of pus in large quantity without evidence of antecedent and coexisting empyema or pulmonary abscess, and the expectoration coming from the bronchial tubes of the right lung, render the diagnosis altogether probable. The presence of bile or disintegrated hepatic tissue affords demonstrative proof of the source of the purulent expectoration, but these are rarely present. A reddish or brown color of the expectorated pus is of diagnostic import. If the abscess discharge into the pleural cavity, the diagnosis is established by symptoms of hepatitis and suppuration having preceded the sudden development of pyothorax.

The discharge of the abscess into the stomach or intestine is followed by the vomiting of pus or its appearance in the stools. The diagnosis is to be based on these events, together with antecedent symptoms pointing to the existence of suppurative hepatitis. The discharge into the peritoneal cavity, pericardium, and vena cava gives rise to no phenomena distinctive of hepatic abscess. Its existence may have been foreshadowed by the symptoms preceding the discharge, but the proof can only be afforded by an autopsical examination. The discharge into the pelvis of the kidney gives rise to pyuria, but it may be difficult or impossible to determine that the pus comes from the liver and not from the kidney or some other source.

PROGNOSIS.—The prognosis, even in the cases in which the abscess is evacuated in the most favorable directions, is unfavorable. When it discharges into the peritoneum, pericardium, or vena cava death speedily follows. If it discharge into the pleural cavity the termination is usually fatal. The cases which offer a fair prospect of recovery are those in which the discharge takes place through the integument, the bronchial tubes, or into the alimentary canal.

The prospect of recovery is of course less when two or three abscesses exist than when there is a single abscess.

Statistics show the duration in fatal cases to be longest when the discharge takes place through the bronchial tubes. The average duration in fatal cases is between three and four months. In cases which recover statistics show the longest duration to be when the discharge is through the integument. The average duration in cases which recover is between four and five months.

TREATMENT.—From what has been said respecting the clinical history and diagnosis, it follows that there is seldom an opportunity to employ therapeutic measures with a view to prevent suppuration. Even if the existence of circumscribed hepatitis were early ascertained, it is doubtful if the formation of an abscess could be prevented. Cases only in which the abscess is appreciable by palpation or an exploratory puncture, and those in which the contents are discharged into the bronchial tubes and alimentary canal, admit of treatment with a positive knowledge of the existence of the affection. In a case in which the abscess is ascertained to be making its way through the abdominal or thoracic parietes an early opening should be made and the pus evacuated. If a free opening be made before the pus has made its way

beneath the integument exterior to the abdominal or thoracic walls, there is danger of the pus escaping into the peritoneal cavity in consequence of the absence of peritoneal adhesions over the abscess. Under these circumstances, in order to avoid this danger, an incision may be made through the skin and muscles down to the peritoneum without opening the abscess, and the wound filled with lint. This procedure induces firm adhesions around the wound, and in three days the abscess may be opened with safety if a spontaneous opening do not in the mean time occur. If, however, the walls of the abdomen or chest have been perforated by ulceration, a free opening may be made at once without hesitation. Prof. Janeway directs attention to the following methods of determining whether or not adhesions have taken place between the liver and abdominal wall: Hepatic friction murmur shows the absence of adhesions, but renders probable their speedy formation. Adhesions exist if the liver do not descend with inspiration. If a long needle be introduced into the liver, the part projecting will move upward as the liver descends, and downward as the liver ascends, if no adhesions exist. He advises the application of a bandage to promote adhesions by preventing movements of the liver.¹

It is advisable to resort to aspiration as soon as the existence of an abscess is demonstrated by an exploratory puncture. The withdrawal of the pus by means of a hollow needle or trocar of small size, attached to Davidson's syringe or some one of the different instruments for aspiration now in use, need not be delayed on account of any doubt respecting peritoneal adhesions. If these have not taken place, there is no risk of the escape of pus into the peritoneal cavity. By promptly aspirating, the danger of rupture of the abscess from delay is avoided, and also whatever harm may result from the entrance of air. The pus should be removed as soon as it is discovered. The aspiration should be repeated if there be a reaccumulation of pus. By pursuing this plan a free opening may perhaps not be required. If, however, there be reaccumulations of pus, an opening should be made and the abscess treated here as in other situations. The details of the treatment belong to surgery. Aside from the local treatment, tonic and supporting measures are indicated. Good diet and out-of-door life, in so far as the patient's strength will permit, are far more important than medication.

When the abscess evacuates through the bronchial tubes or the alimentary canal, palliative remedies are called for to relieve undue irritation of the bowels and air-passages. In addition to these, measures hygienic and medicinal, which tend to support, strengthen, and invigorate the system, are indicated, as when the discharge is through the integument.

Chronic Interstitial Hepatitis—Cirrhosis of the Liver.

An attempt has been made to distinguish various forms of cirrhosis of the liver, but concerning some of these forms there is much controversy. It seems proper to recognize at least three forms of hepatic cirrhosis—namely, the cirrhosis of Laennec, biliary or hypertrophic cirrhosis, and syphilitic cirrhosis; and these will receive separate consideration. The present article is devoted to a description of the cirrhosis of Laennec, which is the form longest recognized and the one generally understood when the term cirrhosis of the liver is used.

ANATOMICAL CHARACTERS.—The name *cirrhosis*, signifying a tawny or orange color, was applied by Laennec to the affection under consideration on account of the yellowish color of the nodules which the liver usually

¹ Vide paper in *Transactions of the New York State Med. Association*, vol. i.

presents in this disease. These nodules, now known to be parts of the pre-existing liver-substance, were supposed by Laennec to be new growths replacing the original parenchyma. As the essential change, however, was found to consist in the development of fibrous tissue, the term cirrhosis came to be applied not only to the liver, but also to the fibroid induration of other organs, especially of the lungs and kidneys, although this application is etymologically incorrect. The term sclerosis, signifying induration, is more appropriate. The customary division of the pathological changes of cirrhosis of the liver into two stages, in one of which the liver is enlarged and smooth or slightly granular, and in the other small, firm, and nodular, is wholly schematic and is not based upon pathological observation. A cirrhotic liver is usually small, but it may be of normal size or enlarged, even in cases of long duration, and there is no proof that the large cirrhotic livers are to be regarded as early stages of the contracted form. The left lobe is often disproportionately reduced in size, so as to appear as a mere membranous appendage of the right. The surface is nodular; but in exceptional cases it may be smooth. The nodules vary in size from a pin's head to a pea, and may be larger. Some livers are coarsely nodular, others finely granular, although the size of the nodules or granules varies much in the same liver. The nodules are usually of a yellowish or greenish color, and consist of one or more hepatic lobules in which the liver-cells are bile-stained and usually contain oil-globules. The nodules are separated from each other by grayish-white bands of newly-formed connective tissue. This nodulated aspect has given rise to the term hob-nailed as applied to some examples of cirrhotic liver. The consistence of the liver is firm, sometimes almost cartilaginous. The cut surface is dry and anæmic.

The microscopic examination shows that the most important change is an increase of the connective tissue which accompanies, under the name of the capsule of Glisson, the medium-sized and small branches of the portal vein. This increase of the interlobular tissue is not uniform, but is in the form of bands or masses which surround usually a number of lobules. The new growth of connective tissue is not always confined to that surrounding the ramifications of the portal vein; but it often invades the lobules, and also appears around the central vein, so that the lobules may be split up into larger or smaller portions by bands of fibrous tissue. The new tissue is usually rich in lymphoid and spindle cells, and with age it generally has a tendency to become fibrous. It invades the walls of the interlobular veins, so that they lose their glasticity and many of them become obliterated. The most important symptoms are referable to this destruction of a number of branches of the portal vein. The new tissue, however, is not poor in vessels, many of which are probably newly formed and derived from the hepatic artery. The branches of the hepatic artery and the bile-ducts suffer much less from the compression of the new tissue than the thin-walled portal vessels.

This development of connective tissue is attended by atrophy of hepatic lobules and destruction of a large number of liver-cells. The atrophy of the hepatic parenchyma has usually been attributed to the compression of the liver-cells by the fibrous tissue, but an equally important factor is the lack of nutrition consequent upon the obliteration of the interlobular veins. The remaining hepatic cells usually contain oil-globules and are stained with bile-pigment.

There is much plausibility in the view first advanced by Weigert, and now adopted by several authors, that the primary change in cirrhosis is degeneration and necrosis of a certain number of liver-cells. This view is based upon investigations which show that in similar chronic interstitial inflammations in

the kidney and elsewhere the primary change is degeneration of the epithelium or parenchymatous cells, and the new growth of connective tissue is secondary to this.

In many cases of cirrhosis of the liver a number of branching, narrow channels, containing a single or double row of cubical epithelial cells and resembling the interlobular bile-ducts, are met with in the connective tissue. They are too many to consist of only pre-existing interlobular ducts, and there has been much discussion as to their origin. Three theories have been advanced: one, that they are offshoots by new growths from the old bile-ducts; a second, that they are intralobular bile-capillaries which have acquired an epithelial lining; and a third, which is perhaps the most probable, that they are rows of liver-cells altered in shape and arrangement by the growth of connective tissue into the lobule.

The capsule of the liver is thickened, and often presents little villous projections of vascularized connective tissue, which develop into the fibrous adhesions so frequently connecting the liver with the diaphragm and abdominal wall.

Cirrhosis may be combined with extensive fatty infiltration and with amyloid degeneration of the liver. Especially in the latter case the liver may be of very large size.

The changes in other organs are chiefly referable to the portal obstruction and consequent damming back of blood upon the rootlets of the portal vein. The effects of this obstruction are only imperfectly relieved by the establishment of collateral channels. The spleen in the great majority of cases is enlarged and firm. This enlargement is due to congestion, and sometimes also to hyperplasia of its stroma—a condition which may be referable to the same cause as the cirrhosis. The size of the organ is not usually more than twice or thrice the normal. The increase cannot always be made out during life. The mucous membrane of the stomach and intestine is usually thickened, pigmented, and coated with more or less muco-pus; in other words, in the condition of chronic inflammation. Ascites and, in the later stages, general œdema are present. Hemorrhages into the stomach and intestine, and in other parts of the body, as in the retina, may be found after death.

The small kidney and other forms of chronic diffuse nephritis occasionally complicating cirrhosis of the liver are probably effects of the same cause.

Cirrhosis is to be regarded as a chronic inflammatory affection involving the interstitial tissue of the liver.

CLINICAL HISTORY.—Cirrhosis, as a rule, gives rise to few or no symptoms which point to the liver as the seat of disease prior to the occurrence of hydro-peritoneum. Preceding this event and afterward, pain in the region of the liver exists in only a small proportion of cases. Dropsical effusion is usually the first symptom to suggest the existence of the affection. The dropsy may occur when the patient supposes himself to be in his habitual state of health, or it may be preceded and accompanied by indefinite ailments. The dropsical accumulation increases, usually with considerable or great rapidity. It is rare for the quantity of liquid to remain at a moderate amount for a considerable period. Œdema of the lower limbs in a moderate degree is observed in a considerable number of cases before the patient's attention has been directed to enlargement of the abdomen. It is, however, probable that an amount of dropsical effusion not sufficient to attract attention always precedes the œdema of the lower limbs. After considerable abdominal enlargement has taken place the œdema increases. The limbs often are largely swollen, and the genitalia may become more or less œdematous. The œdema in these situations is attributable to pressure of the peritoneal effusion upon

the iliac veins. **Edema** of the face and upper extremities does not occur **except** in cases in which cardiac or renal disease coexists. **Edema** of the lower limbs does not occur in all cases.

Jaundice is present in a small proportion of cases, and is rarely great. The lesion does not necessarily occasion obstruction of the biliary ducts, although it must diminish the secretion of bile. **Pallor** of the prolabia and skin exists in the majority of cases. In general, the anæmic aspect is marked in proportion as other symptoms show the condition of the patient to be unfavorable. **Febrile** movement does not accompany the disease in its progress. The pulse may be not increased in frequency, or it may be more or less accelerated. It is generally soft and feeble. When the pulse is frequent, the other characters denote diminution of the vital forces, or *asthenia*.

The obstruction of the portal circulation is compensated, in a measure, by new channels of communication between the portal and the systemic veins. The most important of these are anastomosing branches which pass to the liver between the folds of the falciform ligament and in the ligamentum teres, communicating with the veins of the abdominal parietes through the epigastric and the internal mammary veins. The course of the blood in the anastomosing branches in cases of cirrhosis is the reverse of that in health, being in the latter in a direction toward, and in the former from the liver. Owing to this, the abdominal veins become dilated, and those superficially situated in some cases are seen to be more or less enlarged. A collateral circulation, in a measure, is also established through communications between the inferior mesenteric and the hypogastric veins in the hemorrhoidal plexus; by anastomosing branches between the vena portæ and the veins of the serous covering of the liver; between the coronaria ventriculi and the œsophageal veins; and by newly-formed vessels in the tissue by which the liver adheres to the diaphragm. The size of the superficial abdominal veins on either side of the median line is sometimes enormous. The dilated network of radiating veins around the umbilicus gives rise to the appearance called the *caput Medusæ*. The conservative effect of compensatory development of veins communicating with the two circulations is shown by the fact that examples of great enlargement of the vessels upon the abdomen may be observed in patients who are free from dropsy, notwithstanding a notable amount of cirrhosis.

Hemorrhage from the stomach and bowels is an occasional event. **Gastrorrhagia** occurred in 6 of about 40 cases which I have analyzed, the histories not being complete in all the cases. It preceded the hydro-peritoneum in 3 cases. **Hæmatemesis** may proceed from varices at the lower end of the œsophagus. **Enterorrhagia** coexisted with **gastrorrhagia** in 2 cases, and occurred without it in 2 cases. **Vomiting** is occasionally a prominent symptom, and **diarrhœa** is prominent in a small proportion of cases.

At an advanced period of the disease hemorrhage is liable to occur from the nostrils, sometimes from the gums, and also into the retina. In these situations the hemorrhage is attributable, not to the portal congestion, but to an altered state of the blood. The appetite is usually impaired. A sense of fulness after taking food is generally complained of if the dropsy be sufficient to distend the abdomen. Progressive emaciation attends the progress of the disease, and in an advanced stage the attenuation of the upper portion of the body, the distended abdomen, and the lower limbs enlarged by œdema render the general aspect highly characteristic.

Albuminuria is rare in cases of cirrhosis. Of 28 cases in which the condition of the urine in this respect was noted, in only 1 case was albumen present. The urine is generally scanty, but in some cases it is abundant. The coloring matter of the urine is abnormally abundant—a fact attributable to the

deficient secretion of bile; and the blood-pigment which serves for the production of the bilirubin, not being expended in the liver, is eliminated in the kidneys. The abundance of the coloring matter may be such as to give to the urine the appearance of being bloody. The urates are usually deposited in great quantity, and are notably red from the abundance of pigment.

In the great majority of cases there are no important symptoms pertaining to the nervous system. The mode of dying is usually by slow asthenia. However, the abdomen be greatly distended or if the dropsical accumulation take place very rapidly, death may be due in part to the extent to which respiratory function is compromised. The mental faculties are generally preserved up to the last moments of life. To this rule, however, there are exceptions. In 3 cases I have noted the occurrence of delirium several days before death; in 1 case the delirium was hilarious; in 1 case the patient appeared bewildered; and in 1 case the patient lapsed from childlikeness into imbecility. These cases ended in coma. In 3 other cases the patients died comatose. In 1 case convulsions occurred, followed by coma.¹ The symptoms of *icterus gravis* may appear in the last stage.

CAUSATION.—Cirrhosis in the vast majority of cases is due to spirit-drinking. Hence the significance of the term *gin* or *whiskey liver* applied by British writers to this affection. In most cases an inquiry into the mode of drinking will show that the habit has been to take raw spirits at different periods of the day, before breakfast and at other times, on an empty stomach, a little water being generally drunk after the spirits. In this mode the greatest amount of effect from a given quantity of alcohol is obtained. Occasionally patients declare that they have been accustomed to drink only wine or beer. If the use of alcohol in any form be denied, it may perhaps be said, in connection with the disease, that etiological laws are more trustworthy than human testimony. In a considerable number of cases the statements of patients in regard to the quantity of spirits taken are not reliable.

The disease is sometimes attributed to other causes than alcohol—namely, to malarial poisoning, syphilis, chronic peritonitis, chronic phosphorus-poisoning, and occlusion of the common bile-duct. The efficiency of these causes is open to doubt. At all events, if the diagnosis of cirrhosis of the liver be made, the inference of spirit-drinking is always warrantable. As to the action of alcohol in producing this affection, the explanation is that, passing readily into the portal blood from the stomach and carried at once to the liver, it excites by contact inflammation of low grade in the interlobular spaces, and hence the production of adventitious tissue; or, according to Weigert's view, it causes primarily death of a certain number of hepatic cells. So far as my observations go, they furnish no evidence of the agency of disease of the heart in the causation of this affection.

Cirrhosis very rarely occurs at less than thirty years of age, and in the majority of cases the age exceeds fifty years. Still, cases of typical cirrhosis have been observed in young children. [The late Prof. R. Palmer Howard of Montreal published a report of sixty-three cases of infantile cirrhosis, and Laure and Honorat have collected a series of fifty-one cases, mostly from English sources. It has been suggested by Wesley Carpenter of New York that cirrhosis in infants may be caused by the milk of a mother or nurse addicted to the intemperate use of alcoholic drinks.—H.] The affection is generally a result of the habitual abuse of alcohol continued for a long period. Males are affected much oftener than females—a fact readily

¹ This account of the symptomatology is based on an analysis of 46 cases of hydro-peritoneum, cirrhosis existing in nearly all the cases. (Vide *Clinical Report*, already referred to.)

explained by the dependence of the affection on the use of spirits in the manner stated.

DIAGNOSIS.—The diagnosis in most cases of cirrhosis after dropsy has occurred is made without difficulty. Hydro-peritoneum, occurring as a local dropsy—that is, irrespective of general dropsy—in a person addicted to spirit-drinking warrants an inference that this affection exists. Additional proof is afforded by the diminished size of the liver. This is ascertained by percussion. The upper margin of the liver is accurately determined by finding the line of hepatic flatness; and the lower border is determined not so accurately, but approximately, by the line of demarcation between hepatic flatness and the tympanitic resonance due to gas in the transverse colon. The latter is not exact, because tympanitic resonance is conducted for a certain distance above the lower margin of the liver, and, moreover, a distended colon may rise above the lower margin of the liver. The vertical diameter of the liver in health, on the *linea mammillaris*, is about four inches. Directly after the operation of tapping, while the abdominal walls are relaxed, the lower border of the liver may frequently be grasped by the fingers pressed upward beneath the false ribs, and its indurated, nodulated condition appreciated by palpation. It is to be remembered that a normal or even increased size of the liver would not exclude the diagnosis of cirrhosis.

The physician is rarely called upon to make the diagnosis prior to the occurrence of dropsy. It may be practicable in some cases to determine, by palpation, induration and a nodulated condition of the lower part of the organ before dropsy has taken place; and, this information obtained, the diagnosis is highly probable if the patient be addicted to spirit-drinking. Hemorrhage from the stomach sometimes precedes the occurrence of dropsy, and in a spirit-drinker this renders the existence of cirrhosis probable. Hydro-peritoneum, it is to be borne in mind, occurs in other pathological connections, as well as in cirrhosis of the liver. (Vide p. 526.) When it occurs as a result of occlusion of the portal vein by thrombosis, the peritoneal dropsy occurs rapidly, the spleen may become greatly enlarged, and the liver is undiminished in size. A number of cases of gastrorrhagia from cirrhosis without dropsy have come under my observation. I have known most profuse hemorrhage, proceeding from cirrhosis without dropsy, to be followed by the recovery of a fair condition of health. On the other hand, I have known it to cause sudden death.

PROGNOSIS.—Cirrhosis is to be regarded as an incurable lesion. After it has led to dropsy, in the majority of cases its course is progressively toward a fatal termination. The duration in sixteen fatal cases, dating from the occurrence of dropsy, varied between six weeks and seventeen months, the average duration being about five months; but doubtless in all cases the disease has existed for a considerable period before dropsy occurs. In a certain proportion of cases, the dropsy being removed, the patient may regain comfortable or even good health, and remain free from any manifestations of the disease for months and years; but sooner or later, as a rule to which there are very few exceptions, the dropsy returns, and unless life be destroyed by some intercurrent affection the disease ends fatally. Circumstances which preclude much expectation of improvement are—the coexistence of cardiac, renal, or any other important disease, considerable emaciation, sufficient debility to keep the patient in bed, greatly impaired appetite and digestion, speedy reaccumulation of liquid after tapping, and the occurrence of jaundice.

TREATMENT.—As regards treatment in cases of cirrhosis and in the great majority of the cases of hydro-peritoneum, the indications are the same.

The reader is therefore referred to the Treatment of Hydro-peritoneum, considered in the preceding chapter.

Hypertrophic Cirrhosis of the Liver.

It has already been mentioned that exceptionally in ordinary alcoholic cirrhosis the liver may be large throughout the whole course of the disease, presenting the same microscopical appearances and giving rise to the same symptoms as the more usual contracted liver. French writers¹ were the first to call attention, under the name *hypertrophic cirrhosis with severe icterus*, to a disease which they consider to possess distinctive pathological and clinical characteristics. The liver, as a rule, is considerably enlarged, its surface smooth or finely granular, and its consistence firm. Its free and cut surfaces present little yellowish islands of liver-parenchyma, between which are grayish bands and masses of connective tissue. The lobular markings are indistinct or obliterated. The new connective tissue is more uniformly distributed than in ordinary cirrhosis. It surrounds and penetrates the individual lobules² rather than surrounding groups of lobules, and is particularly rich in so-called newly-formed bile-ducts. It is maintained by Charcot and Gombault that this form of cirrhosis begins as an inflammation of the interlobular bile-ducts, and extends to the surrounding connective tissue.³ This opinion, however, is hypothetical. The spleen is constantly enlarged, usually to a greater extent than in ordinary cirrhosis.

As a characteristic feature of this form of cirrhosis, marked icterus is present throughout the greater part of the disease. Ascites is less marked than in ordinary cirrhosis, and it appears later or may be absent. Symptoms referable to the digestive tract are present, as in ordinary cirrhosis. In the later stages marked cerebral symptoms—coma, convulsions, and delirium—are frequent. Here, too, the only well-established cause is the abuse of alcoholic liquors. The duration of the disease is usually more than a year, and may be five or six years. The chief points in the diagnosis are the enlargement of the liver, the presence of icterus, the enlargement of the spleen, and the absence of marked ascites. The even surface and uniform enlargement of the liver distinguish hypertrophic cirrhosis from enlargement due to echinococcus, carcinoma, and other new growths. The causation is also to be considered in making a diagnosis. In some cases of otherwise typical hypertrophic cirrhosis with icterus, ascites has been a marked feature.

Syphilitic Hepatitis.

There are several forms of syphilitic disease of the liver. Diffuse syphilitic hepatitis is observed as a frequent manifestation of congenital syphilis, but very rarely if ever in the adult. In this condition the liver is enlarged, smooth, firm, and anæmic. The lobular markings are obscured. Upon microscopical examination there are found an increase of the connective tissue, both within and without the lobules, and a quite uniform infiltration with small round cells.

A second form of syphilitic hepatic disease is characterized by the pres-

¹ P. Olivier, Hayem, and especially Hanot, *Étude sur une Forme de Cirrhose hypertrophique du Foie*, Paris, 1876, and Charcot et Gombault, *Arch. de Physiologie*, 1876.

² For this reason it is called by Charcot insular or monolobular cirrhosis, in distinction from annular or multilobular cirrhosis, which is the ordinary form.

³ Hence this form of cirrhosis has also received the name of biliary cirrhosis. There is another form of biliary cirrhosis which is chiefly of pathological interest. This latter form is due to obstruction of the main bile-ducts, usually by a gall-stone. The retained bile causes the death of some liver-cells, and a resulting increase of interstitial tissue.

ence of gummata in the liver. These sometimes appear in new-born children as very abundant, yellowish, miliary nodules scattered throughout the substance of the liver. In the adult, gummata generally appear in the liver as scattered nodules varying in size from a pea to a hen's egg, with a dry, yellowish, caseous centre, surrounded by a grayish zone of fibrous tissue which encroaches upon the hepatic parenchyma.

One of the most characteristic forms of syphilitic disease of the liver, the one often called the *syphilitic liver*, is that in which the liver is greatly distorted in size and shape by coarse bands of fibrous tissue, which pass from the thickened capsule into the substance of the organ and cause deep cicatrix-like depressions. In this condition the surface of the liver is coarsely lobulated, and presents an absolutely characteristic appearance. In the fibrous bands gummata may be present, and it is held by the majority of writers that the fibrous tissue is developed only around gummata or as cicatricial tissue in their place. Not infrequently, however, gummata are absent in these livers, and Virchow, denying that the caseous products of a gumma can ever be wholly absorbed, regards this disease of the liver as a chronic interstitial hepatitis developed in a circumscribed form, either with or without the presence of gummata.

Finally, amyloid degeneration of the liver, either occurring independently or complicating one of the previously described conditions, is one of the manifestations of the syphilitic taint.

Syphilitic disease of the liver, as is the case with all forms of visceral syphilis, appears chiefly in the tertiary stage. Although in itself not common, it is one of the most frequent forms of visceral syphilis.

Syphilitic disease of the liver, especially the gummatous form, may give rise to no evident symptoms. The lobulated syphilitic liver may remain latent, so far as symptoms are concerned, but it usually is accompanied with some or all of the symptoms of ordinary cirrhosis, from which it is to be distinguished by the syphilitic history of the patient and the characteristic feel of the liver. The coarse nodules which can be felt on these livers resemble very much those present in carcinoma of the liver, and the distinction between them is not always easy. The umbilication, which can sometimes be felt on the cancerous nodules, may be of assistance in the diagnosis. The spleen is usually enlarged in syphilitic liver, and is not enlarged in cancer of the liver. The history of the patient is, however, the capital point in the diagnosis, as bearing upon the presence or absence of cancer or of syphilitic disease in other parts of the body.

Acute Yellow Atrophy of the Liver.

This affection is characterized, as the name denotes, by a rapid reduction in the size of the liver. Its anatomical characters were first recognized by Rokitsansky in 1842. The same disease has been known under the names *malignant* or *fatal jaundice*, *hemorrhagic icterus*, and *diffuse parenchymatous hepatitis* (Frerichs). It is a comparatively rare disease.

ANATOMICAL CHARACTERS.—In typical cases the liver is much diminished in size in all directions, but especially as regards its thickness. The volume and likewise the weight may be reduced one-half or even two-thirds. Occasionally the size of the liver is not below the normal. This happens especially when the disease attacks a liver previously enlarged or when the affection is of unusually short duration. The consistence is soft and flabby, so that the organ when resting on its concave surface is flattened, or when supported on its edge it folds up from its own weight. The capsule is wrinkled in conse-

quence of diminution in bulk of the liver-substance. In the living body the shrunken liver may sink back toward the vertebral column, so that coils of intestine find place over its anterior surface.

Upon its cut surface the liver appears intensely jaundiced. The color may be yellow throughout, but the prevailing yellow color is usually mingled with some reddish-brown patches. The reddish color may preponderate over the yellow. Great variety exists in the relative proportion and the distribution of the yellow and the red substance. The yellow substance is soft and friable. Its color is due to bile-staining and the presence of fat. The red substance is of lax texture, but of tough consistence, and on section it is seen somewhat depressed below the level of the yellow. It appears homogeneous, without any trace of the hepatic lobules, or at the most presents the faint outlines of very small lobules. In the yellow substance the outlines of the lobules are very much obscured. If seen at all, the lobules are found to be larger than in the red substance, but as a rule they are smaller than normal. The disease is often farther advanced in the left lobe than in the right. The former may be almost uniformly red, while the latter is yellow mottled with some red spots.

The microscope shows that the atrophy is due to an actual destruction of the hepatic cells by the process of fatty degeneration. Different stages of the process can usually be found in the same liver. At first the hepatic cells are swollen, cloudy, and bile-stained; but later their outlines are obscured and their substance is occupied by fat in the form either of granules or of large and small globules. There is reason to believe that the fat is formed directly from the albuminous material of the cell. Finally, there is left no trace of the liver-cells, but in their stead we find a mass of granular detritus and drops of fat, with crystallized and amorphous bile-pigment. All these conditions may be observed in different parts of the yellow substance, the degree of destruction of liver-parenchyma varying much in different cases. In some instances the detritus resulting from the disintegration of the cells seems to be more albuminous than fatty.

The red substance is usually regarded as representing a later stage of development of the yellow portion. Its color was formerly supposed to be due to blood-extravasations which may be present in the liver of acute yellow atrophy. Upon microscopical examination, however, the red substance is found generally to be composed chiefly of connective tissue, blood-vessels, and probably newly-formed bile-ducts. Some granules and small drops of fat, together with bilirubin crystals, may still be found in the connective tissue, but the greater part of the disintegrated liver-cells has been absorbed. Cells which can be recognized as hepatic cells are entirely absent or are present in small number. Leucocytes, sometimes in abundance, are found in the connective tissue. The increase in connective tissue is partly apparent, in consequence of disappearance of the liver-cells and of their fatty detritus, and partly real, by means of a new growth of the interlobular tissue. In this red substance are often found narrow, branching channels filled with a single or double row of small polyhedral cells. These epithelial canals resemble the small interlobular bile-ducts; but they are too many to consist only of pre-existing ducts. They are considered by Waldeyer, Zenker, and others as offshoots by new growth from these bile-ducts, and intended for the regeneration of the destroyed liver-parenchyma. Klebs and Perls, however, regard the cells in these canals as rows of pre-existing liver-cells altered in shape. Attempts at artificial injection of the blood-vessels of the liver after death fail in consequence of the escape of injecting material between the liver-cells.

The larger bile-ducts are usually empty. They may be inflamed and contain a secretion of muco-pus, or they may contain bile-stained fluid. The

gall-bladder contains a mucous fluid either colorless or bile-stained. It may contain apparently normal bile. Leucin and tyrosin crystals often form in the substance of the liver after death. Rod-shaped bacteria and micrococci have been found by Klebs and others in the bile-ducts and in the atrophied liver-tissue. Their accumulation in large numbers in the bile-ducts has led to the belief that they have made their way there from the intestine, but whether before or after death is a matter of uncertainty.

The changes in other organs are similar to those found in certain acute infectious diseases. The tissues are jaundiced. The blood is fluid or loosely coagulated and contains leucin and tyrosin. The cardiac muscle and the renal epithelium usually show decided fatty degeneration, not approaching, however, in degree that of the liver. The stomach and intestine frequently show evidences of inflammation. The epithelial cells of the gastric tubules undergo parenchymatous degeneration. The spleen is found swollen and soft, unless its size have been reduced by hemorrhage from some of the rootlets of the portal vein. Multiple hemorrhages occur in the majority of cases. These occur especially from vessels of the portal system. Blood is often found in the contents of the stomach and intestine, also in the mucous membrane of the bladder, pelvis of the kidneys, beneath the serous membranes, in the lungs, etc. Hemorrhages very rarely take place in the brain.

CLINICAL HISTORY.—The affection is either developed abruptly or is preceded by a prodromic stage. The premonitions are symptoms denoting gastro-duodenitis and are not significant of the affection. Without or with premonitions lasting usually from three to five days, but sometimes much longer, jaundice occurs. This is an almost constant symptom, but it may be absent. It is usually marked, but not intense, and does not differ, as regards the coloration of the skin, from ordinary jaundice. Intense cephalalgia and delirium, occurring either simultaneously with the jaundice or after a period varying between two and twenty-one days, become prominent symptoms. The delirium is often active, patients crying out and sometimes requiring restraint; but in some cases the delirium manifests itself only in quiet wandering. In a third of the cases convulsions occur. These in some cases are epileptiform, in some cases they consist of general tremor or rigor, and in some cases they are limited to a few muscles. Trismus has occasionally been observed. To the delirium and convulsions stupor is added, eventuating in profound coma. The pupils are sometimes contracted, but are usually dilated, and in some cases they are unaffected, responding readily to light. When the jaundice first appears the pulse is slow, but when delirium occurs the pulse is more or less frequent. During the progress of the disease the pulse fluctuates remarkably as regards frequency. At one time it may rise to 120, at another time falling to 80 or 90. The pulse varies also as regards other characters. In the latter part of the disease it becomes persistently rapid, increasing progressively in frequency and becoming more and more attenuated and feeble. There is generally a moderate rise of temperature in the early stage, but at a later period fever may be absent, except that sometimes shortly before death a considerable rise (104° or 105°) occurs. Hemorrhages take place in various situations, generally into the stomach and intestines, in females from the uterus, and occasionally there is hæmaturia. Extravasations are not uncommon, giving rise to petechiæ and to ecchymoses found after death in various situations. Pains in the epigastrium are common, extending to the right hypochondrium. Tenderness on pressure exists in these regions. The bowels are generally constipated. The stools are sometimes clay-colored, sometimes green and bilious, and sometimes dark from blood. The breathing is likely to be early accom-

panied by sighing, and after coma occurs the respirations are irregular and stertorous. The urine has been found to contain biliary salts by a number of observers. The small quantity present and the difficulty in the detection of these salts may explain some of the negative results of other observers. The amount of urea is notably diminished, especially in the latter part of the disease, when it may entirely disappear. Leucin and tyrosin are found in the great majority of cases. Leucin in the form of globules somewhat resembling fat is found only after evaporating the urine. Tyrosin in the form of needles appears as a spontaneous sediment. Albumen is found in a moderate quantity. Coolness and dryness of the surface exist, except under the excitement of delirium and convulsions, when the heat of the skin is sometimes increased. Enlargement of the spleen in a greater or less degree exists in most cases of this disease.

The duration of the affection is usually short. In 28 cases, a fatal termination took place in 13 within a week, in 6 during the second week, in 5 during the third week, and in 4 during the fourth week.

The termination in the great majority of cases is fatal.

PATHOLOGICAL CHARACTER.—As regards the anatomical changes in the liver, according to many authors they denote a diffuse parenchymatous inflammation. As opposed to this view, the alterations formerly regarded as evidence of parenchymatous inflammation are now attributed to degenerative processes. The theory, based upon the presence of leucocytes in the interstitial tissue, that the inflammation is interstitial, is not satisfactory. The wandering cells are most abundant in the red substance, and their presence may therefore be regarded as a secondary change. The greater number of pathologists at the present time regard the changes in the liver as primarily regressive and produced by an acute fatty degeneration.

As to the pathological character of the disease, there have been many speculations, most of which possess only historical interest, such as that the changes in the hepatic cells are due to an over-production of bile, to paralysis of the bile-ducts, to disturbances in the innervation of the liver, etc. The hypothesis now most strongly advocated is that acute yellow atrophy of the liver is an infectious disease. The changes in the liver may be regarded as local manifestations of a general infection, or the infectious principle may be considered to act primarily upon the liver and secondarily upon the blood and other organs. According to the latter view, the special poison makes its way into the system through the liver, perhaps by means of the ingress of the infectious material (bacteria?) from the intestine into the bile-ducts.

The symptomatic phenomena which form the clinical history of the disease are in a greater or less degree effects of the action of the infectious principle, the existence of which may be assumed. Certain of the grave phenomena, however, are attributable to the non-elimination of excrementitious principles which it is a function of the liver to excrete. The retention of these in the blood is denoted by the term *acholia*. The physiological discovery that the cholesterin in bile is an excretory product derived chiefly from the destructive metamorphosis of nerve-tissue is sustained by, and affords a rational explanation of, the phenomena in this disease which are referable to *acholia*. That these are effects of cholesteræmia is evidenced by clinical observations showing in this disease a notable accumulation in the blood of cholesterin, and by experiments showing the production of phenomena analogous to those of this disease in animals by the injection of cholesterin into the blood.¹ *Uræmia* is

¹ Vide "Experimental Researches into a New Excretory Function of the Liver," by A. Flint, Jr., *Am. Journ. of Med. Sciences*, 1862; also, Flint's textbook of *Human Physiology*.

less in many cases a pathological element, but the clinical history shows no toxic effects other than those referable to that element.

STATISTICS.—Of 143 cases analyzed by Thierfelder, 88 were women and 55 were men. Of the 88 women, 30 were attacked during pregnancy and 3 in childbed. Of the 143 cases, 93 were between the ages of twenty and thirty-nine; 2 were less than one year of age, and 5 were more than one year of age.

Aside from the influence of age, sex, and the condition of pregnancy, known by the above statistics, we have no knowledge of causative agencies. Held by many, the disease to be specific or infectious, it involves, of course, a special cause.

DIAGNOSIS.—The symptoms are not diagnostic of this disease prior to the occurrence of the grave toxæmic phenomena—namely, delirium, hemorrhages, etc.—in connection with jaundice. The fevers—typhus or typhoid, septicæmia, pyæmia, yellow fever—are excluded by the absence of the diagnostic features which belong to them severally, and sometimes by the absence of a febrile temperature. Diminution of the size of the liver while the patient is under observation, in connection with the clinical history, renders the diagnosis positive; but this effect does not always take place. More often it is sometimes difficult to determine accurately the vertical diameter of the liver by percussion, owing to the fact that the tympanitic resonance of the colon may be conducted upward, so as sometimes even to meet the hepatic vesicular resonance when the size of the liver is normal. Therefore, a liability to error in deciding that the liver is reduced in size. This difficulty applies to cases in which the transverse colon is distended with gas, but generally it may be correctly ascertained whether the size of the liver has diminished. The presence of leucin and tyrosin in the urine is diagnostic. The sex of the patient and the existence of pregnancy have no weight in the diagnosis, as well as the gravity of the disease, as judged by the symptoms and the rapid progress toward a fatal termination. The affection with which acute yellow atrophy is most apt to be confounded is acute phosphorus-poisoning. The latter may be recognized by the history of the case, the sudden onset of the symptoms, the severe gasping, and the demonstration of phosphorus in the vomited matters.—H.]

PROGNOSIS.—It is questionable whether this disease ever ends in recovery. A few cases of recovery have been reported, but there is perhaps more probability in these cases there was an error in diagnosis than that the disease really ended and terminated favorably.

Thierfelder gives the following statistics in regard to the duration after the appearance of grave symptoms, based on an analysis of 118 cases: twenty-four hours or less in 10; from twelve to forty-eight hours in 46; from two to three days in 26; from three and a half to four days in 17; five to seven days in 15; nine days in 2; and ten and fourteen days, in 1 case.

TREATMENT.—A few words will embrace all that is to be said with reference to treatment. With our present knowledge nothing is to be expected, but palliation, from remedies. Drastic purgatives and emetics have been tried, but the propriety of these or of other perturbatory measures is very doubtful. Symptoms which furnish indications for palliative remedies are vomiting and hemorrhages. For the vomiting and gastrorrhagia ice in small quantities, bismuth, and anodynes may be prescribed. The mineral acids are contraindicated. The symptoms referable to the circulation—namely, the fre-

quency and feebleness of the pulse, with coolness of the surface—indicate tonics and stimulants. Inasmuch as the convulsions and coma may be due to uræmia, it would be desirable, if possible, to excite the action of the kidneys; and if this be not practicable the hot-air bath and perhaps hydragogues suggest themselves as means of effecting the vicarious elimination of urea. Hemorrhage from the bowels is to be controlled by cold applications and opiate enemas. Revulsive applications over the site of the liver by means of fomentations and stimulating embrocations or rubefaciants may be of some service. Quinia in full doses deserves further trial.

CHAPTER XII.

DISEASES OF THE LIVER (CONTINUED).

Fatty Liver.—Parenchymatous Degeneration of the Liver.—Waxy Liver.—Cancer of the Liver.—Other New Growths in the Liver.—Hydatid Tumors of the Liver.—Multilocular Echinococcus.—Other Parasites in the Liver.—Pigmentary Deposits in the Liver.—Hypertrophy and Atrophy of the Liver.—Changes in the Position and in the Shape of the Liver.—Congestion of the Liver.—Portal Thrombosis.—Adhesive and Suppurative Pylephlebitis.

HAVING considered inflammatory affections of the liver, I shall take up next in order, structural affections of this organ. The more important of these are incident to an abnormal accumulation of fat, to the waxy or lardaceous alteration, to carcinoma, and to hydatid tumors. These will be considered in this chapter.

Fatty Liver.

The liver is one of the normal situations for the deposition of fat. In well-nourished, healthy individuals, the liver-cells in the periphery of the lobules contain some oil-drops. As there is great variation in the quantity of fat contained in the livers of healthy persons, it is by no means easy to determine the amount which is to be regarded as abnormal.

It is customary to distinguish between fatty infiltration and fatty degeneration of the liver. The distinction may be here repeated: In fatty infiltration or fatty growth the protoplasm is displaced by the fat, but does not suffer materially in its integrity, except by a slow process of atrophy from compression. If the fat be derived from the albuminous constituents of the cell, these are, in great part at least, renewed. In fatty degeneration or fatty atrophy the cell-substance is directly converted into fat, and is not at all or is insufficiently regenerated. There are important exceptions to the rule that in fatty infiltration of the liver the fat is present in the form of large drops, whereas in fatty degeneration it appears as small drops or molecules. The most typical example of fatty degeneration of the liver is acute yellow atrophy of this organ, to which no further reference will be made in this connection, as it has been already considered. Some writers regard the other forms of fatty liver as examples of fatty infiltration. It is true that, as a rule, they present the gross and microscopical appearances which

have been considered characteristic of infiltration; but these morphological appearances do not suffice for the diagnosis between infiltration and degeneration.

A fatty liver is usually more or less enlarged, its margins rounded, and its surface smooth. The consistence is less than in health. The specific gravity in extreme cases is so light that the organ floats in water. The weight, however, owing to increase in volume, is usually greater than in health. The color is yellowish, and the lobular markings are often obscured. Drops of oil adhere to the knife in making a section. The organ is anæmic. While the amount of fat which can be extracted by ether from a normal liver is estimated at from 3 to 5 per cent., that present in extremely fatty livers may rise as high as 40 or 45 per cent.

In the physiological accumulation of fat in the livers of women during lactation the fat is present chiefly in the central cells of the lobules. In most other cases of fatty infiltration the fat appears primarily in the hepatic cells in the periphery of the lobule, and extends, as the fatty accumulation increases, to the cells in the centre. The fat appears first as small drops, which increase in size and coalesce, until finally one large drop occupies nearly the whole of the space within the cell-contour. An hepatic cell thus altered is spherical in shape, its nucleus is pushed to one side, its protoplasm forms a narrow ring around the oil-drop, and the whole cell resembles an adipose-tissue cell. The fat may also exist between the hepatic cells, either free or in stellate cells in the intercellular spaces.¹

The essential condition for the development of fatty metamorphosis of the liver is that more fat be either introduced or produced than can be oxidized. This failure of oxidation may depend either upon an excessive introduction or production of fat in the organ, or upon a diminution in the oxidizing processes due usually to a deficient supply of oxygen to the cells. We thus find fatty livers in conditions apparently the most opposite—namely, in cases of great obesity and in cases of extreme emaciation. The causes of fatty liver may be summarized as follows:

1. Lactation. The accumulation of fat in the centre of the lobules before and during lactation is to be regarded as physiological rather than pathological.
2. Obesity. Persons who take little muscular exercise, whose food contains an excess of hydrocarbonaceous substances, and who have a predisposition, either hereditary or acquired, to the deposition of fat, may develop very large fatty livers as well as an excessive panniculus adiposus.
3. Continued and excessive indulgence in alcoholic stimulants. This leads often, but not constantly, to fatty infiltration of the liver as well as to cirrhosis.
4. Pulmonary phthisis, and less frequently other cachectic conditions, such as cancer, chronic dysentery, profound anæmias, etc. The largest fatty livers met with are those developed during chronic pulmonary tuberculosis, especially in females.
5. Phosphorus-poisoning. Although the liver here presents the appearance usually considered as characteristic of fatty infiltration, it is probable that poisoning by phosphorus leads to fatty degeneration of the liver, as well as of the kidneys, muscles, etc. Arsenic and some other poisons also occasion fatty metamorphosis of the liver.
6. The acute fatty degeneration of the new-born described by Hecker and Buhl.² The liver takes part with other organs in the general fatty degeneration.
7. Yellow fever. The fat is present in large drops, but the process is fatty degeneration. The hepatic cells usually contain fat in cirrhosis and in chronic passive conges-

¹ Perle, *Lehrbuch der allgemeinen Pathologie*, Bd. 1, p. 177; Platen, *Virchow's Archiv*, Bd. 74, p. 268.

² *Klinik der Geburtskunde*, 1, 1861.

tion of the liver. The cause here is local and referable to the interference with the circulation.

Our present knowledge is not sufficient to enable us to determine the pathological importance of fatty liver. The pressure of the fat appears to be sufficient to render the organ anæmic, but not to occasion obstruction enough to give rise to peritoneal dropsy. If the latter coexist with fatty liver, cirrhosis is combined, or there exists some other cause for the hydro-peritoneum. The spleen does not become enlarged. There may be some obstruction to the passage of bile in the minute hepatic ducts, but this is not sufficient to occasion jaundice. The function of the secreting cells must be more or less impaired when these are filled with fat, but we are unable to refer any symptoms to this condition.

The diagnosis of fatty liver can be made only when the organ is enlarged. There are no subjective local symptoms other than those dependent on the increase of size. The enlargement may be determined by percussion and by manual exploration below the false ribs. The blunt or rounded lower margin may sometimes be ascertained. The smoothness of the surface is appreciable, and sometimes also the diminished consistence; or, at all events, the absence of induration may be ascertained. An enlarged liver presenting these characters, occurring in a patient affected with pulmonary phthisis, an intemperate person, or a person of luxurious, indolent habits, may be considered as probably fatty. The probability is greater in females than in males. Simple enlargement, in this pathological connection, is not sufficient for the diagnosis of fatty liver, inasmuch as waxy liver is not infrequently associated with pulmonary phthisis; and it is not always easy to determine the physical characters which distinguish these two forms of enlargement from each other.

Fatty liver occurring in cases of pulmonary phthisis does not claim treatment. In fact, the treatment of phthisis, which in certain cases is highly useful—namely, with cod-liver oil and alcoholics—may be supposed to favor the deposit of fat in the liver. Nor, as a general remark, with our present knowledge, does it claim treatment when associated with other important affections. Occurring in persons addicted to the use of alcohol and to over-feeding, especially as regards fatty articles of diet, it is to be treated by a reformation of the habits of living—namely, by temperance or total abstinence in respect to the use of alcoholic beverages, by restricting the diet in a great measure to articles not abounding in fat, and, if the strength will permit, by increased muscular exercise. The remedies indicated are those which will tend to strengthen and invigorate the system. Fatty liver combined with chronic alcoholic gastritis offers a bad prognosis.

Parenchymatous Degeneration of the Liver.

By the terms parenchymatous degeneration and cloudy swelling of the liver is designated a condition of the organ often met with after death from fevers, diseases involving severe blood-poisoning, and affections accompanied with a high temperature. The liver is sometimes enlarged and the outlines of the lobules are indistinct. The liver-cells are swollen and filled with granules which are coarser and more abundant than normal. These granules at first are albuminous, and they disappear on the addition of acetic acid. They may, however, give place to fatty granules and drops. Some regard parenchymatous degeneration as an essential stage in the process of fatty degeneration. The clinical importance of parenchymatous degeneration of the liver is not well understood.

Waxy Liver.

The liver is one of the organs frequently attacked by waxy degeneration. This degeneration, called waxy, amyloid, lardaceous, or albuminoid, consists in the deposition of an albuminous substance, which strikes with a solution of iodine a reddish-brown or mahogany-brown color, with iodine and sulphuric acid a blue color, and with methyl-violet a red color. The reaction with iodine alone suffices as a test.

In cases of advanced waxy degeneration of the liver the organ is much enlarged. The enlargement is in some cases enormous. The weight may be twelve or fourteen pounds, and is not infrequently double the normal weight. The form of the organ is not materially altered. The surface is smooth, and the edges are usually, but not always, blunted or rounded. The consistence is notably stiff and board-like, so that thin slices are easily taken off. Notwithstanding its firm consistence, the organ cuts easily, like uncooked bacon. The interior of the liver is dry and anæmic. The cut surface, especially when examined in thin slices held to the light, presents a characteristic translucent appearance compared to uncooked bacon, wax, smoked salmon, and tissues soaked in glycerin. The lobular markings are obscured, but even in extreme cases opaque yellowish-white lines can be seen usually about the periphery and in the centre of the lobules. The amyloid or waxy change is not, as a rule, uniformly distributed, but some lobules are more affected than others; and with the naked eye, even in advanced degrees of the degeneration, lobules and parts of lobules, usually of a yellowish color from fatty metamorphosis, can be seen without the characteristic translucence. In the lesser degrees of the waxy change the organ is not at all or but slightly enlarged, and the affected parts can be distinguished only by the chemical tests mentioned. The earliest stages are to be recognized only by microscopical examination of sections stained with iodine or with iodine and sulphuric acid or methyl-violet.

Under the microscope the amyloid material appears as a white, structureless, translucent, refracting substance. The amyloid degeneration begins first in the terminal branches of the hepatic artery and in the walls of the capillaries within the lobule. If we imagine the lobule to be divided into three concentric zones, the amyloid deposit appears first chiefly in the middle zone, and then gradually extends to the centre of the lobule, while the peripheral part remains longest unaffected. The peripheral hepatic cells usually contain oil-drops, and the central cells are often stained with bile-pigment. The hepatic vein and its branches and the interlobular branches of the portal vein may become waxy. In the arteries and veins the waxy material first replaces the muscular fibres of the middle tunic, and may then extend to the other coats. In the interior of the lobules the waxy material is deposited along the capillaries between their endothelium and the liver-cells. The capillaries appear to be changed into canals with very narrow and finally obliterated lumen and thick refracting walls, between which the liver-cells are compressed and finally disappear. It is uncertain whether the waxy material be ever deposited within the hepatic cells. A large number of liver-cells are destroyed by pressure when the whole lobule becomes waxy. Usually, when the liver is the seat of this morbid change other organs are also affected, especially the spleen and kidneys, then the intestine, lymphatic glands, heart, large arteries, etc. Sometimes, even in comparatively slight degrees of the degeneration, the waxy substance is deposited in the liver as a homogeneous nodule, of the size of a walnut or even larger, and more like a tumor than a centre of infiltration or degeneration.

The affection is rare in infancy and in old age. Of 116 cases analyzed by

Frerichs and E. Wagner, 24 occurred at between ten and twenty years of age; 37 between twenty and thirty years; 31 between thirty and fifty years; 16 after the age of fifty; and 8 prior to the age of ten years. It is met with in cachectic patients who have suffered from caries or necrosis of bones. It is incident to prolonged suppuration, especially of bone, as in hip-joint disease, Pott's disease, etc.; also to cachexia from tumors, slowly-growing cancers, and other causes. It occurs in persons affected with syphilis. It has been observed to follow malarial fever. It accompanies pulmonary phthisis, especially when there are suppurating cavities. In all these connections it is a secondary affection. In a small proportion of cases it is not preceded by any other disease. Cohnheim has demonstrated that three or four months suffice for the change to be brought about. It occurs in the male sex oftener than in the female.

The pathological importance of waxy liver and its clinical history are to be based on the study of cases in which the affection is not associated with other serious affections. Such cases are not easily collected, for if the affection be not secondary, the kidneys, spleen, and other parts are liable to be similarly affected. It is undoubtedly an important affection. The functions of the liver must be compromised in proportion to the amount of the deposit. It may impede the portal circulation through the liver sufficiently to give rise to peritoneal dropsy. Jaundice very rarely occurs. Pain referable to the liver is wanting. If the kidneys be affected, general dropsy is likely to occur.

The DIAGNOSIS of this affection is to be based on the existence of enlargement and the exclusion of other affections of the liver involving increase of size. From fatty liver it is to be distinguished by the greater resistance on palpation and by the margins being in a less degree blunt or rounded. The existence of peritoneal dropsy in some cases aids in the exclusion of fatty liver. From cancer of the liver it is distinguished by the absence of tumor and the smoothness of the surface. The absence of subjective local symptoms, especially pain, aids in the exclusion of cancer. Cirrhosis generally leads to contraction of the organ; but this affection is excluded by the smoothness of the surface when it can be felt, and by either the absence of peritoneal dropsy or the existence of only a small amount of effusion. The coexistence of enlarged spleen, and the evidence of disease of the kidneys afforded by albuminuria, general dropsy, and perhaps uræmic symptoms, strengthen the diagnosis. A capital point in the diagnosis is the coexistence of affections to which, as clinical observation shows, this affection is secondary—namely, prolonged suppuration, necrosis of bones, syphilis, etc.

The PROGNOSIS is unfavorable. The lesion must be regarded as, in most cases, incurable. There seem to be some data for believing, especially in cases of cured hip-joint disease, that patients may regain good health after waxy degeneration of the liver has been established, but it is doubtful whether the waxy material be absorbed. Frerichs, Graves, and Budd, however, have observed diminution of the size of the liver in cases in which this affection was supposed to exist. Generally, the fatal termination is to a greater or less extent due to the diseases with which the affection is associated.

The TREATMENT must have reference to the morbid conditions under which the affection is developed. The iodide of potassium and the iodide of iron are considered by Frerichs as sometimes successful in cases in which syphilis is involved. In scrofulous or tuberculous patients the therapeutic measures should be directed especially to the cachexia which is to be considered as standing in a causative relation to the affection. Budd recommends the muriate of ammonia, from five to ten grains three times daily. Frerichs

attaches importance to mild alkaline remedies and the use of the sulphurous mineral waters. Dietetic and other hygienic measures are of the first importance. The body should be well nourished, the surface properly protected against vicissitudes, and as much out-of-door life as the strength will permit is advisable. Disorders of any of the functions are to receive appropriate attention. Diarrhoea occurs not infrequently, and this will claim astringent remedies and perhaps opium in small doses. Albuminuria and general dropsy furnish indications the same as when these symptoms occur in connection with any of the renal changes which, collectively, are called Bright's disease.

Cancer of the Liver.

Of the various forms of tumor which may occur in the liver, cancer is the one of greatest importance. While primary cancer of the liver is a very rare disease, the liver is one of the most frequent seats of secondary cancer. The statistics of Leichtenstern show 74 cases in which the cancer was primary, and 358 in which it was secondary. Primary hepatic cancer may develop either from the epithelium of the bile-ducts or from the liver-cells. In secondary cancer of the liver the primary tumor may be seated in various organs of the body, but it will be found most frequently in the stomach,¹ and then, in order of frequency, in the intestine, including the rectum, and the uterus. It has been demonstrated that the secondary cancerous nodules may be developed from emboli of cancer-cells transmitted from the primary growth along the portal vessels or the lymphatics into the liver, and it is believed that this is the most frequent mode of propagation. A cancer in an adjoining organ, especially the stomach, may invade the liver by continuous growth.

Primary carcinoma of the liver usually presents itself in the form of a single large tumor, more or less distinctly circumscribed, and often surrounded with several smaller cancerous nodules. Primary cancer of the liver may also occur in an infiltrated form, and in this case the liver sometimes bears considerable resemblance to a large cirrhotic liver, but the parts corresponding to the lobules are larger and of a yellowish-white color, and they present the microscopical appearances of cancer. Secondary carcinoma of the liver is almost invariably presented in the form of multiple circumscribed nodules of varying size and number. These are usually many, but the whole organ may be studded with them, while sometimes only a few nodules are present. The cancerous nodules have generally a whitish color, with scattered yellowish dots and lines. Extravasations of blood into the cancerous mass are occasionally observed. The consistence is sometimes that of scirrhus, but more frequently that of medullary carcinoma. The tumors are present as well on the surface as in the interior of the organ. A quite characteristic appearance of those nodules which reach the surface is the presence of a cup-shaped depression in the centre. This so-called umbilication is due to degenerative and wasting changes in the central or oldest part of the tumor. Partial peritonitis, causing adhesions, is generally developed when the tumors project beyond the surface, and in some cases the peritonitis becomes general.

The type of the secondary cancer conforms generally to that of the primary growth. As a rule, the cancerous alveoli are large and close together, and contain irregularly-shaped, polygonal cells. The cells may, however, be of the cylindrical epithelial type. So-called melanotic carcinoma of the liver is secondary, usually, to similar primary tumors of the choroid coat of the eye or of the skin. They are usually melano-sarcomata.

The cancerous affection usually gives rise to more or less enlargement of

¹ Of 1574 cases of cancer of the stomach analyzed by Welch, the liver was the seat of secondary cancer in 475 (30.2 per cent.).

the liver. The increase in size and weight is sometimes enormous. The weight has been known to reach twenty-five pounds. Primary as well as secondary cancer of the gall-bladder and larger bile-ducts has been repeatedly observed.

Cancer here, as in other situations, rarely occurs in early life. Of 472 cases analyzed by Leichtenstern, the ages in 37 were between twenty and thirty years; in 61, between thirty and forty years; in 250, between forty and sixty years; and in 33, more than sixty years. Of 756 cases, 334 were men and 422 were women.¹

It is a singular fact that cancer in this situation is more infrequent in tropical than in temperate climates.

Cancer of the liver being generally secondary, the symptoms in most cases are combined with those referable to other affected organs. It is much oftener secondary to an affection of other abdominal viscera than to a primary cancer of a part not connected with the portal circulation; and when developed secondarily under these circumstances the hepatic affection is liable to be overlooked.

The general manifestations of the cancerous cachexia—namely, waxy pallor, progressive emaciation, and debility—are usually present sooner or later; but in this as in other situations the affection sometimes makes considerable progress before cachectic phenomena are apparent. The affection in some cases remains for a longer or shorter period quite latent. The general symptoms may be manifest without local phenomena pointing to the seat of the affection; but in the majority of cases the affection speedily gives rise to both general and local symptoms. Pain is usually more or less prominent, referable to the liver and shooting in different directions. Tenderness on pressure is a frequent symptom. Jaundice occurred in 67 of 146 cases analyzed by Leichtenstern. In the cases in which it occurs the jaundice persists until death. Peritoneal effusion occurs in about the same proportion of cases—namely, 78 of 154 cases. This may be due to peritonitis excited by the cancerous tumors or to pressure upon the portal vein. In the latter case the effused liquid is serum without lymph; in the former, more or less lymph is exuded. Occasionally blood, extravasated into the cancer, escapes into the peritoneal cavity. The accumulation of liquid may be so great as to call for tapping. The appetite and digestion are early impaired, and at a later period diarrhoea not infrequently occurs. Oedema of the lower extremities is liable to occur in the latter part of the disease. Emaciation and loss in weight are progressive, and death takes place by slow asthenia if the patient be not carried off by some intercurrent disease. A fatal termination may be hastened by peritonitis induced by the local affection, by abundant hemorrhage, by coexisting cancerous affections elsewhere, and by various accidental complications. Aside from these circumstances the progress of the affection is sometimes rapid and sometimes slow. The duration varies from a few weeks to a year, rarely, if ever, exceeding the latter. The average duration is twenty weeks.

In most cases the DIAGNOSIS is made without difficulty. The enlargement of the organ, the presence of one or more nodules or tumors appreciable by the touch, with pain and tenderness, and frequently the knowledge of the existence of cancer in some other situation, render the nature of the affection sufficiently clear. The hepatic affections to be excluded are—abscess of the liver, cirrhosis, waxy liver, hydatids, and syphilitic growths. For their diagnostic characters the reader is referred to the articles treating of these affections. Tumors situated near the liver are to be discriminated—namely, aneurism, cancer of the stomach, peritoneal or omental cancer, a distended

¹ Vide Ziemssen's *Handbuch*.

gall-bladder, and fecal masses in the ascending or transverse colon. The antecedent and coexisting symptoms, taken in connection with the local signs, are in most cases sufficient for the differential diagnosis. Progressive loss in weight and the appearances which denote the cancerous cachexia point to a malignant disease.

The diagnosis is difficult when no evidence is obtained by palpation. If the cancerous growth be confined within the liver, and the organ be simply enlarged—still more, if the size be normal or below the size in health—the existence of the affection can only be conjectured in view of more or less pain and tenderness over the liver, conjoined with a cachectic condition and the existence of cancer elsewhere. The diagnosis is impossible in the few cases in which there are no physical signs and when the affection is latent as regards local symptoms.

The age of the patient, peritoneal effusion, persisting jaundice, and hereditary predisposition are to be taken into account in the diagnosis.

The TREATMENT has reference only to the palliation of symptoms and the prolongation of life. Pain will often require the habitual use of opium. An advantage of an early diagnosis consists in the avoidance of injurious medication. Every debilitating measure will tend to shorten life. The system is to be supported, as far as practicable, by tonic remedies, nutritious diet, and other hygienic measures. The object in this, as in other chronic incurable affections, is to endeavor to aid the system in resisting as long as possible the fatal termination.

Other New Growths in the Liver.

A brief enumeration of the more common of the other tumors found in the liver must suffice, since they generally possess no clinical interest. Primary sarcoma is not known to occur in the liver. Secondary melanotic sarcoma has been mentioned under the head of Cancer. Spindle-celled sarcomata and lympho-sarcomata have been observed as secondary growths in the liver. Tubercle appears in the liver in the form of countless miliary nodules of small, often microscopic, size in the course of general tuberculosis and in chronic pulmonary tuberculosis. Large, solitary, cheesy tubercles may occur in the liver, as in the brain and spleen, but they are pathological curiosities in this situation. Lymphomata are present in many cases of leucocythæmia and pseudo-leucocythæmia. Little nodular accumulations of lymphoid cells in the portal canals, so-called miliary lymphomata, are often observed after death from typhoid fever, and in cases of diphtheria, smallpox, and scarlatina. Adenoma presents itself in two forms—either as a nodular hyperplasia of liver-substance or as an atypical growth of bile-ducts in a nodular form. Cysts of retention developed from bile-ducts, and cysts apparently of new formation, are not infrequent, combined sometimes with cystic disease of the kidney. These cysts are sometimes lined with ciliated epithelium. Little nodules of cavernous tissue are often observed in the liver. Gummata have been mentioned under the head of Syphilitic Hepatitis.

Echinococcus or Hydatid Tumors of the Liver.

The echinococcus represents the larval stage of *tænia echinococcus*, a tape-worm about one-sixth of an inch in length, which infests the small intestine of the dog. The embryos developed from the eggs of the *tænia* which have been introduced into the human alimentary canal make their way through the blood-vessels and lymphatics into the various organs of the body, where they undergo further development. It is held that these embryos may enter the

liver also by way of the bile-ducts. An hydatid tumor or echinococcus cyst consists of a membranous bladder, varying in size from that of a pin-head to a child's head, enclosed in a fibrous capsule developed from the surrounding tissue. The hydatid vesicle is not adherent to the surrounding sac. Its wall is composed of an outer cuticular layer, which appears, under the microscope, clear and translucent, with exceedingly characteristic parallel lines, indicating a lamellated structure, and an inner granular, germinal layer provided with cilia. In simple echinococcus cysts minute whitish particles, called *brood-capsules*, which contain several *scolices* or tapeworm heads, project as outgrowths from the inner germinative layer into the cavity of the sac, which is filled with fluid. A scolex has in front four suckers and a double row of from thirty to forty hooklets. It is capable of invaginating the anterior portion of the head, so that the hooklets may appear to be in the dilated posterior part. This scolex undergoes no further development in man, but, finding its way into the alimentary canal of certain animals, especially the dog, it becomes a fully-developed tapeworm. Simple echinococcus cysts are not common in man. Usually there is an endogenous proliferation of so-called daughter-vesicles, so that the main or mother-cyst contains floating globular or ovoid cysts varying in size from that of a pea to a hen's egg, and in number from a few to several thousand. The daughter- (and sometimes grand-daughter-) cysts produce from their inner germinal layer brood-capsules containing scolices, in the manner described for the mother-cyst. Very rarely in man, but frequently in the ruminants, there is an exogenous instead of an endogenous growth of daughter-vesicles, which then appear as small sacs outside of the mother-cyst. The fluid contained in an echinococcus cyst, free from regressive or inflammatory changes, is clear, somewhat opalescent, neutral or slightly alkaline, and with a specific gravity between 1007 and 1015. It is devoid of albumen or has only a trace, is rich in chloride of sodium, and it frequently contains grape-sugar, inosite, succinic acid and succinates, and some less important ingredients. (For a description of the modifications, some of a rather complex nature, which may occur in the structure of echinococcus cysts, the reader is referred to works treating specially of entozoa.¹) Brief reference, however, must be made to the regressive changes and to the multilocular echinococcus. The fluid may be absorbed or thickened, the vesicles and scolices may undergo fatty and calcareous metamorphoses, and the fibrous capsule may shrink so that nothing is left but a fatty calcareous nodule, usually containing cholesterin and hæmatoidin crystals. The hooklets are preserved among the *débris* and aid in the diagnosis. In this way spontaneous cure may ensue. It is maintained that the destruction of echinococci is sometimes due to the entrance of bile into the mother-cyst. Inflammation, resulting in suppuration, of an echinococcus cyst may take place. Sometimes no scolices are developed. Such cysts, with or without daughter-vesicles, are called *acephalocysts*.

Echinococci occur in the liver oftener than in all other parts collectively. They may be present in any organ of the body. Usually there exists a single tumor, but there may be a dozen or more. Similar tumors sometimes coexist in other organs, especially in the lungs and spleen. Oftener found in the right than in the left lobe, they may exist in any part of the organ. The growth of the echinococcus is very slow, extending usually over years; but it is sometimes continuous, or it may become arrested at any stage by the death and consequent regressive changes of the parasite.

The echinococcus disease is less frequent in the United States than in

¹ The following works may be consulted: Davaine, *Traité des Entozoaires*, 2me édition, Paris, 1877; Leuckart, *Die menschlichen Parasiten*, i., Leipzig, 1863; Heller, in *Ziemssen's Cyclopædia of the Practice of Medicine*, vol. iii.; Cobbold's *Treatise on Parasites*.

Europe and some other countries. It is said to be particularly common in Iceland, where the inhabitants live in close community with dogs. Osler has collected 61 cases occurring in this country. Of these, fully one-third, and probably more, were in foreigners. Echinococci are said to be not infrequent in hogs and cattle in this country.¹

The clinical history offers nothing which points to this or any affection of the liver until the tumor attains a sufficient size to occasion inconvenience by pressing on the adjacent parts. As long as the tumor is contained within the gland it is usually completely latent. It gives rise to neither pain nor tenderness, and the hepatic functions are not appreciably disturbed. Hydatids of considerable size are not infrequently discovered unexpectedly in autopsical examinations. If, however, the cyst be situated near the periphery and project considerably beyond the organ, it is likely to give rise to local symptoms directing attention to the part. Usually, under these circumstances pain is slight or wanting, but there is a sense of fulness and uneasiness in the neighborhood of the liver. When pain is present it is due mainly to inflammation developed by the pressure of the tumor. The pressure upon adjacent parts gives rise to symptoms which differ according to the direction in which the tumor extends. Extending into the thoracic space, it gives rise to dyspnoea on exertion, cough, and palpitation. Pressure on the stomach and intestine is liable to produce vomiting and constipation. If the vena cava be compressed, oedema of the lower extremities follows. The growth of the tumor is attended by little or no constitutional disturbance. There is no febrile movement, and the nutrition of the body may be unimpaired.

Important local and general symptoms, however, are incident to the bursting of the cyst or the discharge of its contents by ulceration. These symptoms will depend on the direction in which the opening occurs. Pleuritis, pericarditis, and peritonitis are results of the rupture respectively into the pleural, pericardial, and peritoneal cavities, and the two latter affections thus induced are uniformly fatal. The first of these three affections is very likely to prove fatal. Opening into the vena cava, it gives rise to the symptoms of obstruction of the pulmonary circulation from embolism. If the lung be perforated without general pleuritis, cough and expectoration are prominent symptoms, and in the latter are contained, from time to time, hydatids, together with bile in some cases. If perforation of the lung ensue after the evacuation into the pleural sac, the phenomena of pneumo-hydrothorax are developed. Perforation of the stomach or colon is usually attended by severe pain, and is followed by the discharge, either by vomiting or stool, of hydatids. The discharge of the hydatids into the biliary passages gives rise to jaundice. Jaundice, irrespective of this cause, is rare in cases of hydatid tumor. Dropsy of the peritoneum does not belong to the clinical history of the affection. Both jaundice and hydro-peritoneum, however, are occasional effects of the pressure of the tumor on the biliary passages without the liver and on the vena portæ.

A DIAGNOSIS is impracticable so long as the growth does not extend beyond the gland. The affection can be recognized only when either the tumor is discoverable by physical examination or hydatids are discharged through some outlet. A tumor extending from the anterior surface or from the inner or lower margin of the liver, after it has attained a certain size is appreciable by the touch. The diagnosis now involves its discrimination from other tumors. When situated over the liver it is to be discriminated from cancer and hepatic abscess. This discrimination may generally be made without much difficulty. From cancer it is distinguished by its smooth and globular

¹ Osler, *Am. Journ. of the Med. Sciences*, Oct., 1882.

form, its elasticity and the sense of fluctuation, the freedom from pain, and the absence of the cancerous cachexia. From hepatic abscess it is distinguished by the slowness of its growth, absence of pain and tenderness, and by its being unattended by the constitutional symptoms to which suppuration generally gives rise—namely, chills, fever, etc. Extending from the left border, it is to be discriminated from cancer of the stomach or of the pancreas, and from an aneurismal tumor. The connection of the hydatid tumor with the liver, and the disconnection of other tumors, may generally be ascertained by palpation and percussion. Cancer of the stomach or of the pancreas is usually accompanied by pain, and in the former situation by notable gastric symptoms. The cancerous cachexia may be apparent. A cancerous tumor is generally irregular or lobulated. An aneurismal tumor is distinguished by its anterior and lateral pulsation, the frequent occurrence of murmur, and generally by persistent gnawing pain referable to the back.

A physical sign sometimes obtained by percussion is highly distinctive of a hydatid tumor. If percussion be made upon the tumor, the fingers of the left hand or the whole hand being placed over the tumor, the collision of the floating hydatids with each other causes a characteristic tactile vibration known as the hydatid fremitus. The sensation is compared to that felt when percussion is made upon the hand resting on a mass of jelly. By placing the stethoscope over the tumor and practicing percussion, a peculiar sound is elicited, which in some cases has a musical intonation like the sound from a violoncello. These signs are obtained in only a certain number of cases.

An hydatid tumor encroaching more or less upon the thoracic space gives rise to flatness on percussion and absence of respiratory murmur from the base of the chest upward in proportion to the height to which the tumor extends, with perhaps more or less displacement of the heart. The signs are those of pleuritis with effusion. Attention to the following point will suffice for the discrimination in many if not in most cases: In pleuritis the level of the liquid effusion when the patient is sitting or standing is denoted by flatness extending upward on the anterior aspect of the affected side of the chest to about a uniform height; but the flatness due to a tumor extending into the thoracic space generally has an irregular limit; that is, the flatness extends higher at some than at other points. Moreover, the test of the presence of liquid effusion afforded by the results of percussion when the position of the body is changed from the vertical to the recumbent is not available in the case of a tumor.

The diagnosis in cases in which the tumor opens externally or its contents are discharged by expectoration, vomiting, or stool, is established by the discovery of hydatids, either entire or the remains left after their destruction. If entire, they are easily recognized with the naked eye. If not entire, the microscope is to be employed to discover shreds of the characteristic membrane and hooklets of echinococci.

The most certain means of arriving at a positive diagnosis in cases in which the contents of the tumor are not discharged through some outlet externally is by withdrawing a portion of the liquid by means of an exploring canula. If the fluid withdrawn be clear, free from albumen, and rich in chloride of sodium, there can scarcely be room for doubt as to the nature of the tumor. The presence of succinic acid or of glucose is evidence in favor of echinococcus. If the contents have become mixed with blood or inflammatory products, the chemical examination is not conclusive. If scolices or their hooklets, or portions of the finely-striated but otherwise homogeneous echinococcus membrane, be found in the fluid, the diagnosis is established.

Hydatid tumors are not in themselves serious, but they do harm by pressure upon adjacent parts. They prove serious also by opening into certain situa-

tions in which grave or fatal diseases are induced by their presence. The prognosis in these cases has been already stated. If the opening occur into a situation from which the contents are discharged from the body—namely, through the integument into the bronchi or into the alimentary canal—recovery may be hoped for or expected according to the circumstances in individual cases. If recovery do not take place, the fatal termination is preceded by protracted irritation and progressive exhaustion, due generally to suppuration within the sac.

In the TREATMENT of hydatid tumors of the liver there are two objects to which measures may be directed. One object is the evacuation of the tumor, and the other is to arrest its growth and promote absorption of its contents. Medicinal means are applicable to the last-named object only; and the first object is of course to be effected exclusively by surgical interference.

Several internal remedies have been proposed as capable of destroying the hydatids. On the death of the parasite the tumor ceases to grow, and, gradually diminishing in size, it may finally disappear. This is the mode in which a spontaneous cure not infrequently takes place. Calomel, common salt, and the iodide of potassium have been thought to have the power of effecting the destruction of the hydatids, these remedies acting by being absorbed and exerting a poisonous effect upon the parasites. Their efficacy, however, does not appear to have been established by clinical observation.

An effectual surgical measure in certain cases is to make an incision into the tumor sufficiently large to remove both the liquid and the hydatids which it may contain. This operation is warrantable when the tumor extends in an outward direction, provided adhesions have taken place around a space in which the opening is made, so that there is no danger of the escape of the contents into the peritoneal sac. A method of determining whether adhesions exist or not is to ascertain if the tumor or the liver be depressed by a forced inspiration or remain fixed in the same position. This point is readily ascertained by marking on the chest or abdomen the situation of the tumor, or the lower margin of the liver, or its upper margin, successively at the end of an expiratory and an inspiratory act. After evacuating the tumor cicatrization may be expected to follow, but this result may be preceded by suppuration within the sac, which may be continued so as to involve danger from constitutional irritation and exhaustion.

A simple method of treatment which often suffices for the cure is to withdraw a portion of the liquid by aspiration, puncturing the sac with a fine hollow needle or trocar. The destruction of the parasite may be in this way effected, and the risk of the escape of the liquid into the peritoneal cavity is extremely small. The injection of medicated liquids into the sac is unnecessary, and increases the liability to suppuration. If suppuration occur, a free opening may be required. In order to avoid danger from a free opening, Simon recommends the following procedure: "The tumor is punctured with a fine trocar and the canula allowed to remain; in twenty-four hours peritoneal union will have taken place. Eight days afterward a second trocar is thrust in at some distance from the former, and the canula again allowed to remain. After about twenty-two hours the two punctured wounds may be united by an incision."¹ For the destruction of the parasite electricity, transmitted through needles introduced into the tumor, has been effective.

The prophylaxis of hydatids in the liver and elsewhere is to be based on the source—namely, the ova of the *tænia echinococcus* developed in the intestine of the dog. Hence it is important, as far as practicable, to avoid the possibility of the introduction of ova from the excreta of this animal into the human intestine.

¹ Vide Heller, in *Ziemssen's Cyclopaedia*, Am. ed., vol. iii.

Multilocular Echinococcus.

The echinococcus multilocularis represents a peculiar form of development of this parasite. With very few exceptions it has been found only in the liver. It forms a hard, smooth tumor, often of very large size, which takes the place of the liver-parenchyma. Upon section this tumor bears a striking resemblance to a colloid cancer, with which it was formerly confounded. In the meshes of a firm, fibrous stroma are small cavities containing a gelatinous material in which are present the characteristic echinococcus membranes, rarely in the form of vesicles. Fully-formed scolices are rarely found, but their hooklets are more frequently observed. The tumor has a tendency to form in its central part ulcerative cavities sometimes filled with pus. Virchow, who first recognized the nature of the disease, holds that the echinococcus multilocularis develops in the lymph-vessels; and Friedreich, that it grows in the blood-vessels and bile-ducts.

The disease has been observed almost exclusively in South Germany and Switzerland. Prudden describes a case occurring in a German who had been in this country five years.¹ The symptoms are usually more pronounced and graver than those of ordinary echinococcus. They are—jaundice, often intense and rarely absent, gastric irritation, enlargement of the spleen, sometimes pain and tenderness in the region of the liver, progressive emaciation, and, at the last, often hemorrhage from different mucous membranes. The prognosis is very grave. The enlarged liver presents usually a smooth, hard surface, and not the nodular swellings of ordinary echinococcus and cancer. The duration, too, is longer than that of cancer, which is not usually accompanied with enlarged spleen or such intense jaundice. There is no effectual treatment.

The other parasites which are found in the liver are of little clinical importance, at least in this climate, on account either of their infrequency or their innocuousness. The cysticercus cellulosæ is a rare parasite in the liver. Various species of distoma, of which the most common in this climate are distoma hepaticum, or liver-fluke, and distoma lanceolatum, produce serious disturbances in dogs, sheep, and some other animals, but they are infrequent in man. They are found in the gall-ducts and in the gall-bladder. In India, and especially in China, certain species of distoma, known as distoma crassum and distoma spathulatum, or sinense, are said to be common and to cause serious hepatic disorders. The distoma hematobium, found by Bilharz in Egypt, occurs in the portal veins, but causes no lesion of the liver.

The pentastoma denticulatum, the larval stage of pentastoma tænioides, infesting the nasal cavities of dogs, horses, and some other animals, has been frequently found, especially in parts of Germany, in the human liver, where it usually occurs in small calcareous cysts. The pentastoma constrictum has been observed, especially in Africa. A specimen of this parasite, which had been expectorated by a patient under his care, was sent to me by Dr. M. M. Campbell of Missouri. From seventy-five to one hundred of these parasites had already been expectorated. The liver was much enlarged, and the primary habitat of the parasites was probably in this organ.² The pentastomes are not known to interfere with the hepatic functions.

The ascaris lumbricoides sometimes enters the common bile-duct from the intestine. It may cause obstruction of the ducts and jaundice, but this occurrence is very rare. The psorosperms which are so common in the rabbit's liver have been occasionally found in the human liver, where they generally prove harmless.

Pigmentary Deposits within the Liver.

A deposit of dark-brown granules in the liver, giving to the organ a steel-gray, chocolate, or bronzed appearance, is observed not infrequently after death from malarial fevers. A similar deposit generally coexists in the spleen, and may be found in other organs. It is found in the blood, especially within the portal vessels. The source of the pigmentary matter, together with its pathological relations and effects, cannot be considered as settled. With our present knowledge, the pigment-liver is hardly entitled to be reckoned in the list of hepatic affections. It will be referred to hereafter as entering into the anatomical characters of the periodical fevers.

A certain amount of bile-pigment is often present in normal livers, and this amount is increased in diseases causing obstruction to the flow of bile.

In severe anemia, particularly in pernicious anæmia, the liver contains a large number of colorless granules which are stained greenish-black by treatment with sulphide of ammonium, and which therefore contain iron. These ferruginous particles are probably the result of an extensive destruction of red blood-corpuscles.

Hypertrophy and Atrophy of the Liver.

Hypertrophy of the liver was supposed to be not infrequent before the several degenerative affections to which this organ is liable were as well understood as now. While the liver may be greatly increased in size by tumors, abscesses, fatty and amyloid degenerations, congestion, and certain forms of cirrhosis, there is no evidence that a simple hypertrophy of the liver with preservation of its normal structure occurs as a pathological condition. The size of the liver varies considerably within normal limits.

It has been proven by experiments that the liver possesses to a moderate degree the power of regeneration of its tissue when this is destroyed to a limited extent. We may assume that this regenerative power is active after such degenerations of liver-cells as sometimes occur in phosphorus-poisoning, typhoid fever, cholera, and certain other diseases.

Simple atrophy of the liver occurs as a senile change and in diseases accompanied with prolonged marasmus. The liver is uniformly diminished in size, and the liver-cells often contain a considerable amount of reddish-brown pigment (brown atrophy).

Changes in the Position and in the Shape of the Liver.

Aside from congenital malformations, which are of no special clinical interest, the liver may undergo changes of position which it is important to understand for diagnostic purposes.

The liver is readily displaced downward by pressure from above, as by large pleuritic effusions, and is displaced upward by fluid accumulations in the peritoneal cavity, by abdominal tumors, and by tympanitic distension of the intestines. It possesses a certain degree of mobility upon its transverse axis, and, in consequence of this, pressure from below, as by the distended colon, may cause the liver to rotate, so that its anterior surface becomes superior, and the normal liver-flatness in front almost or wholly disappears. Its mobility may be abnormally increased by relaxation of its ligaments, and sometimes, especially in women with flabby abdominal walls who have borne many children, it is considerably dislocated and is very movable (*hepar mobile*). Sometimes coils of intestine, particularly the transverse colon, may pass between the liver and the anterior abdominal walls, so as to substitute a tympanitic resonance for the normal hepatic flatness.

The liver may be variously distorted by pressure. The most important of these distortions is that produced by tight-lacing. In consequence of constriction of the lower part of the chest it is compressed from side to side, and a circular furrow or depression is produced which may be so deep as to almost divide the organ, especially the right lobe, transversely into two parts, of which the lower may even be tilted up over the upper division. Corresponding to the tight-lace furrow the liver-substance is atrophied and the capsule is thickened and opaque.

The liver may be dislocated downward by the traction of peritoneal adhesions below the organ. In an instance observed at Bellevue Hospital the lower margin was a little above the crest of the ileum. In a case reported to the New York Medical and Surgical Society by Willard Parker the dislocation was an effect of a fatal injury. Dr. Alex. Y. P. Garnett has reported a case in which dislocation followed a violent muscular exertion, a spontaneous return of the organ to its normal situation taking place within three days.¹

Restoration in cases of dislocation—or, as it has been termed, wandering liver—is to be effected, if practicable, by pressure from below, and the organ should be retained in place, by a properly-adapted abdominal supporter.

Congestion of the Liver.

Congestion of the liver may be either active or passive. Active congestion is caused by an increased flow of blood to the liver through the hepatic artery or the portal vein. Passive congestion is the result of some obstruction to the outflow of blood from the hepatic veins.

A physiological *active congestion* of the liver occurs during digestion, and it is believed by many writers that this form of congestion may become abnormal in degree or in persistence in those who indulge excessively in the pleasures of the table and who lead sedentary lives. It is held also that highly-spiced food and immoderate use of alcohol tend to produce active hyperæmia of the liver. Active congestion is said to be more common in tropical than in temperate climates, and is attributed to the use of highly-seasoned food, to telluric influences, and to malarial infection.

Congestion of the liver formerly played a more important rôle in pathological speculations than at the present time. It entered into the conception of so-called abdominal plethora, and in connection with an abnormal secretion of bile it was regarded as an important cause of the so-called bilious disorders. A sense of weight in the right hypochondrium, impaired appetite and digestion, sometimes nausea and vomiting, a bitter taste in the mouth, pain in the head, a coated tongue, and a sallow complexion, are symptoms often attributed to hepatic congestion. It is by no means certain that this pathological condition is represented by the foregoing symptoms. Active congestion doubtless occurs, but the agencies producing it and its morbid effects are not understood. The diagnosis with our present knowledge is not practicable, and the physician, therefore, in treating it acts upon the suspicion of its existence.

Chronic passive congestion, on the other hand, is a well-defined condition, the causation of which is understood. Anything which obstructs the current of blood through the hepatic veins, through the inferior vena cava above the entrance of the hepatic veins, through the lungs, or through the heart causes passive congestion. The obstruction is usually seated either in the heart or in the lungs. The various forms of uncompensated valvular lesions of the heart, particularly mitral and tricuspid lesions, insufficiency of the power of the heart's action due to myocarditis and obstructions in the pulmonary cir-

¹ Vide *Am. Journ. of Med. Sciences*, Jan., 1881.

lation, such as those resulting from emphysema, chronic pleurisy, fibroid thisis, or tumors of the mediastinum, are the most frequent causes of chronic passive congestion.

In consequence of the damming back of blood upon the hepatic veins, first the central veins of the lobules, and next the lobular capillaries immediately surrounding these veins, become over-distended with blood. Thus the centre of the lobule presents a dark-red color, increased usually by the presence of brownish pigment-granules in the central hepatic cells. In contrast with this the periphery of the lobule is pale and yellowish from the comparative anæmia in that situation and from the presence of oil-drops in the peripheral liver-cells. A liver presenting the appearance described is called a nutmeg-liver. It is usually more or less enlarged, and is firm in consistence.

When the congestion is long continued and severe, the tissue at the centre of the lobule consists of little else than dilated blood-vessels, between which the liver-cells have become atrophied from compression. Whole lobules may be reduced to this cavernous tissue, which appears on section dark red and depressed. This change is called red or cyanotic atrophy of the liver. It is thus a late stage of the nutmeg-liver. The organ is diminished in size, the consistence is firm, and the capsule is usually thickened and opaque. Cyanotic atrophy is often associated with more or less increase of the interlobular connective tissue.

When the condition of chronic passive congestion is well marked during life, it is possible by means of palpation and percussion to make out enlargement of the liver. It may extend a hand's breadth below the free border of the ribs. There may be considerable variation from time to time in size, corresponding to variations in the amount of obstruction to the circulation.

The SYMPTOMS referable to the nutmeg-liver are not well defined. There may be a feeling of weight, but rarely of actual pain, in the right hypochondrium. A slight icteroid hue of the conjunctivæ and of the skin may be present, and this, combined with the cyanotic color, gives a characteristic aspect to many cases of heart disease and of emphysema. The obstruction to the flow of blood through the liver leads to congestion in the rootlets of the portal vein, causing passive congestion of the spleen, of the stomach and intestine, and of the peritoneum. In this way digestive disturbances and a certain amount of ascites are produced. These effects, however, belong to the general venous congestion which is present in most cases of nutmeg-liver, and only exceptionally are they out of proportion to other symptoms of general venous congestion. In the atrophic stage of the nutmeg-liver the symptoms of portal congestion become more marked.

The TREATMENT in cases of chronic passive congestion of the liver is directed not to the condition of this organ, but to the causes which obstruct circulation; that is, to heart disease, emphysema, or some of the other causes already mentioned. Saline laxatives are useful in relieving temporarily the portal congestion.

Portal Thrombosis—Pylethrombosis—Adhesive and Suppurative Pylephlebitis.

Thrombosis of the main trunk of the portal vein or of its larger branches may be due to pressure from without, caused by enlarged glands, abscesses, or impacted gall-stones, fibrous bands resulting from localized or general peritonitis or from a chronic inflammation of the surrounding connective tissue (portal phlebitis). It may be caused by foreign bodies within the vein or by calcific plates resulting from chronic endophlebitis. It may be secondary

to cirrhosis. A blow upon the abdomen has been known to cause portal thrombosis. In rare instances the thrombus is due to general weakness of the circulation in consequence of marasmus.

In recent cases the thrombus is grayish-red or yellowish in color and more or less adherent to the inner coat of the vessel. It either partially or completely occludes the vessel. In the so-called adhesive pylephlebitis the presence of the thrombus leads to secondary changes in the wall of the vessel, resulting in what is regarded as an organization of the thrombus. The thrombosed vessel is converted into a fibrous cord, either solid or canalized. In the latter case the circulation may be partially or completely re-established, and recovery takes place. If the main trunk of the portal vein be occluded, life is not prolonged sufficiently for the organizing process to take place.

The SYMPTOMS of adhesive pylethrombosis or pylephlebitis are referable to the mechanical obstruction of the portal circulation. If the occlusion be complete or nearly so, it gives rise to peritoneal dropsy. The rationale is the same as in dropsy caused by cirrhosis of the liver. From the latter it is distinguished by a more rapid accumulation of liquid, and by its occurrence in persons not addicted to spirit-drinking, this being the cause, *par excellence*, of cirrhosis. Hemorrhage from the stomach or intestine may occur, as in cases of cirrhosis, and sometimes this precedes the occurrence of dropsy. The spleen is more or less enlarged. The superficial abdominal veins may become dilated. Anorexia and loss of digestive power are symptoms occurring without much delay. Diarrhœa occurs frequently. The lower limbs and genitals become greatly œdematous. There is progressive loss of strength without fever, and death may take place within a few weeks by asthenia. Rapidly fatal asthenia may follow a profuse hemorrhage. Jaundice is often present. Its occurrence may be explained by the diminished pressure in the branches of the portal vein, or in some cases by a coincident obstruction of the bile-ducts from the same causes which induce thrombosis of the veins. In general, however, the substance and the functions of the liver are little disturbed by a simple portal thrombosis. This is due to the fact that, as has been shown by the experiments of Cohnheim and Litten, the blood carried by the hepatic artery is sufficient for the nourishment of the liver and for the secretion of bile.

The TREATMENT embraces, as an important palliative measure, paracentesis abdominis, repeated as often as the dropsical accumulation recurs. Measures to arrest hemorrhage are indicated when this occurs. Additional measures are those to meet other symptomatic indications and to support the powers of life.

Recovery has taken place in several cases under my observation, in which ascites and intestinal hemorrhage were referable to portal thrombosis.¹

In pylethrombosis, as just described, or adhesive pylephlebitis, inflammation is limited to the site of the thrombus. The phenomena of the disease are referable to occlusion of the portal vein. *Suppurative pylephlebitis*, on the other hand, involves the presence of emboli or thrombi, which act, not only mechanically, but by the agency of a noxious principle. Owing to this principle they give rise to multiple hepatic abscesses. The clinical history is that of pyæmia, often without symptoms pointing directly to the liver. Pain and tenderness in the right hypochondrium, jaundice, and enlargement of the liver may be present. To these symptoms are added those of obstruction if, as may or may not be the case, the portal vein or its principal branches be occluded.

The most frequent causes of suppurative pylephlebitis relate to ulcerative

¹ Vide paper entitled "Early Tapping in Cases of Ascites." (See note, p. 532.)

and suppurative processes within the district of the portal circulation. In this category belong abscesses of the spleen, typhlitis and perityphlitis, ulceration of the gall-bladder, stomach, and intestinal tract, particularly dysenteric and sloughing ulcers, abscesses and ulcers of the rectum, such as sometimes follow surgical operations in that neighborhood, and inflammation of the umbilical vein in the newly-born infant. A foreign body in the portal vein may give rise to suppurative pylephlebitis. In an autopsy at Bellevue Hospital by Dr. Janeway a fish-bone two inches long was found, one half in the superior mesenteric and the other half in the portal vein. The portal vein contained puriform matter and the liver multiple abscesses. Another similar case has been reported. A thrombus in the portal vein is sometimes a direct continuation of a thrombus primarily formed in some of the rootlets of the vein at the diseased part. Sometimes the thrombosis follows the lodgment of an embolus broken off from a thrombus situated in some of the afferent branches of the portal vein.

In suppurative pylephlebitis the thrombus breaks down into a puriform mass from which emboli are detached, the vascular walls become infiltrated with pus-cells, and the suppurative process extends to the surrounding connective tissue and the hepatic parenchyma, the result being the production of abscesses in which the presence of bacteria can be demonstrated. The abscesses are usually not of large size, but they are many, and their distribution can sometimes be seen to follow the course of the portal vessels within the liver.

The DIAGNOSIS of suppurative pylephlebitis is to be based on the local symptoms already stated, in conjunction with the symptoms of pyæmia and the antecedent existence of some one of the causative conditions which have been named. Certain of the latter are not discoverable before death, and there are cases in which the post-mortem examination sheds no light on the etiology. The affection is then said to be idiopathic.

There is no ground for encouragement in the way of prognosis, and the treatment has relation solely to symptomatic indications and to support.

CHAPTER XIII.

DISEASES OF THE BILIARY PASSAGES.—JAUNDICE.

Inflammation of the Biliary Passages.—Dilatation of the Gall-bladder: Cancer of the Gall-bladder.—Jaundice, or Icterus.—Weil's Disease—Acute Febrile Icterus—Infectious Icterus.—Functional Affections of the Liver.

Inflammation of the Biliary Passages.

THE most frequent form of inflammation of the biliary passages is *simple inflammation*, or, as it is often called, catarrhal inflammation. The seat of the inflammation is usually the lower part of the ductus communis ledochus, particularly the part contained in the wall of the duodenum. Inflammation is in the great majority of cases simply a continuation of similar inflammation affecting the stomach and the duodenum. The anatomical changes in simple inflammation of the common bile-duct

consist in hyperæmia and swelling of the mucous membrane and increased secretion of mucus. As in similar inflammations elsewhere, these changes may not be well marked after death, the congestion and swelling especially being often absent upon post-mortem examination.

The importance of acute simple inflammation of the common bile-duct consists in the obstruction which is offered to the flow of bile by the swelling of the mucous membrane and the accumulation of mucus. Inasmuch as the force which propels the bile through the biliary passages is slight, being chiefly due to the continued secretion of bile by the liver-cells and the movements of the diaphragm, even an insignificant obstruction suffices to impede its flow. The obstruction offered to the passage of bile causes an accumulation of bile in the ducts within the liver and an absorption of accumulated bile by the lymphatics. The bile thus absorbed enters the blood-current by way of the thoracic duct and causes jaundice.

The jaundice which is produced by simple inflammation of the intestinal part of the common bile-duct is usually called simple jaundice or catarrhal jaundice. Simple jaundice, caused in this way, is a very common affection. Being secondary to simple gastro-duodenitis, simple jaundice is usually preceded for a few days by moderate disorder of the gastric functions, such as anorexia, bad taste in the mouth, belching of gas, lassitude, and occasionally by vomiting. These symptoms continue for a time after the appearance of jaundice. The bowels are usually constipated.

The DIAGNOSIS is based chiefly upon the exclusion of other causes of jaundice, particularly the impaction of gall-stones, and severe structural affections of the liver, such as cirrhosis, acute yellow atrophy, tumors, etc. In general, the diagnosis is easily established.

The DURATION of an attack of simple jaundice is generally from about three to six weeks. Constitutional symptoms disappear, as a rule, a considerable time before the jaundiced color is lost.

The CAUSATION is that of gastro-duodenitis. In some cases there is evidence of some specific or infectious cause. This, at least, is the probable explanation of the occasional accumulation of cases of simple jaundice at certain times and in certain places, giving to the affection an epidemic or an endemic character.

Simple jaundice, if uncomplicated, is not a serious affection, and nearly always terminates favorably. It is to be remembered, however, that some cases of acute yellow atrophy of the liver begin with the symptoms of simple jaundice.

As the natural tendency of simple jaundice is to recovery, active medical interference is not indicated. The patient's diet should be regulated, fats especially being excluded. As the bowels are usually constipated, a cathartic may be occasionally administered, for which purpose some of the laxative saline waters, such as Carlsbad, may be employed. A time-honored remedy is calomel or blue mass, given at night and followed by a dose of salts in the morning. Devices for the displacement of the assumed plug of mucus from the bile-duct are of doubtful efficacy. Such devices are, pressure upon the gall-bladder, faradization over the gall-bladder, and the injection of large enemata of cold or lukewarm water with the intention of arousing intestinal peristole.

Nothing is known of simple inflammation of the bile-ducts within the liver as an independent affection.

Purulent inflammation of the biliary passages may be caused by the presence of gall-stones or of parasites, and is sometimes, though rarely, a complication of infectious diseases, such as pyæmia, typhoid fever, and cholera. Sometimes the inflammation is secondary to suppuration or necrosis of the

issues in the neighborhood of the ducts. Purulent inflammation of the bile-ducts outside of the liver may lead to ulceration and perforation of the affected portion, with consequent peritonitis. Purulent inflammation of the ducts within the liver leads to the formation of abscesses containing bile and usually biliary concretions.

Croupous and diphtheritic inflammations of the biliary ducts have been described, but they are rare and only of pathological interest.

The various forms of inflammation which have been described may attack the gall-bladder, with or without coincident disease of the bile-ducts. *Inflammations of the gall-bladder*, except those caused by the presence of gall-stones, which have already been described (p. 466), do not call for consideration in works the purpose of which is mainly clinical. Ulceration and perforation of the gall-bladder may occur independently of the presence of calculi. I have met with a case in which an abscess within the walls of the gall-bladder led to perforation and fatal peritonitis.

Dilatation of the Gall-bladder (Hydrops Cystidis Felleæ).

The two most common causes of obstruction of the biliary passages—namely, gall-stones and mucus-plugs—have already been described. Further reference will be made to these, as well as to other causes of obstruction to the flow of bile, in the article on Jaundice. Closure of the common bile-duct causes, in addition to jaundice, an accumulation of bile within the gall-bladder, but this accumulation is not generally sufficient to produce marked symptoms. Exceptionally, however, under these circumstances the gall-bladder becomes enormously distended with bile, as in a case related by Van Swieten in which the gall-bladder contained eight pounds of thick bile.

Some consideration is due to obstructions of the cystic duct. These do not lead to jaundice, but manifest their effects upon the gall-bladder. By far the most common cause of occlusion of the cystic duct is the impaction of one or more gall-stones. Other causes are stenosis from cicatrized ulcers, accumulation of inflammatory products, and pressure from without, as by tumors and peritoneal bands. Congenital stenosis is a rare condition.

As a result of occlusion of the cystic duct the gall-bladder becomes distended with a clear, usually somewhat viscid fluid, which is free from bile. This condition is called *hydrops cystidis felleæ*, although the fluid is not of dropsical origin, but is a secretion from the glands and mucous membrane of the gall-bladder. The gall-bladder, thus distended, forms a tumor, usually about the size of the fist, but sometimes as large as a man's head or even larger. In the latter case the tumor extends to the pelvis and occupies the greater part of the abdominal cavity.¹ The shape of the tumor produced by *hydrops cystidis felleæ* is globular or pyriform.

There are usually no SYMPTOMS, other than the presence of a tumor, and this in ordinary cases is not so large as to cause much inconvenience.

The DIAGNOSIS is based upon the situation and the characters of the tumor. The normal situation of the fundus of the gall-bladder corresponds to the median extremity of the ninth or tenth right costal cartilage. It can usually be ascertained by palpation and by percussion that the tumor projects in this situation from the lower margin of the liver. The tumor is generally movable, although it may be fixed by adhesions. It usually follows the respiratory movements of the diaphragm. Unless the tumor be greatly distended, sense of fluctuation can be appreciated. In exceptional cases there may be

In a case described by Erdmann the amount of fluid is said to have been from sixty to eighty pounds.

considerable difficulty in diagnosis, as when the colon makes its way between the upper part of the tumor and the abdominal wall, so that a tympanitic resonance may be found between the liver and the tumor. Cases are recorded in which the tumor has been so constricted as to resemble the kidney in shape, and, in fact, it has been mistaken for a wandering kidney. It suffices to call attention also to the possibility of mistaking a distended gall-bladder for an echinococcus cyst, a cancer, a hydro-nephrosis, or an ovarian cyst; but such errors are not likely to occur. An exploration of the tumor by a hypodermic syringe may be of assistance in diagnosis.

The TREATMENT must have reference to the circumstances in individual cases. In many cases no treatment is required. Aspiration of the gall-bladder may be employed if the degree of dilatation warrant this procedure. The fluid, however, is almost certain to be renewed. If it be decided to make a free opening into the gall-bladder, the same precautions are to be adopted with reference to the formation of peritoneal adhesions and the avoidance of septic inflammation as in making similar openings into abscesses and hydatid cysts of the liver.

Sometimes, instead of a clear, bland fluid, pus accumulates in the gall-bladder (*empyæma cystidis felleæ*). The affection is then, of course, of a very grave nature, and is likely to terminate fatally. If the diagnosis can be made, the evacuation of the pus by a free incision is indicated.

Primary cancer of the gall-bladder occurs, but in its symptoms and course it cannot be discriminated with any certainty from cancer of the liver, and it therefore does not require separate clinical consideration.

The parasites which are sometimes found in the biliary passages have already been considered (p. 498).

Jaundice, or Icterus.

The presence of bile-pigment in the blood and lymph in sufficient quantity to give to the conjunctiva and to the skin a yellow color, greater or less in degree, constitutes the morbid condition known as *icterus*, or *jaundice*. The terms *icterus* and *jaundice*, of which the latter is the more commonly used, relate to yellowness of the surface from the presence of bile-pigment, whereas *cholæmia* implies the presence of all of the bile-constituents in the blood.

Jaundice is strictly never an individual disease. It is merely an effect or a symptom of disease; but as it is an obvious and striking morbid condition dependent on various affections, and occurring sometimes when its causation is not evident, it is convenient to give it separate consideration. This removes the necessity of much repetition in treating of the manifold affections of which jaundice is a symptom.

The presence of bile in the blood, or *cholæmia*, is a result of the entrance into the blood of bile after its secretion. The bile-pigment and the biliary salts (the glycocholate and the taurocholate of soda) are formed within the liver, and do not pre-exist in the blood. The bile, however, contains at least one excrementitious principle—namely, cholesterin. The latter constituent of bile accumulates in the blood if the secretion of the liver be from any cause suspended.

Whether the bile-pigment be ever formed in the circulating blood is a matter of uncertainty. *Hæmatoidin*, a pigment identical with bilirubin, is often formed in old blood-extravasation; and this fact, together with other facts, has given rise to the supposition that in certain cases of jaundice the bile pigment is formed outside of the liver, probably in the circulating blood. Jaundice thus produced is called *hæmatogenous jaundice*, in distinction from that caused by the absorption of bile, or *hepatogenous jaundice*. Th

hypothesis of a hæmatogenous jaundice is advanced to explain certain cases of jaundice in which none of the recognized causes of the absorption of bile from the liver have been found. A hæmatogenous origin has been urged especially for the jaundice occasionally occurring in certain infectious diseases, such as septicæmia, pyæmia, remittent fever, and certain cases of poisoning, as by phosphorus and the mineral acids, in which destruction of red blood-corpuscles doubtless occurs. It must be admitted, however, that there are serious objections to the acceptance of the theory of a hæmatogenous jaundice, and that this theory has of late lost, rather than gained support. Hæmoglobin, which is set free by destruction of red blood-corpuscles in the circulating blood, is eliminated by the kidneys in the form of meth-hæmoglobin, and here is no proof that it is ever converted within the blood into bile-pigment, although dissolved hæmoglobin increases the formation of bile-pigment within the liver. There is a tendency to refer many cases which some writers have regarded as hæmatogenous jaundice—for instance, the jaundice of many acute infectious diseases—to a mild inflammation of the large bile-ducts; but the anatomical proof of this view is deficient for a considerable number of the cases. Nor is the theory that the absorption of bile in these cases is the result of lowered blood-pressure in the liver to be regarded as established. It must be admitted, therefore, that while a certain number of the cases of jaundice formerly considered as hæmatogenous are in reality of hepatogenous origin, we possess no satisfactory explanation of the cause of the jaundice in the remaining cases.

In all cases in which we possess an adequate explanation of the causation the cause is to be found in some obstruction to the flow of bile in its passage from the liver to the intestine. The causes of such obstruction are various, and they may be classified—*first*, as abnormalities in the interior of the bile-ducts; *second*, as alterations in the walls of the ducts; and *third*, as lesions causing pressure upon the bile-ducts from without.

The most frequent of the first of these causes are plugs of mucus resulting from simple inflammation of the common bile-duct secondary to gastro-duodenitis (simple or catarrhal jaundice) and gall-stones, including concretions of inspissated bile. Lodgment of parasites in the bile-ducts is a rare cause of jaundice. These parasites are lumbricoid worms, the various forms of distoma and echinococcus. Pus, blood, and fibrin may block up the bile-ducts in rare instances.

Of the changes in the walls of the bile-ducts which may encroach on the lumen of these tubes, the most important are inflammatory swelling, either that of acute or of chronic inflammation, cicatricial thickening, and contraction following ulceration and new growths. Congenital stenosis of the bile-ducts is a rare condition.

The most important of the causes which produce jaundice by external pressure on the bile-ducts are tumors and inflammatory products. Cancers of the liver, of the gall-bladder, of the lymphatic glands in the porta of the liver, of the pylorus, of the duodenum, and of the head of the pancreas, may all cause jaundice by compression of the common bile-ducts. Less frequently cancer in other situations and other forms of tumor produce jaundice in a similar way. Hepatic abscesses and echinococcus cysts may compress the main bile-ducts. The pressure of the gravid uterus and of fecal accumulations in the transverse colon belongs in this group of causes. Obstruction may also be due to peritoneal adhesions, which cause traction on the peritoneal fold which contains the common bile-duct. The compression of a large number of intra-hepatic ducts in cirrhosis of the liver leads to a certain amount of jaundice. The quantity of smooth muscular tissue in the walls of the bile-ducts appears to be too slight to support the theory of jaundice produced by spasm

of the ducts. Although it is possible, it cannot be considered proven, that bile may be absorbed, and that jaundice be thus caused by diminution of the blood-pressure in the liver. This, however, is the usual explanation of the jaundice occurring in cases of portal thrombosis. As has already been mentioned, bile is not absorbed in cases of jaundice directly by the blood-vessels, but it is first taken up by the lymphatics in the liver, is carried to the thoracic duct, and thence enters the blood. Another supposed agency in producing jaundice in certain cases is enfeebled respiration. This is based upon the idea that the movements of the diaphragm aid in the propulsion of the bile, so that when these are weakened there may be a sufficient stasis of bile in the bile-ducts for the production of jaundice.

The jaundice which frequently occurs in from two to four days after birth, and is called *icterus neonatorum*, has not received any explanation which has met with general acceptance. This jaundice is peculiar in the fact that the urine is generally free from bile-pigment, and that the blood after death, as well as the papillæ of the kidneys, and sometimes other organs, contain a large quantity of crystalline pigment.

Yellowness of the conjunctiva and skin takes place after a certain amount of bile has entered the circulation. Prior to the appearance of jaundice the bile-pigment may be found in the blood, the urine, and the liquid of serous cavities. The coloration of the surface depends on the presence of the bile-pigment in the transuded liquid which infiltrates the tissues. Other things being equal, the intensity of the yellow color is proportionate to the degree of the cholæmia. The presence of the bile-pigment in the serum of the blood is shown by the yellow color of the liquid beneath the epidermis if a blister be applied.

The urine in cases of jaundice contains bile-pigment in abundance, very often hyaline casts and sometimes epithelial casts. Not infrequently a small quantity of albumen is present in the urine. The presence of the pigment is apparent to the eye, and it gives to linen a yellow stain. The perspiration contains it, and the body-linen may also be stained yellow, especially from the abundant cutaneous secretion in the axilla. Bile-pigment is rarely, if ever, contained in the saliva, nor, as a rule, is it found in mucus, but it may be found in the sputa of pneumonitis developed in a person affected with jaundice. The milk of nursing women rarely contains it, although its presence in this secretion has been observed. The humors of the eye do not contain it, except in some cases in which the jaundice is unusually intense. The "jaundiced eye" (*xanthopsia*) is so rare an event that the phrase is to be regarded as a poetical license.

The tissues in the interior of the body are more or less colored. The coloration is seen especially in the areolar tissue, the serous membranes, and the muscles. The substance of the brain escapes, except in cases in which it is unusually infiltrated with serum, that is, oedematous.

Bile in the blood acts as a sedative on the circulation and nervous system. The heart's action is usually diminished in frequency. The pulse frequently falls to 50, 40, or even lower, in cases in which the jaundice is not associated with acute inflammation or fever, and if thus associated the frequency of the pulse is less than if jaundice did not coexist. The effect is attributed to the presence in the blood, not of the pigment, but of the biliary salts. The temperature of the body may be lowered. The respirations diminish in frequency in proportion to the effect on the circulation. The mental faculties are dull and there is a disposition to somnolency. *Pruritus* of the surface, especially in the axilla and the inguinal region, troublesome particularly at night, is an occasional symptom. It is sometimes a source of great annoyance. An occasional complication is *urticaria*, denoted by the characteristic

evacuations on the skin, or wheals, which present a deeper yellowness than the surrounding integument and occasion intense pruritus.

The symptoms referable to the digestive system are frequently due to co-existing duodenitis or gastro-duodenitis. Anorexia, nausea, and sometimes vomiting, thirst, more or less pain in the neighborhood of the epigastrium, and tenderness in that situation, are symptoms denoting subacute inflammation of the gastro-duodenal membrane. In cases of jaundice disconnected from this affection the appetite may be but little or not at all impaired, and certain articles of food are apparently digested without difficulty. Fatty food is imperfectly digested, and chemical examination of the evacuations from the bowels shows fat in more or less abundance. Patients have an antipathy to fatty articles of diet. The nutrition for a time may be but little affected, but sooner or later, loss in weight takes place; and this is progressive if the jaundice continue.

The appearance of the dejections is important, as affording evidence of the completeness or otherwise of obstruction to the passage of bile into the intestine. If complete occlusion exist, the stools are ashy or clay-colored, owing to the presence of fat. On the other hand, they have more or less of the yellowish or brownish color of health if the obstruction be only partial. The feces, when the intestines are devoid of bile, emit an odor of putrescence, and the formation of gas is frequently troublesome, bile in the intestinal canal being an antiseptic as regards the fecal contents. Generally, the bowels are constipated, but this is by no means always the case, even when complete occlusion exists.

Jaundice may exist for a greater or less period without giving rise to notable disturbance. The system sometimes tolerates the accumulation of bile for a long time. Not infrequently, patients are able to be up and about as in health, experiencing but little inconvenience. The symptoms and the gravity will depend in a great measure on the pathological conditions with which the jaundice is associated. If the jaundice depend on obstruction in connection with subacute gastro-duodenitis, the prognosis is always favorable. Simple gastro-duodenal jaundice usually continues for from three to six weeks. If it depend on the impaction of a gall-stone in the common hepatic duct, the recovery will depend on the passage of the stone into the intestine or backward into the gall-bladder. Permanent obstruction from a gall-stone or the pressure of a tumor involves of course persistence of the jaundice. Under these circumstances serious results may not take place for a considerable or even a long period. Cases have been under my observation in which the nutrition of the body was not greatly impaired for one, two, and even four years. In one case under my observation the jaundice had persisted for eight years. Life has continued for a much longer period. Sooner or later, however, the body wastes, the patient becomes anæmic and cachectic, the vital powers gradually fail, and the termination is fatal, irrespective of either the morbid condition giving rise to the jaundice or of intercurrent affections of other organs than the liver. The color of the skin becomes dark or almost black in some cases of long-persisting jaundice. In the majority of cases of jaundice from permanent obstruction, however, the duration of life does not extend beyond several months.

When life is destroyed purely in consequence of the retention of bile, the liver takes on important lesions. The bile-ducts within the liver become dilated; the gall-bladder may or may not become distended with bile; the liver is at first increased in volume from the accumulation of bile, but subsequently its volume is diminished and it becomes flabby and wrinkled. There often is a new growth of interstitial tissue, constituting one of the forms of biliary cirrhosis of French writers. The persisting distension of the hepatic

bile-ducts at length leads to an arrest of the secretion of bile. In proportion as the secretion of bile is arrested the jaundice diminishes, and the patient suffers from the retention in the blood of the excrementitious portion of the bile—namely, cholesterin. In some cases death is preceded by convulsions and coma. In these cases *cholesteræmia* may be supposed to exist, but these phenomena in a certain proportion of cases are due to *uræmia*. Post-mortem examinations show an accumulation of granules of bile-pigment in the uriniferous tubes when jaundice has existed for a considerable or long period; and the *uræmia* proceeds from the morbid condition of the kidneys. Hydro-peritoneum may occur in the latter period of the affection, and general dropsy is sometimes a result of the superinduced renal affection.

The DIAGNOSIS of jaundice is readily made if the examination of the patient be made in the daytime, but the yellowness may not be apparent by artificial light. The yellow tint of the surface seen in some cases of cancer, intermittent fever, and chlorosis is readily discriminated from slight jaundice by the absence of yellowness of the conjunctiva, the latter being always present in jaundice; but to determine the causative pathological conditions in individual cases is not always easy or in all cases practicable. The dependence on duodenitis or gastro-duodenitis is to be inferred from the symptoms of these affections preceding and accompanying the jaundice—namely, anorexia, nausea, vomiting, and tenderness over or in the neighborhood of the epigastrium. The presence of a gall-stone may be inferred from the pre-existence and coexistence of the symptoms of hepatic colic. A tumor which presses upon the common duct may be discoverable by manual exploration. From the character of the tumor and the coexisting symptoms its cancerous nature may sometimes be inferred. Occlusion as a result of inflammation of the ducts exclusive of duodenitis, from lumbricoid worms in the common duct, and from other causes, cannot be determined during life. The existence only of obstruction is determinable in such cases. Not infrequently the distended gall-bladder may be felt, and this is positive evidence that the jaundice involves obstruction of the common duct.

In the TREATMENT of jaundice it has been the custom to prescribe active cathartics and emetics under an idea of removing the obstruction by their operation. If, however, the jaundice be connected with duodenitis or gastro-duodenitis, not only are these measures ineffectual, but they can hardly fail to do harm. If the obstruction be caused by a gall-stone, its passage will not be hastened by these measures; and they will weaken the patient without doing good if the jaundice depend on a tumor pressing on the common or hepatic duct. As remedies, then, addressed to the obstruction giving rise to the jaundice, cathartics and emetics are contraindicated.

The treatment of jaundice in the majority of cases is to be addressed to a subacute inflammation of the stomach and duodenum. Laxatives or cathartics are required only for the relief of constipation, and when required the mildest forms are to be preferred. There is no ground for the supposition that mercury exerts any special efficacy, but a few grains of calomel and blue mass frequently prove as mild and effective as any form of cathartic or laxative, followed, if necessary, by a saline draught. The latter alone will often suffice. The saline mineral waters, such as the Congress or Kissingen water, will frequently secure an adequate laxative effect. Remedies to soothe the inflamed mucous membranes are useful, such as small doses of morphia or some of the succedanea of opium—namely, belladonna, hyoscyamus, conium, etc. Conium has been considered as a remedy having special efficacy in jaundice. Its apparent efficacy may be accounted for, in part by its usefulness as a soothing remedy and partly by its supplanting active cathartics and emetics, which are injurious. The diet should be bland and digestible.

Fatty articles of food should be excluded, and to these the patient generally has an antipathy. A blister over the epigastrium has seemed to me to be useful. Accidental symptoms will of course claim appropriate palliative measures. If a distended gall-bladder can be felt, pressure upon it will sometimes remove the obstruction, the tumor disappearing under this procedure. This fact I have verified. Pressure, however, should not be made with such force as to incur risk of rupture. Gerhardt has found the induced current of electricity to be useful by exciting spasmodic contractions of the muscular coat of the gall-bladder.¹ A bubbling sound, caused by the passage of the bile into the duodenum, may sometimes be heard occurring with the disappearance of the tumor.

In cases of jaundice connected with the passage of gall-stones the palliation of pain is the chief object of treatment. The occurrence of jaundice does not add indications to those which have been already considered as pertaining to the passage of gall-stones or hepatic colic. (Vide p. 469.)

Jaundice dependent on irremediable causes, such as permanent occlusion of the biliary ducts or the pressure of a tumor, does not admit of cure, and the existence of an irremediable cause is to be inferred when the jaundice persists for several months or years. Yet I have repeatedly met with cases in which, after the persistence of jaundice for many months, recovery at length took place, and I have known recovery to take place after a persistent jaundice for several years. A fecal tumor in the transverse colon and a movable right kidney have been known to give rise to jaundice by pressing on the common duct. A fecal tumor may be removed, but, in general, tumors so situated as to produce obstruction are persisting. In cases not admitting of cure the objects of treatment, as regards the jaundice, are the elimination of bile by the renal and cutaneous emunctories and the support of the powers of life in order to postpone as long as possible the fatal termination. With a view to the elimination of bile, the action of the kidneys may be excited by the vegetable diuretic remedies, and the functions of the skin maintained by the use of the warm bath and by guarding against vicissitudes of temperature. The powers of life are to be supported by a nutritious diet, together with all the hygienic means, moral and physical, of invigorating the system.

In cases of jaundice ending in recovery it is to be borne in mind that the yellowness of the skin continues for some time after the absorption of bile has ceased. The coloring matter, being outside of the vessels, remains when the cholæmia no longer exists. Of the continuance of the cholæmia or of the condition which occasioned the jaundice the urine affords the most reliable evidence. The affection is to be considered as having ended when the coloring matter ceases to be apparent in the urine. I have known yellowness of the skin to persist for several months after the disappearance of bile-pigment from the urine. In the case in which this was observed the jaundice had existed for a year. The absorption is probably slow in proportion as the jaundice has been of long duration.

[Weil's Disease—Acute Febrile Icterus—Infectious Icterus.

In 1886, Prof. Weil of Heidelberg reported four cases of an affection characterized by fever, headache, vertigo, somnolence, and delirium, associated with swelling of the spleen and liver, albuminuria, digestive disorders, and jaundice. In a few days—from five to eight—these symptoms and signs gradually subsided and the patient was apparently restored to health. The disease, however, was not at an end, for after an intermission of variable length—from one to seven days—a relapse occurred in three of the four

¹ *Ueber Icterus gastro-duodenalis*, von C. Gerhardt, Leipzig, 1871.

cases and the course of the primary attack was repeated. Convalescence was protracted, the patients not being discharged from hospital until from four to ten weeks after their admission.

The following reasons for regarding this affection as an independent one have been advanced: From acute yellow atrophy of the liver it is distinguished by the swelling of that viscus, by the high temperature, by the simultaneous swelling of the spleen, by the involvement of the kidneys, and by the absence of hemorrhage; and from catarrhal jaundice, by the higher range of temperature and the implication of the spleen, liver, and kidneys. It resembles relapsing fever in many respects, especially the variety called by Griesinger "bilious typhoid." The latter disease, however, never exists in sporadic form, and hence may be excluded even in the absence of the important negative evidence that would be furnished by an examination of the blood for the spirillum of Obermeier. The concurrence of jaundice, apyretic intervals, and distinct relapses suffices to exclude the view that the affection is an abortive typhoid complicated with jaundice. It is admitted without further parley that the affection belongs to none of these nor to any similar category, and in the absence of further information we confess ourselves unable to classify the cases reported by Weil. Happily, such information is at hand. In the short time that has elapsed since Weil's publication a number of similar cases have been reported, several of which were fatal and were examined post mortem. In 1887, under the title of "acute parenchymatosis," Aufrecht reported two cases of acute fever with jaundice and albuminuria, which, after a rapid course characterized by brain-symptoms such as somnolence and convulsions, ended in death. In both cases necropsies were held. In one the liver was small, in the other enlarged. In the latter the cellular elements of the liver and kidney were filled with strongly-refracting granules which Aufrecht, without proving his supposition by appropriate staining methods, regarded as micrococci.

Nauwerck examined post mortem two cases of fatal febrile icterus, in one of which death occurred within forty-eight hours. In this rapidly-fatal case the liver was not enlarged. In the intestine were small superficial ulcerations and enlargement of solitary follicles and Peyer's patches. An intestinal mycosis was supposed to be the fundamental process, inasmuch as the mucous membrane contained small foci of cellular infiltration, in part necrotic, in the immediate neighborhood of which accumulations of bacilli were found. The parenchyma of the liver and kidneys presented a high degree of albuminous, fatty, and necrotic degeneration. In the second case, which lasted seventeen days, the intestine was perfectly sound, while the lesions of the liver and kidneys were identical with those of the first. Nauwerck concludes from these examinations that anatomical and etiological unity are both wanting in "Weil's disease." The third case of this affection in which a necropsy was held was reported by Brodowski and Dunin. The patient, a male thirty-six years of age, presented, in addition to febrile icterus and swelling of the liver and spleen, a symptom that has been wanting in all the other cases reported—viz. swelling of all the superficial lymph-glands. They were tender on pressure and enlarged, some of them to the size of walnut. On section, these, as well as the enlarged mesenteric and bronchial gland were soft and of a reddish-gray color. In the liver could be seen with the naked eye gray spots and nodules which corresponded to round-celled infiltrations of the acini and their neighborhood. The cells were in a well-marked state of cloudy swelling. Analogous appearances were observed in the kidneys, and the interstitial tissue of the lungs was infiltrated with cells. The spleen was five times the normal size. No definite conclusion could be drawn from the bacteriological investigation.

From the reports of these necropsies it is evident (1) that the post-mortem appearances were in no single case identical with those of any other, and (2) that the only lesion common to all the cases—the cloudy swelling of the liver and spleen, with small-celled infiltration of the connective tissue of these glands—was in nowise typical. The same appearances are characteristic of a number of infectious diseases, such as scarlatina, diphtheria, typhoid fever, and especially septic infection.

The question next in natural order is whether any facts support the view that sepsis may give rise to the symptoms described by Weil, and the answer is most decidedly in the affirmative. Since 1876, Fiedler has observed thirteen cases of febrile icterus, all of which recovered. Swelling of the spleen and liver and albuminuria were not always present, and in only two cases was there a distinct relapse. The only symptoms invariably present were fever, icterus, and pain in the calves, which latter Fiedler regards as pathognomonic. The most remarkable etiological fact in connection with these cases is that, out of the twelve males among them, nine were butchers who were actively at work in the Dresden abattoir until the time of their seizure.

The most remarkable case of this sort yet reported was observed by Fraenkel, and the evidence it brings to the support of the septic theory of "Weil's disease" is of the strongest kind. The patient was a medical student who, while fencing, received a wound of the forehead. In addition there was a slight excoriation in the right temporal region. The wound was dressed antiseptically and covered with a bandage, which, however, did not protect the excoriation. On his way home the patient wore a hat which had been kept in the dissecting-room. The wound was received on the 3d of August. On the 5th there was a chill followed by high fever, and on the 7th by an erysipelatous redness around the excoriated spot. On the 10th there was pronounced icterus, and, without going into further details, all the symptoms of Weil's cases, including the apyretic interval, the relapse, and the protracted convalescence, were well marked. The spirillum of Obermeier was sought for in vain.

Among the widely-varying symptoms and post-mortem appearances of the numerous cases of "Weil's disease" now on record, there is nothing distinctive of a hitherto unrecognized disease. On the other hand, there is strong evidence that some of them were cases of septic poisoning. In Fraenkel's case, which corresponded in all respects with the cases described by Weil, the point of septic infection was a wound of the head; and in Fiedler's cases, at least in the nine butchers, the infection may have entered the system in a similar manner, through cuts and abrasions too slight to attract attention or through the ingestion of decaying meat. The designation of such manifestations of sepsis as "Weil's disease," while it has served the valuable purpose of directing more special attention to them, is a misnomer. Much more appropriate is the term septic or infectious icterus, proposed by Fraenkel.—H.]

Functional Affections of the Liver.

Functional affections of the liver have hitherto held a prominent place in pathological speculations, and they are still often mentioned by physicians in conversing with each other and with their patients; but in a clinical point of view, with our present knowledge, the importance of the functional affections of the liver is in striking contrast with the frequency with which this organ is referred to as the source of morbid phenomena.

It is customary with many to refer a certain group of symptoms to congestion of the liver. The nature of these symptoms and the propriety of

considering them as dependent upon hepatic congestion have already been discussed in the article on Congestion of the Liver (p. 564).

Physiology teaches us that the liver is endowed with various functions, of which the most important are the secretion of bile, the production and perhaps the transformation of glycogen, and the metamorphosis of the albuminous and other constituents of the products of digestion which are absorbed by the portal vein.

The action of the liver upon the products of digestion which are absorbed by the rootlets of the portal vein, although not well understood, is probably an important one. The liver seems to be an important, although not the sole, seat of the formation of urea. It may be believed, therefore, that structural and functional disorders of the liver interfere with the alterations which the absorbed products of digestion normally undergo in the liver, but our knowledge of this subject is too imperfect to admit of more than profitless speculation.

Functional disorders of the biliary secretion are a morbid excess, a morbid deficiency, and a vitiation of the bile. A morbid excess of bile is supposed to enter into the etiology of diarrhœa, colic, and sporadic cholera in certain cases. Deficiency of bile is often treated as a functional affection under the name of *torpor of the liver*, remedies being given to increase the biliary secretion. A whitish or ashy color of the stools probably is evidence of deficient secretion, although this appearance may arise from undue absorption of bile from the intestinal canal. Every practitioner is familiar with this appearance of the stools in young children and after the administration of opium. The production of the so-called *bilious stools* by the use of mercury is well known. Torpor of the liver is a phrase often applied to cases in which the morbid condition is obscure. It affords an acceptable explanation to patients, owing to the popular notion that the liver plays an important part in the ailments referable to digestion and to the nervous system; and, whatever may be the rationale, a mercurial cathartic or laxative often affords relief of the symptoms, which are vaguely called *bilious*. A deficiency of precise knowledge respecting excess and deficiency of the secretion of bile as functional disorders must be confessed, but as regards vitiation of bile the deficiency of knowledge is still greater. Acrid bile is supposed to be sometimes secreted, and the greenish color of the stools, often observed, especially in children, has been regarded as denoting a morbid quality of bile. It is not improbable that a vitiated bile may be secreted, but it is impossible to determine whether morbid changes be due to a faulty secretion or to causes acting within the alimentary canal; and nothing can be more vague than to regard a vitiated secretion of bile as a functional disorder furnishing therapeutical indications.

CHAPTER XIV.

DISEASES OF THE SPLEEN.—DISEASES OF THE PANCREAS.

Diseases of the Spleen.

MOST of the diseases of the spleen are secondary to other diseases, and they are therewith considered. It is desirable, however, to bring together the various affections of the spleen, although few of them require

consideration as independent diseases. The spleen bears to the current much the same relation that the lymph-glands do to the lymphatic current. This explains the frequency with which the spleen is involved in the various blood diseases, particularly in those characterized by the presence of infectious substances.

Acute congestion of the spleen is one of the morbid elements in the production of an acute splenic tumor, to be presently considered.

Chronic passive congestion of the spleen is caused by mechanical interference with the portal circulation. The most important of its causes are pyelophlebitis, inflammation of the liver, compression of the portal vein by tumors, cardiac disease, emphysema of the lungs, large effusions in the pleural cavity, and intrathoracic hemorrhage. The spleen is enlarged, dark red in color, firm in consistence, and its capsule is usually thickened. The enlargement can usually be determined by physical examination, and this is often of considerable assistance in diagnosis. The most common complaint is a feeling of weight and tension in the left hypochondrium, but in general no definite symptoms are referable to chronic passive congestion of the spleen.

The spleen, next to the kidneys, is the most frequent seat of *embolic infarction*. The emboli are usually derived from the left side of the heart, but they may come from any part of the aorta above the origin of the splenic artery. The branches of the splenic artery do not anastomose with each other, so that the mechanical effect of an embolus in this organ is the production of infarction. Splenic infarctions are wedge-shaped, with the apex directed toward the hilum of the spleen. Splenic infarctions may be hemorrhagic, or mixed infarctions. Most frequently the centre is white and the periphery is hemorrhagic. They are on the average of larger size than cerebral infarctions. It is said that sometimes the lodgment of an embolus in the spleen is attended by a sensation of pain, but this is not proven; nor are we able to refer any symptoms to the bland infarctions of this organ.

If life be sufficiently prolonged, an embolic infarction terminates in the formation of a fibrous cicatrix which may contain blood-pigment and debris.

If an embolus contain infectious substances, generally in the form of bacteria, it produces, in addition to its mechanical effects, suppuration, leading to the formation of an abscess. In rare instances a gangrenous abscess is produced by an infectious embolus.

Embolic abscesses are produced in many cases of acute ulcerative endocarditis and in pyæmia. Such abscesses are generally of small size and do not admit of positive diagnosis. The symptoms are those of the disease in which they are caused. These diseases are usually attended by more or less enlargement of the spleen, whether abscesses be present in this organ or not. Large abscesses may, however, attain a large size, especially by the coalescence of a number of abscesses. Splenic abscess may be produced independently of emboli. It may be caused by wounds of the spleen. It rarely follows injuries without wounds which involve this organ. It occurs sometimes as a complication of various infectious diseases, such as relapsing fever, typhoid fever, and intermittent fever, where an embolic origin cannot be demonstrated.

Abscess may be caused by perforation of a gastric ulcer into this organ or by extension of suppuration from adjoining parts. Sometimes no definite signs can be determined for an abscess in the spleen. The size of the abscess may be enormous. Sometimes all of the splenic tissue is destroyed and only the capsule remains. The abscess may burst in different directions, into the peritoneal cavity, the stomach, the intestine, the chest, and externally. Except when the abscess presents itself as a fluctuating tumor a diagnosis from symptoms and signs is impracticable. An exploratory

puncture may aid in the diagnosis by demonstrating the presence of pus. The prognosis and treatment in cases of splenic abscess are essentially the same as in abscess of the liver. (See p. 537.)

Acute splenic tumor is one of the most important pathological changes of the spleen. By this name is designated the enlargement of the spleen which forms one of the most frequent and essential lesions of many acute infectious diseases. Nearly every acute infectious disease may at times be accompanied by splenic enlargement, but there are certain of these diseases in which swelling of the spleen is more constant than in others. Acute splenic tumor is nearly always present in relapsing fever, typhoid fever, typhus fever, and intermittent and remittent fevers. It is usually or frequently present in pyæmia and septicæmia, including puerperal fever, in epidemic cerebro-spinal meningitis, erysipelas, acute lobar pneumonitis, diphtheria, acute yellow atrophy of the liver, acute miliary tuberculosis, the acute exanthematous fevers, etc. It has been observed during the primary and the secondary periods of syphilis.

The spleen is enlarged, often twice or thrice its normal size; its consistence is soft, its color dark red or bluish-red; and upon section the pulp swells above the surface. The Malpighian bodies are generally invisible, but they may be distinct or even enlarged. The enlargement is due to active congestion and to an increase in the number of cells in the spleen, some of which, at least, are produced by proliferation of the pre-existing cells. The lesion, therefore, in acute splenic tumor is an acute hyperplastic splenitis. In splenic swellings of short duration probably the change does not pass beyond active congestion.

The acute splenic tumor of infectious diseases is believed to be due to the accumulation in the spleen of noxious substances present in the blood, these substances acting as an irritant and causing congestion and inflammation. That these substances, in many cases at least, are micro-organisms seems certain. The accumulation of these organisms, as well as of fine particles in general, is explained by the peculiarities of the circulation in the spleen, which render this organ a kind of filter for the blood, as the lymphatic glands are for the lymph.

Clinically, the chief importance of acute splenic tumor is the aid which its recognition affords in diagnosis. In rare instances the swelling of the spleen has led to rupture of the organ and fatal hemorrhage into the peritoneal cavity. This is an accident which has occurred in typhoid fever, intermittent fever, and other acute infectious diseases.

Under the name of *chronic splenic tumor* are included enlargements which occur in a variety of chronic diseases, of which the most important are malarial fever, leucocythæmia, and pseudo-leucocythæmia. A similar enlargement is met with in some cases of syphilis. The enlargement is due to a chronic hyperplastic splenitis, but the morbid appearances vary in different diseases; in some cases the hyperplasia affecting especially the trabecular tissue, and in others affecting uniformly the cells and the trabeculæ. These differences are considered in connection with the different diseases in which chronic splenic tumor occurs.

Chronic interstitial splenitis occurs sometimes without apparent cause, although in most cases it is referable either to malaria or to syphilis.

Enlargement of the spleen, acute or chronic, is not attended with much pain or with tenderness on pressure. If not greatly enlarged, there may be no local symptoms directing attention to an affection of the organ. If much enlarged, its weight occasions a sense of uneasiness and tension in the left hypochondrium. Disconnected from the pathological associations under which it is generally presented, it may exist without any notable general symptoms.

enlargement is generally ascertained without difficulty, by palpation and percussion. In some cases the enlarged organ extends upward, up the diaphragm, and causing an evident projection of the false ribs on the left side of the chest. Its upper border is accurately indicated by the line of demarcation between pulmonary resonance and flatness on percussion, and the lower border is determined, approximately, by finding the limits of tympanitic resonance. In other cases the organ is dragged down by its weight, and it may descend as low as the brim of the pelvis. In these circumstances, if the abdominal walls be thin and relaxed, they may be grasped by the hand and restored to its normal position. They thus serve to distinguish it from the other abdominal tumors. The pulsation on the anterior border may sometimes be felt through the abdominal wall. An enlarged spleen is depressed by the act of inspiration and recedes from the chest at expiration. Its normal limits in the left infra-axillary region are between the ninth and eleventh ribs. When enlarged, its lower border extends below the ribs and anteriorly. Pulsation of an enlarged spleen, in connection with mitral regurgitation, has been observed.

TREATMENT of acute enlargement involves the indications belonging to the various diseases with which it is associated. Associated with malarial fever, experience shows a special influence of large doses of quinia, salicin, and antiperiodic remedies upon the spleen. These remedies are also useful in chronic malarial enlargement. There is ground for attributing, given in full doses, an effect upon the enlargement in other infectious diseases than malarial fever. The treatment in chronic enlargement of the spleen has reference to the associated diseases—namely, cirrhosis of the liver, leucocythæmia, etc. There is no special course of medication to be pursued.

Generally, chalybeate tonics, continued steadily for a long time, are indicated. They are indicated in proportion as the symptoms and signs of splenic enlargement are marked. Changing the form of the chalybeate tonic from time to time is important. DaCosta has reported a case of splenic leucocythæmia in which an apparent cure was effected by the hypodermic injection of ergot.¹ Hemorrhage of blood sometimes occurs in connection with vascular engorgement of the spleen, and the hemorrhage may lead to rupture of the capsule and escape of blood into the peritoneal cavity. This has been observed in cases of intermittent fever, of typhoid fever, and during an epileptic paroxysm. It occurs in connection with pregnancy, both before and after labor. Death usually takes place immediately from the loss of blood, and in most of the cases which have been observed the duration of life after the rupture has not exceeded twenty-four hours. The symptoms resemble those which follow perforation of the stomach, and the differential diagnosis cannot be made with certainty. Were it practicable to recognize the accident by the symptoms, the treatment would be the same as in cases of perforation—namely, full doses, with perfect quietude of body. It would be proper to observe over the abdomen. Nothing is to be expected from treatment or palliation.

Different structural affections which have been considered as seated in the spleen are sometimes found in the spleen—namely, waxy degeneration, hyaline degeneration, growths, tuberculosis, cancer, and hydatids. These may involve the whole or only a portion of the organ. They occasionally occasion enlargement, in some instances giving rise to splenic tumors, properly so called, of greater size.

degeneration of the spleen rarely exists except in connection with some other affection in other situations, as in the liver, kidneys, and intestinal disease. There are here two forms of waxy spleen—namely, the sago spleen and the

¹ Vide *Am. Journ. of Med. Sciences*, January, 1875.

diffuse waxy spleen. In the former the Malpighian corpuscles are chiefly affected, in the latter the splenic pulp. The enlargement of the organ, as a whole or in part, is sometimes very great. The diagnosis is to be based on the affection of other organs and the causative conditions—namely, suppurative disease of bones or cachexia, especially syphilis.

Tuberculous disease may be manifested anatomically either by miliary granulations or by cheesy collections called solitary tubercles. The former are almost invariably present in the acute miliary tuberculosis of adults and in tuberculous disease affecting children. The spleen is very rarely the seat of a primary tuberculous affection. The organ becomes in some cases moderately enlarged. Pain and tenderness are rarely present, and the enlargement is generally the only evidence that this organ participates in the tuberculous disease.

Cancer of the spleen is never primary, and its occurrence is infrequent. It is always secondary to cancer of the liver or of some other of the abdominal organs. Cancer is to be inferred from the development of splenic enlargement or tumors in the course of cancer seated elsewhere.

Syphilitic affections of the spleen in the form of gummata, causing enlargement or appreciable tumors, are to be diagnosticated by taking into account other antecedent or coexisting evidences of syphilis, and by excluding waxy degeneration. As stated by Mosler, syphilitic affections in this organ "are more frequently the object of anatomical than of clinical observation."

Hydatid tumors in the spleen are rare. Their history and the means of diagnosis are the same as when they are seated in the liver. (Vide p. 557.)

With reference to the anatomical characters, pathology, prognosis, and treatment of the foregoing structural affections of the spleen, it suffices to say that in these regards they are the analogues of the corresponding hepatic affections.

Our present knowledge does not enable us to understand fully the consequences of the impairment or loss of the functions of the spleen. It is well known that this organ may be removed from inferior animals without the destruction of life or serious injury to health. This fact goes to show that whatever may be its functions, they are adequately performed by other organs in its absence. There is reason to believe that this statement is applicable to man as well as to inferior animals. A case was communicated to me in 1861 by Dr. John L. Alston of Texas, in which, after an abdominal wound by a musket-ball, a portion of the spleen protruded three and a half inches in length and two and a half inches in width. The protruding portion was ligated and it dropped off on the fourth day. Recovery took place rapidly, and the patient was in a short time discharged from the hospital entirely well. Cases have been reported in which the entire spleen, having escaped through a wound, was removed, recovery taking place and the health remaining good for years afterward. There have been several cases recorded of congenital absence of the spleen without apparent detriment to health. Within the last twenty-five years several surgeons have ventured upon the removal of this organ for great enlargement. In the majority of instances patients have died from the immediate effects of the operation. In view of the danger the operation is not warrantable.

The spleen is sometimes *dislocated* downward as an effect of tight-lacing or other causes not always apparent (wandering spleen). The organ may or may not be enlarged. It is important to distinguish between the dislocated organ and simple enlargement. If dislocated, the organ is to be restored by pressure with the hand and retained in its normal situation by an appropriate mechanical supporter.

Affections of the Pancreas.

Owing to their infrequency and to their obscurity as regards diagnosis, affections of the pancreas require in this work but a brief notice. This gland may be the seat of inflammation, acute or chronic. Of all the glandular organs—liver, ovaries, testes, kidneys, etc.—the pancreas is perhaps the least liable to become inflamed. Acute *pancreatitis* has been found, on examination after death, to occur in cases of continued fever, of puerperal fever, of pyæmia, and apparently as a result of the employment of mercury. The morbid appearances denoting acute inflammation are hyperæmia, softening, enlargement, and suppuration. Gangrene has been observed, and even the discharge of necrosed portions of the pancreas by the rectum. The symptoms which have been observed are, pain referable to the epigastrium, vomiting, diarrhœa, chills, and more or less febrile movement. The data for determining the clinical history of the affection are insufficient. A discharge, by vomiting and stool, of a liquid resembling saliva, supposed to be the pancreatic secretion, has been thought to be a diagnostic symptom, but there is no reliable evidence of the correctness of this opinion. The presence of fat in the stools has been supposed to be a diagnostic symptom. The diagnosis, with our present knowledge, is impracticable. An abscess of the pancreas has been known to open into the stomach. Chronic pancreatitis is, if possible, even more obscure, as regards diagnostic symptoms, than the acute form of the disease. In a case observed by Wilks death followed extreme emaciation without any symptoms pointing to the seat of the disease.¹ From what has been stated with regard to the diagnosis, it follows that it is impossible to form an opinion as to the proportion of cases in which either acute or chronic pancreatitis ends in recovery.

The pancreas may be the seat of either primary or secondary cancer.² Primary cancer most frequently begins at the head of the pancreas. It is usually of the scirrhus variety. Medullary cancer, colloid cancer, and cylindrical-celled epithelioma also occur in this situation. Enlargement of the head of the pancreas from chronic inflammation, cancerous disease, or the formation of cysts may constitute a tumor discoverable by manual exploration. The diagnosis involves its discrimination from other tumors in the same situation. It is most likely to be confounded with aneurism of the aorta and cancer of the pylorus. A pulsation may be communicated to the tumor from the aorta, and this is suggestive of aneurism. The diagnostic symptoms and signs of aneurism of the abdominal aorta are to be sought for, and this affection may be excluded by their absence. A positive discrimination between cancer of the pancreas and cancer of the pylorus can scarcely be made. The main points which weigh in favor of cancer of the pancreas are, less prominence of gastric symptoms than in cancer of the stomach (vide p. 361), the presence of jaundice, fatty stools, and sugar in the urine. The connection between structural disease of the pancreas and fatty diarrhœa has been considered in treating of the latter. (Vide p. 446.) The presence of free fat in the alvine dejections, taken in connection with a tumor supposed to be an enlarged pancreas, is undoubtedly a point of much weight in the diagnosis. The absence of fatty dejections, under these circumstances, is not proof against, but their existence is strong evidence for, the supposition that the tumor is pancreatic. Glycosuria has been observed in several cases of cancer of the pancreas.

Enlargement of the head of the pancreas may give rise to serious results

¹ *Pathological Anatomy.*

² For an analysis of 37 cases by DaCosta, vide *Proceedings of the Pathological Society of Philadelphia*, 1858.

from pressure upon adjacent parts. The duct leading from the pancreas is sometimes compressed, and dilatation of its branches within the organs ensues. Pressure upon the ductus communis choledochus, involving obstruction to the flow of bile, is followed by the retention of this secretion, causing persistent jaundice, dilatation of the bile-ducts, and at length disorganization of the liver. An enlarged pancreas may cause obstruction of the pylorus or duodenum, and this renders it difficult to differentiate the affection from cancer of the pylorus. Pressure upon the portal vein may exist to such an extent as to give rise to hydro-peritoneum.

Disease of the pancreas, particularly atrophy, has been found associated with glycosuria sufficiently often to render not improbable a pathological connection with the latter disease in some although not in all cases.

An abnormal deposit of fat occurs in the pancreas in two forms: first, as *fatty degeneration* of the glandular cells of the pancreas; and second, as *lipomatosis*, or development of adipose tissue between the acini, which may be thereby obliterated. We know no symptoms referable to lipomatosis of the pancreas.

Zenker¹ and Klebs have described cases of sudden death in which the only important lesion found was hemorrhage within and around the pancreas, combined with fatty degeneration. Similar cases have been reported under the name of acute hemorrhagic pancreatitis, in which the interstitial tissue of the gland was infiltrated with lymphoid cells. Necrosis of adipose tissue in and about the pancreas has also been observed in several cases. Sudden death has also been known to attend carcinoma of the pancreas.² The symptoms in some of these cases have been severe epigastric or abdominal pain, sometimes icterus, vomiting, subnormal temperature, and collapse. The explanation offered by Zenker for the sudden death is the occurrence of a reflex paralysis of the heart from a coincident affection, by pressure or otherwise, of the celiac plexus and semilunar ganglion.

Finally, *calculi* sometimes form within the pancreatic ducts, varying in size from that of a pea to an almond. These have been found in considerable number. In their journey along the excretory passage to the duodenum they may occasion severe pain resembling that caused by biliary calculi. Paroxysms of pain due to the passage of pancreatic calculi or attacks of pancreatic colic are doubtless sometimes attributed to gall-stones, and it is not practicable, with our present knowledge, to make the differential diagnosis. The differential diagnosis is not, practically, very important, since the indications for treatment are the same in either case. Clinical observation with reference to the presence of free fat in the dejections may show this symptom to be present in cases in which, without special attention, it is overlooked; and it may be found that this symptom is of much value in the diagnosis of affections of the pancreas.³

A cystic tumor of the pancreas may attain to a large size. Dr. N. Senn has reported a case in which occlusion of the common duct led to the formation of a tumor containing three quarts of liquid. Laparotomy and the removal of the contents of the cyst were followed by complete recovery.⁴

SECTION FIFTH.

DISEASES AFFECTING THE NERVOUS SYSTEM.

CHAPTER I.

DISEASES RELATING TO THE CEREBRAL AND THE SPINAL CIRCULATION.

Cerebral Hyperæmia.—Cerebral Anæmia.—Cerebral Embolism and Thrombosis.—Thrombosis of the Cerebral Sinuses.—Capillary Embolism and Thrombosis of the Brain.—Cerebral Hemorrhage.—Topical Diagnosis of Cerebral Diseases.—Meningeal Hemorrhage.—Insolation, or Sunstroke.—Hyperæmia and Anæmia of the Spinal Cord and its Meninges.—Spinal Hemorrhage.

OF the diseases affecting the nervous system, the greater number relate to the nervous centres—the brain and spinal cord. Important affections, however, are seated in the nervous trunks or their branches; that is, in the peripheral portion of the cerebro-spinal system. I shall consider first those diseases of the brain and the spinal cord, together with their meninges, which, as regards pathological character, are common to all the anatomical systems—namely, hyperæmia, hemorrhage, embolism and thrombosis, inflammation, and various structural lesions—taking up afterward the diseases peculiar to the nervous system, or the *neuroses*. This chapter will embrace hyperæmia, anæmia, embolism and thrombosis, hemorrhage, and insolation, or sunstroke, these diseases forming a group in which are involved morbid conditions pertaining especially to the circulation within the skull and the spinal canal.

Cerebral Hyperæmia.

From the assumption that the contents of the cranium are incompressible by any amount of force which the heart can exert through the arteries, and from the fact that they are enclosed in an air-tight case, Monroe, in the last century, drew the conclusion that the quantity of blood within the skull can never vary. The incorrectness of this conclusion, however, has been abundantly established, particularly by Magendie on rational grounds, and by the direct observations of Donders. Magendie demonstrated that the cerebro-spinal fluid is an important regulator of the cerebral circulation, inasmuch as it recedes from the cranial cavity when the blood-vessels become distended, and is increased when the quantity of blood in the intracranial vessels is diminished. It has since been shown that a similar and an equally important rôle is played by the lymph in the perivascular lymph-spaces. Donders adopted the ingenious device of observing in animals the degree of fulness of intracranial vessels through a glass plate accurately adjusted and hermetically sealed, in an opening made through the skull by trephining. He and afterward other observers were able to prove conclusively by this method that the amount of blood in the intracranial vessels under various influences increases and diminishes. While the possibility of cerebral hyperæmia is now uni-

versally admitted, there is not the same unanimity as to its frequency, importance, and etiology. Within the last few years there has been a decided tendency, especially among neurologists, to deny the clinical importance of affection; but while it is to be admitted that in former times the diagnosis of cerebral congestion was made too frequently and upon insufficient evidence, and while our knowledge of its pathogeny and symptomatology is imperfect, there remains sufficient evidence of its occurrence and importance to justify its careful consideration.

The morbid appearances of congestion of the brain are to be sought chiefly in the brain-substance, and not in the meninges. The mistake is too often made of deciding upon the existence of cerebral congestion merely from distension of the meningeal veins. Distension of these vessels with blood is an index of cerebral hyperæmia during life, being dependent upon the position of the body after death, the length of time during which the blood remains fluid, the manner of dying, and whether the head or the trunk be opened first at the post-mortem examination. It is probable that transient hyperæmia of the brain, as of other organs, may leave no trace of its existence after death. When, however, the congestion is intense and has lasted some time, there are found flattening of the convolutions from turgescence of the brain, a rose-color mixed with the gray of the cortical substance, and red points (*puncta vasculosa*) disseminated over the cut surface of the white matter. The vessels of the meninges, especially the smaller vessels, are also injected. The perivascular spaces are diminished in size or they disappear. Cerebral hyperæmia, especially of the passive or venous variety, may be followed by transudation of serum into the meshes of the pia mater, the choroid plexuses, and the ventricles. The presence of a large amount of reddish-brown amorphous pigment in the walls of the vessels and in the perivascular spaces has been held as an evidence of long-standing congestion. The presence of a certain amount of this pigment is physiological rather than pathological.

Congestion of the brain, as of other parts, may be active or passive. In active congestion an increased amount of blood is brought to the cerebrum by the arteries; in passive congestion the blood accumulates in the brain in consequence of some obstacle to its return by the veins.

It is thought that a full or plethoric habit predisposes to active determination of blood to the brain. Increased force of the heart's action, especially when resulting from simple hypertrophy of the left ventricle, may cause active cerebral congestion. Hypertrophy of the left ventricle is, in the great majority of cases, developed in compensation of some obstruction to the circulation, and has no tendency to produce cerebral congestion; but in the hypertrophy accompanying certain forms of chronic Bright's disease, and in the rare cases of so-called idiopathic cardiac hypertrophy, active cerebral congestion is sometimes developed.

Paralysis of the vaso-motor nerves supplying the cerebral arteries and innervation of vaso-dilator nerves are to be reckoned among the causes of active cerebral hyperæmia. It has been experimentally demonstrated that division of the sympathetic in the neck causes hyperæmia of the intracranial vessels. It may be suspected that strong mental emotion may cause hyperæmia by an affection of the vaso-motor nerves. Nitrite of amyl produces cerebral congestion in this way. There are reasons for believing that one form of migraine or hemicrania is the result of unilateral vaso-motor paralysis causing cerebral congestion.¹

Collateral fluxion of the cerebral vessels, resulting from some obstruction to the flow of blood from the aorta into other branches, has been considered

¹ Ackermann, *Virch. Arch.*, 1858, Bd. 15, p. 431.

² Möllendorff, *ibid.*, Bd. 41; Berger, *ibid.*, Bd. 59.

ing rise to cerebral hyperæmia. As causes of this collateral fluxion, been regarded stenosis of the aorta at the point of entrance of the Botalli, compression of the abdominal aorta and its branches by dis-intestine, tumors and exudations, and obstruction to the cutaneous tion by the action of cold. The adequateness of these causes, how- doubtful. Excessive mental or emotional activity and alcoholic stim- are efficient causes. Cerebral hyperæmia is an element, but probably the most important one, in insolation.

idly-induced *active congestion* of great intensity may produce sudden which may disappear after a few hours or may prove speedily fatal. the pathological explanation of apoplectic attacks in the cases which been distinguished as cases of *congestive apoplexy*. An instance of death from active congestion incident to simple hypertrophy of the has fallen under my observation. When the encephalic functions us suspended, this effect is attributable to intracranial pressure. The s produced by the pressure of the blood within the vessels, as it is by tra-vascular pressure in cases of meningeal hemorrhage. The pressure blood in the large vessels interrupts the circulation in the brain-sub- ; and hence the suspension of the cerebral functions. It is apparently lox that an over-accumulation of blood within the skull should cause and perhaps destroy life by depriving the mass of the brain of a due of arterial blood, yet the fact is sufficiently intelligible. Apoplexy table to active hyperæmia is a rare event, but of its occurrence there no doubt.

SYMPTOMS of active hyperæmia of more or less intensity, but falling of a degree sufficient to produce coma, are as follows: Pain in the head g in degree, sometimes intense, with a sense of heat, fulness, bursting, ght. The pain is not limited to one side or to any particular part of the There is inability to sleep, or if sleep be obtained it is incomplete and shing. Delirium sometimes occurs, and if present it is active. This om occurs especially when the congestion is due to excessive alcoholic tion. Convulsions occasionally occur in the adult. They are less infre- in infancy, but active congestion as a primary affection is not frequent tile life. The countenance is usually but not invariably flushed, the e suffused or injected, with intolerance of light and sometimes scintil- The head is hot; the carotids and the temporal arteries pulsate y; and the patient is conscious of a throbbing sensation in the head. ty to control mental operations, mental confusion, and momentary loss ciousness are occasional symptoms, and also vertigo, tinnitus aurium, me embarrassment in speech. The symptoms are more or less marked ortion as the hyperæmia is greater or less in degree.

ole hyperæmia is merely a functional affection. It involves no lesion; the congestion be removed without much delay the structures are left In a slight or moderate degree it involves no immediate danger. As stated, however, it may be developed rapidly in a sufficient degree to e apoplectic coma, which sometimes proves speedily fatal. Congestion ove an exciting cause of cerebral hemorrhage if the minute arteries brain be the seat of miliary aneurisms or other lesions. Without changes in the coats of the vessels cerebral hyperæmia, however, is very rarely causative of hemorrhage.

DIAGNOSIS of congestive apoplexy involves the discrimination from coma caused by cerebral or meningeal hemorrhage, cerebral embolism, lic intoxication, and uræmia. The differential points cannot be stated it anticipating the clinical histories of these affections. Suffice it to

say here that apoplexy from cerebral hemorrhage and embolism is excluded by the absence of hemiplegic paralysis, and that the symptoms pointing to congestive apoplexy are those which denote a determination of blood to the head, such as a flushed countenance, strong pulsation of the carotids, etc. Circumstances causative of active hyperæmia are also to be considered, such as simple hypertrophy of the left ventricle, alcoholic excess, mental excitement, etc.

Intense active hyperæmia calls for bloodletting. Relief is obtained most promptly by this measure. If the symptoms do not denote a degree of congestion sufficient to call for bloodletting, relief may be obtained by the cold douche, ice to the head, stimulating hot pediluvia, dry cups applied to the neck, and an active purgative. The bromide of potassium and the other bromides are potential remedies, the rationale of their operation being that they diminish the amount of blood within the cranium. They may be employed when the degree of congestion does not indicate either bloodletting or active purgation. Faradization of the cervical sympathetic nerve and ergot relieve active congestion by inducing contraction of the intracranial arteries. Antimony relieves by its sedative effect upon the heart, but it should not be given in doses which produce vomiting. Sinapisms and other excitants of the skin relieve by revulsion.

These measures are for the removal or diminution of existing congestion. The treatment, in addition, should embrace, if possible, the removal of the causes, and if the patient be of a full habit, regulation of diet and occasional saline laxatives are advisable.

Passive congestion differs from the form just considered. Intracranial pressure from over-distended vessels exists alike in both, but in active congestion there is an overplus of arterial blood, and in passive congestion there is an excess of venous blood. This difference accounts for disparity in the symptoms.

In a degree to constitute a morbid condition passive congestion may be produced by any mechanical impediment to the return of blood from the head. This may be due to pressure on the jugular veins in cases of goitre, or of enlargement of the lymphatic glands of the neck, and by the pressure of an aortic aneurism or other tumors on the vena cava. Prolonged effort of expiration, as in some forms of spasmodic cough and in playing on wind instruments, have this effect. Diseases of the lungs occasioning interference with the pulmonary circulation, such as pleuritis with large effusion and emphysema, give rise to passive congestion by leading to an overloading of the right cavities of the heart. It is incident to certain diseases of the heart—especially to obstruction at the right side of the heart from valvular lesion on that side, but more frequently from dilatation of the right ventricle and auricle, together with tricuspid insufficiency as a result of mitral lesions. Obstruction or obliteration of the cerebral sinuses by coagula induces passive congestion in the communicating veins. Diminished force of the arterial circulation—that is, weakness of the *vis a tergo*—is also a cause.

The symptoms denoting passive congestion are somnolency, dulness of mind, blunted perceptions, and sometimes in children convulsions. Throbbing of the carotids and temporal arteries, active delirium, increased heat, and other symptoms denoting active congestion are wanting. The veins of the head are turgid, and the face not infrequently is cyanosed. The symptoms are due in part to intracranial pressure, and in part to the excess of venous or the deficiency of arterial blood.

Passive congestion of the brain is to be considered as not an individual affection, but a morbid element entering into various affections. When

dependent on a mechanical impediment to the return of blood from the head, caused by cardiac lesions, tumor of the neck, etc., the object of treatment is, if possible, to diminish the obstruction. It can do no good to diminish the mass of blood by bloodletting. It is doubtful if aught is to be effected by revulsive measures. Anything which weakens the force of the circulation tends to increase the congestion. If dependent on feebleness of the circulation, the therapeutical indications are to remove, if possible, the causes of exhaustion, and to increase the force of the circulation by digitalis and other cardiac tonics, stimulants, and nutritious diet. The degree of toleration of great venous congestion in some instances—for example, in dilatation of the right side of the heart or when an aneurismal tumor presses on the descending vena cava—is worthy of note, as showing that symptoms are probably often incorrectly attributed to this cerebral condition.

In the foregoing account of cerebral hyperæmia reference has been had to this condition as general; that is, affecting the entire encephalon, and not limited to certain portions of the brain. Hyperæmia more or less circumscribed occurs in connection with tumors which may produce obstruction of vessels or cause a determination of blood within a limited area. Of these two modes, the former gives rise to passive, the latter to active congestion. Passive congestion, limited more or less in extent, is a result of thrombosis of veins and also of both thrombosis and embolism of arteries.

Cerebral Anæmia.

In cerebral anæmia the brain is pale. The puncta vasculosa in the white substance are few or absent. The contrast in color between the gray and white substance is less marked than normal. The perivascular spaces are dilated. Cerebral anæmia is often accompanied by increase in the amount of cerebro-spinal fluid in the subarachnoid space and by serous transudation into the ventricles. This oedematous condition of the brain is often found in persons who have died of wasting diseases and who may not have presented any cerebral symptoms during life. A wet brain, as it is called, is often found as the chief pathological lesion in individuals who have died of acute or chronic alcoholism, and who may have been comatose during the last hours of life.

The quantity of blood sent to the brain is diminished whenever the mass of blood in the body undergoes diminution, as after hemorrhages, and in all diseases in which the constituents of the blood are expended without a proportionate renewal by means of alimentation. An over-accumulation of blood in other organs than the brain has the same effect. Mitral obstruction or regurgitation also occasions a defective supply of blood to the brain. An increase of the subarachnoidian liquid and oedema of the brain, which may be effects of venous congestion, must diminish the amount of arterial blood by pressure on the cerebral arteries. An obstacle to the passage of blood in the distributing arteries may arise from their spasmodic contraction excited by influences exerted through the vaso-motor nerves; and certain mental emotions which are accompanied by notable pallor of the face and a tendency to syncope produce this effect. Anæmia from vaso-motor spasm exists in the first stage of an epileptic paroxysm.

A deficiency of arterial blood in either the whole or a part of the brain is an important pathological element in certain affections of the nervous system which are to be presently considered, the deficiency arising from plugging of a cerebral artery (embolism and thrombosis), the pressure of a clot, of the products of inflammation (fibrin, serum, and pus), and of tumors of different kinds. Inasmuch as the red globules are the chief constituents of

the blood on which depends the normal condition of the nervous centres, a paucity of these as regards morbid effects is equivalent to a diminished supply of arterial blood to the brain. Cerebral anæmia, therefore, is incident to impoverishment of the blood. Thus produced, it is an important element in many affections. Cephalalgia, mental depression, hysteria, and the phenomena referable to nervous asthenia are often attributable to a deficient supply of fully oxygenated blood to the brain in consequence of its impoverishment, or, in other words, a morbid deficiency of the carriers of oxygen—namely, the red globules. Impoverishment of the blood, together with feebleness of the circulation, resulting from intestinal transudation, occasions in children that condition of semi-coma described by Marshall Hall under the name “hydrecephaloid affection”—a condition involving, with deficiency of arterial blood or of red globules, venous congestion.

The immediate effect of a sudden and considerable diminution of arterial blood in the brain is syncope. Consciousness is lost, the face presents a death-like pallor, and convulsions may occur. Syncope occurs in cases of abundant hemorrhage or after a copious venesection, and it may be produced by feebleness of the heart's action without any loss of blood. The phenomena of syncope are due to a certain deficiency of arterial blood in the brain. It is especially liable to occur when the mass of blood in the body is deficient; and impoverishment of the blood also predisposes to it, inasmuch as the efficiency of blood in maintaining the functions of the nervous system depends chiefly on a normal quantity of the red globules. Epileptiform convulsions were produced by Kussmaul and Tenner in rabbits by tying the arteries which supply the brain. Convulsions are not infrequently symptomatic of the anæmia induced by severe post-partum hemorrhage. Coma and paralysis in cases of cerebral hemorrhage, embolism, etc. are attributable to an interruption of the free circulation of arterial blood in the substance of the brain. Notable diminution of the arterial blood sent to the brain may be tolerated in a remarkable degree. This fact was exemplified in a case which came under my observation in which were absence of arterial pulsation in both upper extremities and an extremely feeble pulsation in both carotids, the autopsy showing complete embolic occlusion of the innominate artery, with complete occlusion of the left subclavian artery, and the left carotid artery so nearly occluded as to admit of the passage only of a fine probe. There were aortic lesions and the heart was found enlarged. The patient suffered from frequent attacks of vertigo and blindness, and was incapable of taking any active exercise. Pressure on the carotids produced syncope. There were no other noteworthy cerebral symptoms, and death was due to an attack of pneumonia.

The TREATMENT of syncope embraces measures to increase the quantity of oxygenated blood sent to the head. Recumbency, with the head low to secure the effect of gravitation, is important. Internal stimulants to increase the force of the heart's action are indicated. Dashing cold water upon the face is an efficient measure which acts by causing deep inspiratory efforts. The application of the vapor of ammonia to the nostrils has the same effect. These measures generally are promptly successful, unless the syncope be caused by an excessive hemorrhage or the loss of blood continue. If not successful, another efficient measure consists in compressing the abdominal aorta and the arteries of the upper limbs. In this way, advantage is taken of collateral fluxion.

Cerebral anæmia, as incident to impoverishment of the blood, calls for the remedies and hygienic measures which have been already considered in treating of anæmia as one of the diseases of the hæmatopoietic system (p. 294). The importance of recognizing this condition, with reference not

only to a correct interpretation of pathological phenomena pertaining to the brain, but to disorders in other organs, and to its morbid agency when it is an element of nervous affections, cannot be too strongly enjoined.

It is to be noted that a deficiency of arterial or oxygenated blood may coexist with venous congestion within the skull. The former may lead to the latter in consequence of the contents of the skull being free from atmospheric pressure; and on the other hand congestion of the cerebral veins due to some impediment to the return of blood from the head may be an impediment to freedom of circulation in the distributing arteries, and thus occasion a deficiency of arterial blood.

Cerebral Embolism and Thrombosis.

The presence of an embolus or a thrombus in an artery the branches of which freely anastomose with each other—as, for example, in an artery of a voluntary muscle—produces, as a rule, no appreciable disturbance of the circulation; while the occlusion by embolus or thrombus of an artery belonging to the terminal arterial system—that is, of one whose branches do not inosculate—is followed by an infarction, either hemorrhagic or simply necrotic, in the district supplied by the occluded vessel. It has been demonstrated by Heubner and by Duret that the arteries supplying the so-called basal district of the brain—that is, the region occupied chiefly by the nucleus caudatus, internal capsule, nucleus lenticularis, optic thalamus, and adjoining cerebral substance—are terminal arteries, and that those supplying the cortex cerebri freely anastomose with each other in the pia matter, in which they become much reduced in size before they enter the gray matter. We are thus able to explain why an embolus lodging in one of the cortical arteries in the pia mater (whither, however, it rarely finds its way) produces, as a rule, little permanent disturbance, while an embolus or thrombus occluding one of the basal arteries beyond the circle of Willis is followed by destructive changes in the region from which the blood-supply has been cut off.

The source of the emboli conveyed into the cerebral arteries in the great majority of cases is the left ventricle of the heart. They consist usually of masses of fibrin which have been deposited on the aortic or mitral valves in consequence of acute or chronic endocarditis, and which are washed away by the blood-current into the circulation. Thrombi formed in the heart from any other cause may also give origin to emboli. Cerebral emboli may also be derived from the pulmonary veins, the first part of the aorta, the carotid and the vertebral arteries. Next to disease of the left ventricle, aortic aneurism and atheroma of the aorta form the most frequent source of emboli. The emboli usually consist of portions of a thrombus, but they may be calcareous concretions, fragments of connective tissue, bits of new growth, bacteria, other vegetable parasites, fat, etc.

An embolus may lodge in any artery of the brain, but in the majority of cases it occludes the middle cerebral artery not far from its origin. Next in order of frequency comes embolism of the internal carotid, and then embolism of the basilar artery. The statistics compiled by Gelpke¹ showed that out of 100 cerebral emboli more than 90 affected the arteries which supply the basal ganglia. An embolus enters the left middle cerebral artery more frequently than the right. The explanation of this is afforded by the difference in angle at which the left common carotid and the innominate come off from the aorta; but the predominance in frequency of embolism of the left cerebral arteries over that of the right has been exaggerated. According to

¹ *Arch. d. Heilkunde*, 1875, p. 501.

Gelpke, of 131 emboli of the carotid artery or of its branches, the left was affected 64 times, the right side 54 times, and both sides 13 times.

An embolus usually leads to the formation of a thrombus about it. The cause of spontaneous thrombosis of the cerebral arteries is to be sought in some change in the walls of the affected vessels. The most frequent change is atheroma of the arteries of the brain, but other forms of chronic arteritis, especially syphilitic endarteritis, may also occasion thrombosis. Other rarer causes are—simple fatty and calcareous degenerations of the arteries, compression of the arteries as by a tumor, extension of a thrombus primarily formed in one of the carotid arteries, and possibly mere slowing of the circulation from weakened heart's action.

Cerebral thrombosis occurs chiefly in old age, because the arterial changes to which it usually owes its origin are most frequent at this period of life. When it is present in the earlier periods of life, it is due usually, but not necessarily, to chronic alcoholism or to syphilis. Embolism, on the other hand, may occur at any age.

The effect of the occlusion by an embolus or a thrombus of an artery of the brain belonging to the terminal system is softening of the portion of brain the blood-supply of which has been cut off. For reasons which have already been given, embolic softening in the vast majority of cases is situated in the caudate nucleus, the internal capsule, the lenticular nucleus, the optic thalamus, or island of Reil. According to the size of the artery occluded, a greater or less portion of this region of the brain will be affected. It is especially in the involvement of the internal capsule in the softening that we attribute the hemiplegia which attends embolism of the middle cerebral artery; for in this narrow band of white matter, situated between the lenticular nucleus externally and the caudate nucleus and optic thalamus internally, are compacted together the motor-fibres which supply the opposite half of the body. Embolism of a cortical artery of the brain may do no permanent damage, or it may be followed by softening of the district supplied by the artery. Many of the depressed, soft yellowish patches (*plaques jaunes*) found in the cerebral cortex are of embolic or of thrombic origin.

The first effect of embolism of a cerebral artery is anæmia of the district supplied by that vessel. If a sufficient collateral circulation be established, this anæmia passes off without permanent damage; but if the branches of the artery do not anastomose, the anæmia is followed by a gradually progressive necrobiosis or death of the part, which may or may not be accompanied by hemorrhage. A true hemorrhagic infarction, like that which follows embolism of one of the branches of the pulmonary artery or of the splenic artery, does not occur in the brain, but a certain amount of extravasation of blood in a punctate form is not infrequently present in the anæmic district. It is quite clear why in some cases embolic softening is accompanied by so much blood-extravasation as to resemble a primary cerebral hemorrhage, while in other cases no blood is extravasated. It is probable that increase of pressure in the veins coming from the anæmic spot favors a regurgitant current with hemorrhagic softening, and that low venous pressure opposes it. When a spot of embolic softening is stained with extravasated blood, the process is called red softening; if there be simply anæmic necrosis without hemorrhage, it is spoken of as yellow softening by some and white softening by other writers. It may be mentioned here that the term cerebral softening has ceased to have any exact significance as a pathological process, and that each of the varieties—red, yellow, and white softening—may occur from various causes and indicate various pathological conditions.

In the early stages of embolic softening (and what is said in this connection of embolic applies equally to thrombic softening) the volume of the anæmic

portion of brain is somewhat increased; its consistence is diminished; its boundaries are not distinctly marked off from the surrounding healthy tissue; and its color is red or yellow or whitish-yellow. At a later period the softened spot is diminished in volume and its consistence may be nearly fluid. The final stage of the process is not always the same. Frequently a cyst with fluid contents remains. If the first stage have been red softening, the cyst-wall and the fluid contents are stained with blood-pigment, and the cyst cannot be distinguished from one following a primary cerebral hemorrhage. If hemorrhage have not attended the process of softening, the cyst-wall and its contents are unstained and the embolic origin of the cyst is evident. Sometimes, instead of a cyst there is left a reticulum of connective-tissue fibres and blood-vessels enclosing in their meshes fluid or semifluid contents, frequently of a white color. This is called the cellular infiltration of Durand-Fardel. Other terminations are in a cicatrix and in a dry caseous mass. Finally, the affected tissue may remain indefinitely as a spot of yellow or white softening. In the sequence of changes a spot of primary red softening becomes one of yellow softening in consequence of pigmentary alterations in the extravasated blood.

The microscopic examination reveals, as the most characteristic element throughout the stages of softening, the so-called granular corpuscles, formerly called the inflammatory corpuscles of Glüge. These are large, usually spherical cells, so densely filled with fat-globules as to appear dark by transmitted and white by reflected light. They are usually present in large numbers. They probably have different origins. They consist of emigrant white blood-corpuscles which have taken up the fatty matter resulting from the disintegration of nerve-elements, or they may represent neuroglia-cells, ganglion-cells, adventitious cells of the blood-vessels, or endothelial cells distended with fatty globules. Similar granular cells are found in pathological processes accompanied with fatty degeneration in various other parts of the body, as in ovarian cysts, pneumonia, etc. In the early stages the disintegrated nerve-elements can be recognized in the shape of broken nerve-fibres, drops of myelin, and fatty ganglion-cells. These gradually disappear. Corpora amylacea and red blood-corpuscles, and later amorphous and crystalline hæmatoidin and crystals of the fatty acids, may be detected.

Certain secondary degenerations in the spinal cord which may follow softening of the internal capsule and some other parts will be noticed under the head of Cerebral Hemorrhage.

The preceding description of the anatomical changes resulting from cerebral embolism has been based on the assumption that the embolus is bland in its nature, which is usually true. If, however, the embolus be infectious, it leads to the formation of an abscess here as in other situations; or if an embolus come from a gangrenous focus, such as may be present in the lung, gangrene of the affected portion of the brain or necrosis accompanied by decomposition follows.

CLINICAL HISTORY.—Cerebral embolism is one of the several pathological conditions which are causative of sudden coma or apoplexy. This effect does not occur as a rule, but it is not infrequent. The apoplectic attack is not preceded by premonitions. If antecedent cerebral symptoms have existed, they had no connection with the occurrence of the embolism, the latter depending entirely on the dislodgment of the embolus at its source, and being wholly independent of any previous affection within the brain.

The apoplectic coma may be complete or the patient may be aroused to consciousness by more or less effort. There may be stertor, infrequency of the pulse, vomiting, and immobility or inequality of the pupils; but these

symptoms are rare in embolic apoplexy as compared with apoplexy from cerebral hemorrhage. Convulsive movements occasionally occur.

Hemiplegic paralysis almost always is an effect of embolism of the middle cerebral artery, and this effect is coincident with the apoplexy if the latter occur.

The duration of the coma varies between a few moments and many hours. A fatal termination, the coma existing until death, is rare. The hemiplegia, with few exceptions, persists for a longer or shorter period after the coma has disappeared. It may be permanent. It may or may not include the muscles of the face. It affects the side opposite to the hemisphere in which the embolism is seated. It is chiefly or exclusively motor. Owing to the fact that the embolus is seated oftener in the left than in the right hemisphere, the hemiplegia in the majority of cases affects the right side.

It is not easy to give a satisfactory pathological explanation of embolic apoplexy. The localized anæmia, limited to the district supplied by the occluded artery, and the increased pressure by the arteries dilated in consequence of arterial fluxion, seem *a priori* inadequate to account for the sudden coma, and other causes are not apparent.

In a considerable, perhaps the larger, proportion of cases embolic hemiplegia is not preceded by an apoplectic attack. The hemiplegia occurs suddenly without premonitions. The paralytic, like the apoplectic, stroke takes place unexpectedly, the patient being free from any cerebral symptoms up to the instant of its occurrence.

Cerebral thrombosis very rarely causes apoplectic coma. Coma, if it occur, is developed gradually, and is due to an extension of the thrombus by fresh deposits, thus enlarging the district from which the arterial supply is cut off. Hemiplegia takes place, not by a sudden stroke, but by degrees, not infrequently becoming greater by successive steps instead of by a continuous increase. Moreover, the occurrence of coma or of hemiplegia is preceded by premonitions, such as vertigo, impairment of mental faculties, difficulty in speech, etc. These premonitions may in some instances be due to embolism, which causes a partial obstruction, the occlusion being rendered complete by a thrombus added to the embolus. The so-called softening of the brain of old people, which is accompanied by increasing dementia, is usually the result of thrombosis.

Disturbances of speech often occur in cases of cerebral embolism and thrombosis. Loss of speech, not from any affection of the organs concerned in phonation or from mental imbecility, is expressed by the term *aphasia*. The terms *aphemia* and *atalia* have the same significance, but are not generally used. Aphasia is to be distinguished from *aphonia*, a term denoting inability to speak in consequence of either laryngeal disease or paralysis of the laryngeal muscles. Aphonia is the loss of voice, and aphasia is the loss of speech; the former relating exclusively to the vocal organs, the latter proceeding from a cerebral affection. In aphasia the patient is mute from an inability to use words expressive of the ideas which are in the mind. The loss of speech may be complete or partial, and the patient in some instances is absolutely dumb. Sometimes a single word can be spoken, such as "yes" or "no," and this is uttered whenever the attempt to speak is made; in other instances the vocabulary is larger, but limited to a few words; and in different cases there is every degree of incompleteness in the aphasic condition. A difficulty of speech may consist in an inability to use the proper words to express the mental ideas. Things are not called by their right names, and the language in sentences either spoken or written is incongruous and unintelligible. This difficulty is sometimes distinguished as *paraphasia*.

An important distinction is denoted by the terms *amnesic* and *al-*

aphasia. In ataxic aphasia the mind recognizes the proper signification of words, and the difficulty consists in an inability to give utterance to the words. The name ataxic implies that this inability proceeds from a lack of power to co-ordinate the muscles concerned in speech. Something more than simple ataxia, however, seems to be involved. A lack of co-ordinating power would be manifested by movements responding to, but not governed by, the will, and the result would be inarticulate phonetic sounds. This evidence of ataxia is sometimes manifested, but generally the patient will not make any effort to speak—that is, if the aphasia be complete—and if a few words be uttered, these may be spoken with distinctness. In amnesic aphasia there is inability to recollect words as the symbols of ideas. Language is lost to the memory.

If the aphasia be purely ataxic, the ability to use language correctly in writing is not lost, and may not be impaired, provided the intellectual faculties be intact. The ability to read is retained, and language spoken by others is comprehended. So far as can be judged, in some cases of ataxic aphasia absolute mutism is not incompatible with undiminished intelligence. Frequently, however, the cerebral affection which causes the aphasia impairs, in a greater or less degree, the mental faculties. In amnesic aphasia, on the other hand, the loss of speech is accompanied by inability to use written language (*agraphia*). The loss of the memory of words does not necessarily carry with it inability to understand their meaning when they are heard or seen. The patient may understand both spoken and written language. Inability in these respects involves, in a greater or less degree, mental imbecility.

In ataxic aphasia the ability to interpret signs or gestures is preserved. If this be lost in either ataxic or amnesic aphasia, there is imbecility in a greater or less degree. Patients affected with ataxic aphasia, even when it is evident that the intelligence is well retained, cannot repeat words after dictation. Patients with purely amnesic aphasia are able to do this, provided the intelligence is not too much impaired. The inability to repeat words is evidence either that the aphasia is not purely amnesic or that there is imbecility.

The ataxic and amnesic forms of aphasia may be combined. The patient can then express ideas neither by spoken nor written language, and is unable to repeat words after dictation. In a form of aphasia which has been called *word-blindness* the ability to read and write is lost, although speech is not affected. I have met with two instances in which the aphasia was exclusively of this character, recovery taking place in each instance. Hemiplegia was wanting in both these instances.

In cases of either ataxic or amnesic aphasia it is not an easy problem to determine whether or not, or to what extent, the mental powers are impaired. This problem is sometimes presented to physicians in medico-legal cases. The instances must be rare in which persistent aphasia, associated with hemiplegia, does not involve more or less impairment of mind. Ataxic aphasia as an isolated affection may exist with the intellect apparently unaffected. It is doubtful if this can be said of amnesic aphasia. Words are the instruments of thought as well as the expression of ideas; and it is difficult to believe that the inability to recollect words is possible without deterioration of the reasoning faculties. The inability to understand spoken or written language and signs is proof of impaired intellect.

A large accumulation of clinical observations within the last few years has established the connection of aphasia, in the vast majority of cases, with lesions localized in a particular part of the brain—namely, the island of Reil, and especially the posterior part of the third frontal convolution. These lesions are not alone those incident to embolism and thrombosis, but those caused by

cerebral hemorrhage, morbid growths, abscess of the brain, etc. Aphasia is therefore a symptom belonging also to the clinical history of diseases which are to be hereafter considered. In a small number of cases lesions have been found in the similar parts of the right hemisphere, or the aphasia has been associated with left-sided hemiplegia. In a certain proportion of the latter cases it was ascertained that the patients were left-handed. It may be doubted if in any case of well-marked persistent aphasia an autopsy has shown conclusively absence of any lesion affecting the island of Reil or proximate parts in one or the other hemisphere. (For statistical facts on which these statements are based the reader is referred to other works.¹)

The theory which, with our present knowledge, furnishes the most satisfactory explanation of these facts assumes the following postulates: The third convolution and the island of Reil are in a direct physiological relation to language. This is true of the left, and not of the right, hemisphere in most persons, owing to the habitual use of the left instead of the right hemisphere in the exercise of the function of language. As exceptions to the rule some persons habitually use the right instead of the left hemisphere in the exercise of the function of language, and these persons are generally left-handed. Injury of the parts in the left hemisphere which are in relation to language do not in these persons cause aphasia, but this result follows injury of the parts in the right hemisphere.² The parts in the right hemisphere which are in a physiological relation to language, although their functional activity has been in abeyance owing to non-use, may assume in some instances activity after the parts of the left hemisphere have been incapacitated by lesions; hence, improvement or recovery from aphasia may sometimes take place, the lesions in the left hemisphere remaining unchanged.

Aphasia attributable to embolism occurs without apoplexy or paralysis. The following case is an example: A young man having ridden all day in an open wagon, the weather being cold, after eating a hearty supper was suddenly unable to utter a word. He went to bed, hoping that the ability to speak would return in the morning. He slept perfectly well, but on awakening he was still unable to speak. In the course of the day he began to use some words, often using wrong words, but in the course of a few days he recovered his speech, although ever since he has had some difficulty in selecting right words. He saw me a year after this occurrence. Meanwhile, nothing had occurred to denote any cerebral disease, except that he was conscious of an uneasy sensation in the left side of the head. He had an aortic regurgitant and a mitral direct murmur, with considerable enlargement of the heart. It can hardly be doubted that in this case the temporary aphasia was due to embolism of one of the branches of the middle cerebral artery.

Cases have been reported of the occlusion, after an interval, of the middle cerebral artery on the two sides, giving rise to double hemiplegia. These cases have furnished examples of left hemiplegia without aphasia, followed by right hemiplegia with aphasia.

DIAGNOSIS.—The diagnosis in most cases of embolic apoplexy requires the exclusion of apoplexy from cerebral hemorrhage. The latter is presently to be considered. If the apoplexy be due to occlusion of the middle cerebral artery, it is accompanied by hemiplegia. This is true also of apoplexy due to cerebral hemorrhage in the situations where it is most likely to take place. As a rule, the other pathological conditions which stand in a causative relation to apoplectic coma do not give rise to hemiplegia. The differentiation,

¹ Vide the very comprehensive article on Aphasia, by Kussmaul, in *Ziemssen's Cyclopaedia*, vol. xiv.

² Vide cases reported in *Trans. London Clinical Society*, vol. xiv.

Therefore, in the great majority of cases is between embolism and hemorrhage cases of apoplexy with hemiplegia. The following are the differential points :

Embolism may occur at any period of life, and it is as frequent in early as in middle or advanced age. Cerebral hemorrhage is rare before the middle period of life. An apoplectic seizure, the patient not having reached the latter period, is therefore more likely to be due to embolism than to hemorrhage. The occurrence of hemiplegia on the right side weighs somewhat in favor of embolism. The existence of endocarditis or of valvular lesions in the left side of the heart renders embolism probable. The absence of symptoms denoting cerebral congestion which often, but by no means uniformly, precede cerebral hemorrhage, has some weight in the diagnosis. The absence of cerebral prodromes, which applies to all cases of embolism, is not as constantly applicable to cases of hemorrhage. Vomiting, an infrequent pulse, restlessness, changes in the pupils, and convulsions are more frequent and more marked in cases of apoplexy due to hemorrhage. The diagnosis of embolism is strengthened by the occurrence of symptoms denoting embolism of the spleen and kidneys. Unilateral amaurosis from embolism of the central artery of the retina, preceding or accompanying the attack, is diagnostic of embolic apoplexy.

These differential points suffice often for a highly probable diagnosis. They do not warrant a positive diagnosis. The physician who ventures upon the latter incurs a risk of being convicted of an error at the autopsy. If, however, the patient speedily emerge from the apoplectic condition, rapid improvement as regards the paralysis subsequently taking place and ending in complete recovery, the diagnosis of embolism is very probable.

Embolic hemiplegia is to be differentiated from hemiplegia due to cerebral hemorrhage and to other conditions—namely, morbid growths, abscess, etc. The difficulty in the diagnosis, however, is chiefly in excluding hemorrhage. The other conditions generally involve antecedent symptoms of cerebral disease, whereas the paralysis caused by embolism is devoid of these ; and this is often true of hemorrhage. Both embolism and hemorrhage may give rise to sudden hemiplegia without apoplexy, but in much the larger proportion of cases this is true of embolism. In sudden hemiplegia without apoplexy, therefore, the chances are that it is embolic. Other differential points are embraced in the list of those which relate to the differentiation of apoplexy from embolism and hemorrhage. Rapid improvement is much more likely to take place in paralysis from embolism, and complete recovery, which is not infrequent in embolic hemiplegia, is rare in paralysis from hemorrhage. Increase of the body-heat two or three days after an apoplectic or paralytic stroke has been regarded as denoting the presence of a cerebral clot, but observations have shown that an equal increase sometimes follows when the apoplexy and paralysis are due to embolism.

For the differentiation of embolism from thrombosis the most important point has been stated—namely, the effects of arterial occlusion occur by the former suddenly, and by the latter more or less gradually. This point of distinction, however, cannot always be relied upon. A thrombus may exceptionally form so rapidly as to simulate embolism in the abruptness of its effects. An attack of hemiplegia, either with or without apoplexy, may occur during sleep, and under these circumstances this differential point may not be available. Again, as already stated, an embolus may cause only a partial obstruction, complete occlusion afterward being produced by a thrombus formed at the seat of the embolus.

Other differential points are as follows : The conditions for thrombus belong to middle or advanced age. The youth of the patient is therefore a point in

evidence for embolism. The existence of endocarditis or valvular lesions of the heart points to embolism, and their absence to thrombosis. Calcification of the radial arteries is a ground for inferring that the cerebral arteries have undergone the same change, this being the most frequent of the conditions which are causative of thrombus.

Embolism and thrombosis of the basilar artery may produce coma, either suddenly or more or less slowly, without hemiplegia. Death takes place in some cases within a few hours. In other cases patients recover, although the artery remains occluded. These statements have been verified by cases under my observation.

PROGNOSIS.—An apoplectic attack caused by embolism of the middle cerebral artery is less likely to prove immediately fatal than apoplexy from cerebral hemorrhage; hence the probable diagnosis has a bearing on the prognosis. In most cases, after a few hours the coma disappears, hemiplegia remaining.

The persistence of hemiplegia, whether preceded or not by apoplexy, depends on the occurrence of softening from necrosis and extravasation of blood as effects of the arterial obstruction. If the circulation within the district in which the blood-supply was furnished by the occluded artery be restored within two or three days, so as to prevent the changes incident to defective nutrition, rapid improvement takes place and is followed by complete recovery. These changes are to be inferred from the persistence of the paralysis. There may be more or less improvement, which will be in proportion to the favorable course of the local process as described in connection with the Anatomical Characters. Complete recovery from the paralysis is not to be expected. If the local process be not favorable, more or less impairment of the mental faculties is added to the persistent paralysis. The duration of life is indefinite. Death is generally caused by antecedent or intercurrent disease.

The prognosis if hemiplegia be caused by thrombosis is less favorable than if it be due to embolism, as the patients are more enfeebled. The prognosis is extremely unfavorable if coma supervene upon hemiplegia.

The prognosis as regards the continuance of aphasia is a matter of much interest to patients and their friends. The restoration of speech may accompany recovery from the paralysis, but it may be otherwise. In a hospital case under my observation the hemiplegia entirely disappeared, the general health was excellent, and the mental faculties were apparently not in the least affected, but complete mutism persisted. The patient made no attempt to speak; and when asked why he was silent he placed his finger on his lips and shook his head. He was discharged in this condition. If, owing to the pathological changes in the affected district of the brain, the paralysis persist, aphasia generally continues. There may, however, be more or less improvement. There are no means of judging beforehand what degree of improvement will take place. Adopting the views stated in regard to the duality of the parts which stand in a physiological relation to language, if the injury destroy the functional capacity in the hemisphere to which the exercise of the function has been limited (usually the left hemisphere), the recovery of speech or the degree of improvement will depend on the ability to develop functional activity of the corresponding parts in the other hemisphere, which had previously been in abeyance. The probability of success is greater in proportion to the youth of the patient. If the aphasia continues without improvement for several months, none is to be expected.

The prognosis is favorable when aphasia occurs without apoplexy, hemiplegia, or other evidence of cerebral disease.

TREATMENT.—The object of treatment in the early stage of embolism and thrombosis is the re-establishment of the circulation within the district deprived of blood-supply, in order to prevent the changes incident to defective nutrition. Bloodletting, cathartics, and any measures which weaken the heart's action contravene this object, and are therefore contraindicated. On the contrary, it is often important to increase the strength of the heart's action by tonic remedies, a nutritious alimentation, and alcoholics. If there be feebleness and irregularity of the heart's action in connection with valvular lesions and dilatation, digitalis is indicated. All forms of counter-irritation are contraindicated. Cold applications to the heart are inappropriate. Warm applications may be useful.

This plan of treatment is to be pursued for several days until it be determined whether or not the patient can escape the local changes which ensue if the circulation be not re-established in the affected district of the brain. If softening take place, the objects of treatment relate to the general condition of the system and to the hemiplegia.

The first of these objects embraces measures for improving and maintaining the nutrition of the body—namely, tonic remedies, a good diet, and an invigorating regimen. In cases of embolism diseases of the heart will often furnish indications for treatment.

Hemiplegia incident to the brain lesions resulting from embolism and thrombosis claims the same treatment as when it is due to a blood-clot in the brain. (Vide Cerebral Hemorrhage.) It consists of passive movements, together with rubbing and kneading the paralyzed limbs, the employment of electricity, and as much voluntary exercise of the muscles as practicable. These measures are important in order to prevent degenerative changes in the muscles and nerves of the paralyzed limbs, to promote the circulation and nutrition in these parts, and to develop as far as possible their functional capacity.

The treatment which has special reference to aphasia consists in persistent efforts to regain the memory of words and their vocal utterance. If the mutism be not complete, perseverance in exercises for these ends may sometimes accomplish much, and their importance is to be enjoined.

Thrombosis of the Cerebral Sinuses.

Thrombosis of the cerebral sinuses, especially of the longitudinal and lateral sinuses, may be the result of slowing of the circulation from weakened heart's action in patients, particularly children who are greatly enfeebled by some wasting disease. This form is called marantic thrombosis. Of a similar nature is the thrombosis sometimes observed in acute infectious diseases, particularly typhoid fever.

Thrombosis may also be occasioned by inflammation of the walls of the sinus or phlebitis of the sinus, secondary, as a rule, to disease of the cranial bones. Thrombi thus formed are usually infectious or purulent. Caries of the petrous portion of the temporal bone following inflammation of the middle ear or of the mastoid cells may be taken as one of the most frequent and typical causes of this variety of sinus-thrombosis. The lateral, petrosal, and in a less degree the cavernous, sinuses are most frequently the seat of purulent thrombi. Large carbuncles and severe erysipelatous inflammation about the head and neck may lead to sinus-thrombosis. Thrombosis of the cerebral sinuses may be accompanied by no very characteristic changes in the meninges and brain. Venous congestion, with punctate hemorrhages in the membranes and in the cortex cerebri, is often observed. Sometimes more extensive hemorrhages follow. The purulent thrombi are often accompanied

with meningitis, and not infrequently abscess of the brain. They may lead also to the formation of embolic abscesses in the lungs and in other parts of the body.

Thrombosis of the cerebral sinuses can rarely be diagnosticated with any approach to certainty. The marantic variety in young children gives rise to symptoms analogous to those attributed to anæmia in the so-called hydrocephaloid affection of Marshall Hall—namely, somnolence and coma, with general and progressive prostration. The symptoms which, added to these, render thrombosis probable are tonic contraction of the muscles of the neck and back, strabismus, and ptosis. In adults indefinite cerebral disturbance gradually eventuates in coma. Turgidity of the external veins limited to certain situations on the cranium is a diagnostic feature in some cases. Thrombosis of the lateral sinus sometimes occasions venous congestion and œdema behind the ear. In a few recorded cases the thrombus has extended into the internal jugular, causing pain and swelling of that side of the neck. Thrombosis of the cavernous sinus has been observed to give rise to congestion of the intraorbicular veins, with prominence of the eyeballs, swelling of the eyelids, and congestion of the retina, with choked disc.

Prominent encephalic symptoms accompanying pyæmia, if preceded by caries of the bones about the ear, by carbuncles or erysipelas of the face, head, or neck, may be referable to purulent thrombosis of the cerebral sinuses.

Capillary Embolism and Thrombosis of the Brain.

Our knowledge of embolism and thrombosis of the cerebral capillaries is too limited for a determination of their pathological effects, symptomatology, and diagnosis. Pigment embolism is incident to malarial fevers, especially in their pernicious forms. Emboli or thrombi may consist of leucocytes, fat-drops, or the salts of lime. Future observations may establish an importance which does not at present belong to occlusion of the cerebral capillaries regarded from the standpoint of practical medicine.

Cerebral Hemorrhage.

ANATOMICAL APPEARANCES.—Intracranial hemorrhage may be conveniently divided into cerebral hemorrhage and meningeal hemorrhage. In cerebral hemorrhage, which will be first considered, the extravasation of blood is into the substance of the brain. Hemorrhages, usually punctate in character, are frequently found in and about tumors, around abscesses, and in foci of embolic softening, but only the so-called *spontaneous* cerebral hemorrhages will be considered in this article.

The ultimate cause of spontaneous cerebral hemorrhage is, probably without exception, disease of the cerebral arteries. Since the publication in 1868 of the investigations of Charcot and Bouchard the bursting of miliary aneurisms has been recognized as the predominant cause of spontaneous cerebral hemorrhage. These aneurisms are for the most part visible with the naked eye as little nodules of the size of a millet-seed or of the head of a pin; but they may exceed these dimensions, or, on the other hand, may be microscopic in size. In the majority of cases the whole circumference of the artery takes part in the aneurismal dilatation. The aneurisms are usually fusiform, but they may be round, and they are sometimes sacculated. The aneurisms are the result of pre-existing disease of the arterial coats. The most frequent form of this disease is chronic deforming endarteritis or atheroma. The

aneurisms may also be caused by obliterating endarteritis and by a hyaline degeneration of the middle coat of the artery.

Aneurisms cannot be found in all cases of spontaneous cerebral hemorrhage. Atheroma, fatty degeneration, obliterating endarteritis, hyaline degeneration, mesarteritis and periarteritis, may so weaken the vascular walls as to prove efficient causes of hemorrhage without the development of miliary aneurisms.

In cases of cerebral hemorrhage occurring in the so-called hemorrhagic diathesis, as in scurvy, purpura, leucocythæmia, etc., it is not always possible to demonstrate any alteration in the vascular walls.

All circumstances which occasion increased arterial tension may serve as exciting causes of cerebral hemorrhage, but they never lead to cerebral hemorrhage unless there be disease of the arteries. Such circumstances will be mentioned under the head of Causation. Here may be mentioned, as an important exciting cause of cerebral hemorrhage, cardiac hypertrophy associated with elevated blood-pressure, particularly the cardiac hypertrophy associated with chronic Bright's disease.

Cerebral hemorrhage occurs by far most frequently in and about the basal ganglia of the brain; that is, in the nucleus caudatus, internal capsule, nucleus lenticularis, optic thalamus, and the adjacent part of the centrum semi-ovale. Much less frequent are hemorrhages in other parts of the centrum semi-ovale, in the pons, cerebellum, crura cerebri, medulla oblongata, and cerebral convolutions. The explanation of the frequency of hemorrhages in the opto-striate bodies (corpus striatum and optic thalamus) and in their neighborhood is found in the fact that the arteries which supply these parts are given off from the anterior, middle, and posterior cerebral arteries near their origin, and penetrate directly, as comparatively large vessels, the brain-substance, where they divide as terminal arteries. These arteries are subjected, therefore, to a relatively high pressure; whereas the arteries which supply the cortex cerebri become almost capillary in size before they dip down from the pia mater into the gray substance, and are therefore less exposed to the direct effects of increased blood-pressure. In the majority of cases the hemorrhage is due to rupture of some of the branches of the middle cerebral artery, which are destined for the supply of the lenticular nucleus, the greater part of the internal capsule and of the caudate nucleus, and a part of the optic thalamus.¹ Of special importance is involvement of the internal capsule; as lesions of most parts of the internal capsule are followed by permanent hemiplegia, whereas the hemiplegia which immediately follows hemorrhages confined to the lenticular nucleus or caudate nucleus is usually temporary, or at least is capable of great improvement.

Cerebral hemorrhage occurs in the form of capillary extravasations and in that of so-called apoplectic foci in which the extravasated blood is collected into a mass. The *capillary hemorrhages* are of the lesser importance. They appear as isolated small red points, either scattered through the brain or collected together in a small space. The capillary hemorrhages may unite to make apoplectic foci. They are often found around the large extravasations; they are present around tumors, abscesses, centres of softening; and they may result from active congestion of the brain and from diseases

¹ According to Duret, the localization of hemorrhage in the region of the basal ganglia depends upon whether the rupture be in the region of the lenticulo-striate arteries, which supply the anterior part of the corpus striatum, or in that of the lenticulo-optic arteries, which supply the posterior part of the corpus striatum and a part of the optic thalamus. Among these arteries, which are branches of the arteria corporis striati, there is one particularly well developed, which supplies the region of the lenticular and the caudate nucleus. This artery, according to Charcot, is so liable to rupture that he designates it as "the artery of cerebral hemorrhage."

attended with severe blood-changes. An *apoplectic focus* or clot is usually about the size of a hazelnut or of a pigeon's egg, but it may be no larger than a pea, or it may occupy nearly the whole of one cerebral hemisphere. If the extravasation take place in the vicinity of one of the lateral ventricles, the blood not infrequently finds its way into the latter. The blood may reach the outer surface of the brain either by breaking directly through the peripheral cerebral substance or by penetrating the third and thence the fourth ventricle, from which it can reach the exterior. Usually only a single hemorrhagic focus is present, but there may be several foci. It is not very uncommon to find remains of a previous hemorrhage.

If the hemorrhage in the interior of the brain be of considerable size, the corresponding hemisphere is swollen, the convolutions are flattened, and the *dura mater* is tense. If the hemorrhage be recent, the apoplectic focus consists of a dark-red clot of blood mingled with the *débris* of cerebral tissue, and contained in a cavity the wall of which is composed of lacerated nerve-tissue surrounded by oedematous cerebral substance. Frequently, in proximity to the clot a number of capillary extravasations are present. If the extravasation be large, the substance of the corresponding hemisphere is anæmic. Careful examination by proper methods will usually reveal miliary aneurisms in or around the focus. Care must be exercised not to mistake for these aneurisms hemorrhages into the perivascular sheaths, the so-called dissecting aneurisms which are usually to be found about cerebral extravasations. If life be prolonged, retrograde metamorphoses occur in the extravasated blood. The color changes from dark red to brownish or yellow in consequence of the formation of blood-pigment in the form of granular and of crystalline hæmatoidin out of the red blood-corpuscles. From dissolved coloring matter the surrounding brain-substance becomes stained diffusely yellow or brown. The fibrin and the lacerated nerve-elements undergo disintegration and are absorbed, granular corpuscles making their appearance. While these regressive changes are going on, a connective-tissue capsule is formed by reactive inflammation around the focus. The final result is the production of a so-called apoplectic cyst. This cyst consists of a fibrous capsule enclosing a brownish or yellowish (rarely a clear) fluid. The cyst-wall and the fluid are stained by blood-pigment. Usually delicate threads of connective tissue traverse the cavity between the cyst-walls. Sometimes the walls of the cyst come together and only a pigmented cicatrix is left. It is probable that a cicatrix may also be formed without the intervention of a cyst. It rarely happens that the inflammation around the extravasated blood is sufficient to cause extensive softening, and abscess seems never to follow. When the hemorrhage is situated in the periphery of the convolutions, the changes are essentially the same, except that here the *pia mater* forms the outer covering of the focus.

The lungs of those dying in the early stages of cerebral hemorrhage are usually congested and oedematous, often containing extravasations of blood, particularly in the lower lobes.

The secondary degenerations which follow after a certain time (from six weeks to several months) hemorrhagic foci situated in certain regions of the brain deserve a brief mention here. These secondary degenerations, first studied exhaustively by Türck, follow not only hemorrhage, but softening and other destructive lesions cutting across the group of motor-fibres which, beginning in the anterior and posterior central convolutions, pass through the *corona radiata*, the internal capsule, the *pes pedunculi*; the pons, and the anterior pyramids of the medulla oblongata to the crossing of the pyramids, where the greater portion cross over and descend in the posterior part of the lateral column of the opposite side, a small portion continuing in the median region

of the anterior column of the same side. Destructive lesions of the internal capsule especially, and also of the central convolutions, lower portion of the corona radiata and of the pes pedunculi, are followed by atrophy of the motor-fibres below the seat of lesion. The secondary degeneration not only consists in atrophy of the nerve-fibres, but is accompanied by increase of the connective tissue between the fibres. It is at first characterized by the appearance of large numbers of granular cells. The atrophied bundles are visible on fresh specimens as gray bands following the course which has just been described as that of the motor—or, as they are called, pyramidal—fibres. Upon making a cross-section of the spinal cord in a case of secondary descending degeneration a triangular gray patch will be observed in the posterior part of the lateral column on the side opposite the lesion in the brain, and a narrow gray band, not always visible to the naked eye, in the anterior column near the median fissure on the side of the lesion. The contrast in color between the healthy and the degenerated parts becomes more distinct in specimens hardened in chromic acid. Lesions confined to the nucleus caudatus, lenticular nucleus, or to regions of the brain other than those named are not followed by these secondary degenerations. The degeneration does not affect the peripheral motor nerves.

CLINICAL HISTORY.—Of the several pathological conditions which occasion sudden coma or apoplexy, cerebral hemorrhage is the most frequent in its occurrence. Some writers limit the term apoplexy to sudden coma caused by extravasation of blood. In a large majority of cases the apoplectic attack is without premonition. It is, however, sometimes preceded by certain cerebral symptoms, such as a sense of weight or fulness, vertigo, tinnitus aurium, and flushing of the face. These symptoms, however, are not sufficiently significant to warrant a prediction of impending apoplexy, especially if the patient have never had an attack. It is not uncommon for an attack to occur at a time when the person attacked feels unusually well.

In an apoplectic attack the loss of consciousness may be so abrupt that the patient, if standing or walking, falls to the ground as if felled by a blow; but in most instances the coma is developed, not instantaneously, but during a period ranging from a few moments to half an hour or even longer. It has happened to me to witness an attack which occurred when I was interrogating a patient who had just stated that he had felt on that day unusually well. I noticed suddenly a change in his appearance, as if he were mentally agitated; his expression changed and he winked with his left eye only. He made an effort to rise and fell from the chair. The right side was paralyzed. He did not at once become unconscious, but was irrational, attempting to speak, being unable to articulate, and frequently making efforts to get up from the sofa on which he had been placed. The respiration soon became heavy, with slight stertor and puffing of the lips. He vomited freely. He became profoundly comatose in about half an hour. He remained in the comatose state and died within twenty-four hours.

The coma in different cases is more or less profound. When complete, the patient cannot be roused in any degree by efforts to awaken consciousness; but in many cases there is not this total loss of mental faculties. Voluntary movements in some cases are entirely wanting; and except that the movements of respiration continue, the body is as motionless as a cadaver. In the majority of cases, however, the patient exerts the will, although all manifestations of intelligence may be wanting. In this way the existence of unilateral paralysis becomes apparent. The movements are limited to the upper and lower extremity of one side, and it is evident that hemiplegia is added to the apoplexy. The paralysis is generally at first complete, and the paralyzed limbs are

motionless as regards volition. The respirations are slow, the rhythm is sometimes irregular, and the inspirations are stertorous or snoring. If the coma be profound, the buccinator muscles and the lips are flaccid and are puffed out in expiration. The pulse is usually diminished in frequency, full, and hard, the artery striking against the finger like a metal rod. Exceptionally the pulse is small and feeble. The face is frequently flushed, and, if respiration be much embarrassed, more or less livid, but it is sometimes pallid. The surface in most cases is warm, but sometimes it is cool. At first the temperature of the body, as determined by the thermometer, is lowered from one to two and a half degrees, but after twenty-four hours there is usually a considerable increase of the body-heat. The pupil may be contracted or dilated, or without either contraction or dilatation, immovable, and some disparity between the two pupils is not uncommon. The muscles are generally flaccid, but in some cases rigid. Rigidity of the muscles is the rule in intraventricular hemorrhages. Convulsive movements are infrequent, but they sometimes occur, especially when the hemorrhage involves the motor cortical region. These are usually limited to one side, and to the side not paralyzed. To this rule there are exceptions. The limbs are sometimes rigid on the non-paralyzed side. Vomiting is usual at or shortly after the attack.

These are the prominent symptoms which characterize the apoplectic state. Its duration varies. It may last for a few moments only, the patient gradually emerging from it, or unconsciousness slowly disappears after the lapse of a few hours, or the state may continue for days and then pass off. As a rule, if the coma persist without any improvement for eight or ten hours, and especially if during this period the coma become more and more profound, improvement is not to be expected, and the attack will prove fatal. On the other hand, the attack may prove fatal in a few moments, the mode of dying being by apnoea; or death takes place after several hours; or, again, the apoplectic state continues, and proves fatal after the lapse of several days, in the latter case the mode of dying being by asthenia and apnoea combined.

Patients emerging from the coma appear as if awakened from sleep, and they rarely evince surprise or ask what has happened to them. A noticeable appearance, lasting for several days, is a lateral deviation of the eyes, and sometimes there is rotation of the head in a direction opposite to the paralyzed side. [This turning of the head and eyes toward one and the same side is known as *conjugate deviation*. It is not associated with any particular lesion, but in the early stages of cerebral hemorrhage conjugate deviation, when present, is away from the paralyzed side or toward the lesion; later, when rigidity of the paralyzed muscles has taken place, the head and eyes are turned away from the lesion—i. e. toward the paralyzed side.—H.] With more or less increase of the body-heat pain is referred to the head. Sometimes there is delirium, and spasmodic movements or contractions of the paralyzed muscles may occur. These symptoms denote circumscribed inflammation of the brain surrounding the blood-clot. As a rule, they disappear after a few days.

The symptoms in apoplexy dependent on cerebral hemorrhage are essentially the same as when coma from compression of the brain follows an injury to the head. The extravasation of blood produces a shock or stunning effect upon the brain proportionate to the rapidity and the amount of the hemorrhage, and the pressure affects the circulation in the whole mass of brain. The pressure impedes the circulation in the substance of the brain, and apoplectic phenomena are measurably due to the want of a proper supply of blood therein. The production of apoplexy depends on the suddenness of extravasation. If it take place gradually, apoplexy is not induced, and if it be not sufficient to destroy life within a brief period, the circulation may become restored sufficiently for the restoration of consciousness.

The symptoms which remain after the disappearance of the coma depend upon the situation of the clot. In the next article will be considered symptoms referable to hemorrhage and other lesions occupying different parts of the encephalon. In the present article the hemorrhages in the usual situation—namely, in the basal ganglia and their neighborhood—will be taken as the basis of description. It is important to distinguish between symptoms due to the destruction of a certain part of the brain by the hemorrhage and symptoms dependent upon pressure, œdema, and other disturbances of nutrition in parts adjacent to the clot. Evidently, the first set of symptoms are permanent, while the second set of symptoms may be, and usually are, recovered from.¹

Hemiplegia is a constant effect of cerebral hemorrhage when the extravasation takes place in the situations in which it occurs in the great majority of cases. After the apoplectic state disappears the hemiplegia remains; but in a small proportion of cases the hemiplegia occurs without loss of consciousness, this proportion being much smaller than in cases of cerebral embolism. The attack of hemiplegia without apoplexy is often sudden, but the paralysis is sometimes developed gradually. The difference as regards this point probably depends on whether the extravasation take place quickly or slowly. The hemiplegia, however, may be at first complete, although unaccompanied by any impairment of consciousness. The following account of the hemiplegia dependent on cerebral hemorrhage is applicable to cases with or without an apoplectic attack.

The paralysis may embrace both motion and sensation, or it may be limited to motion. In the great majority of cases, if sensation be at first lost, it is shortly regained, the motor paralysis continuing. The paralysis may be complete or incomplete, and if incomplete it may be of every gradation as regards degree. The paralysis may be complete in one and incomplete in the other extremity. If incomplete in both extremities, the degree of paralysis is generally greater in one than in the other extremity, and in the vast majority of cases the greater degree is in the upper extremity.

In cases of complete motor paralysis movements may frequently be produced by pricking the integument, tickling the sole of the foot, or applying a heated iron to the surface. These movements take place without volition, and much to the surprise of the patient if the mental faculties be intact. They are purely reflex. They are produced in the lower, but rarely in the upper, extremity. In most cases of cerebral hemiplegia the tendon reflexes are increased on the paralyzed side, and to a less extent on the healthy side; whereas the skin reflexes, including the cremaster reflex, are diminished on the paralyzed side. Direct mechanical irritation of the paralyzed muscles will often cause marked contractions which are possibly of a reflex nature. There is a notable difference in different cases as regards the condition of the muscles of the paralyzed limbs. They are in some cases soft and flaccid, offering no resistance to the movement of the limbs in different directions; but in other cases they are hard and rigid, resembling sometimes muscles in tetanic contraction, and offering much resistance to movements of the limbs.

The paralysis generally involves the muscles of the face, the side affected, as a rule, corresponding to the paralyzed limbs. Exceptionally, the limbs on one side and the face on the opposite side are affected. This is called crossed

¹ It is possible that symptoms due to destruction of brain-substance may disappear by other parts of the brain—for instance, corresponding parts of the opposite hemisphere—taking on vicariously the functions of the destroyed district. This supposition, however, cannot be considered as proven. There is no way of distinguishing between symptoms resulting from destruction of brain-substance and those dependent on disturbed nutrition of brain-substance, except that the latter disappear more or less rapidly.

paralysis (*paralytic alterne*), [and is indicative of a lesion in the pons below the decussation of the facial nerve and above that of the pyramids.—H.] Only the muscles of the lower facial district—namely, the muscles of the mouth, cheek, and nose—are affected. On the paralyzed side of the face the expression is abolished, and when the facial muscles are excited to action, as in speaking or smiling, the mouth is drawn to the opposite side. Voluntary power over the frontal muscle and the orbicular muscle of the eye is rarely lost. The patient is generally able to close the eye on the affected side, but he cannot, as a rule, close the eye on the affected side while the other eye remains open. The power over the orbicular muscle in a certain proportion of cases is very obviously impaired. The patient usually winks on the affected side.

If the patient protrude the tongue, the extremity frequently points to the paralyzed side of the face. In the instances in which the tongue has been thought to point to the opposite side there was probably an error of observation. The tongue may appear to be thus deflected, owing to the different situations of the upper lip and angle of the mouth on the paralyzed side. If the mouth on this side be drawn by the finger laterally, so as to be in symmetry with the opposite side, the tongue, which had appeared to be deflected, may be seen to be protruded in a direct line or to point to the paralyzed side. The loss of certain teeth may cause the tongue to protrude in an abnormal direction. The deflection of the tongue to the paralyzed side may be explained by the action of the stylo-hyoid muscles and of the posterior belly of the digastric, which effect the protrusion of the tongue by elevating the base attached to the hyoid bone. When only the muscles of one side act, the base is elevated upon this side only, and the tip of the tongue is protruded to the opposite or paralyzed side; or the deviation of the tongue may be the result of paralysis of the hypoglossal nerve supplying the genio-glossus muscle. The velum pendulum palati on the side of the paralyzed limbs is sometimes involved in the paralysis. This is shown by an abnormal flaccidity of the velum on one side, which remains motionless when the muscles of the other side are seen to contract on depressing the tongue with a spatula. The uvula in these cases is deflected to the unaffected side; but this alone is not evidence of paralysis, as deflection of the uvula to one side is frequently observed in healthy persons. Occasionally there are ptosis, diverging strabismus, and dilatation of the pupil, sometimes on the same side, but in the great majority of cases on the side opposite to that of the paralyzed limbs. These symptoms show that the third cranial nerve is involved. The other nerves distributed to the eye are very rarely involved. The fifth nerve usually escapes. The eighth nerve is unaffected, save in certain cases of hemiplegia with coma about to terminate fatally. The nerves of special sense almost always escape. The muscles of respiration are not usually involved in the paralysis, the respiratory movements on the two sides being equal. Sometimes, however, the respiratory muscles on the hemiplegic side are parietic, as is made evident by a slower and less complete expansion of that side of the chest than of the opposite side. This lessened expansion may explain a tendency of pulmonary complications, which are common in cerebral hemorrhage, to affect the lung on the side opposite to the hemorrhage. The muscles of the neck and trunk in general remain unaffected. It is a law that muscles which usually act co-ordinately or consensually, such as the muscles of the eye and the respiratory muscles, escape in hemiplegia. The trapezius muscle on the paralyzed side is usually parietic, causing a sinking of the corresponding shoulder.

The clinical history of hemiplegia from cerebral hemorrhage presents much diversity in different cases. It is impossible to judge at first of the prospect

as regards the amount of improvement which will take place. More or less improvement takes place in the majority of cases. The improvement is usually gradual. The sensibility, if this have been lost, is first restored, and it may become abnormally increased on the affected side. The paralyzed condition of the face may diminish or disappear in a short time. Improvement, as a rule, begins sooner and progresses more rapidly in the lower than in the upper extremity. Frequently the patient is able to walk without much difficulty, while the upper extremity remains almost completely paralyzed. The manner of walking varies in different cases. If the rotating muscles of the thigh be relatively but little affected, the limb is thrown forward so as to describe the arc of a circle; but frequently the body is inclined to the opposite side and the limb is dragged after its fellow. Sometimes it is brought forward with a jerking movement. Tremulousness of the limb in walking is sometimes observed. The patient often experiences difficulty in walking, from a depression of the toes which renders him liable to trip.

A remote effect upon the paralyzed parts is deficiency of volume or wasting, this effect being proportionate to the degree of permanent paralysis. Atrophy of the paralyzed muscles, however, occurs later, and is much less in degree, than in cases of paralysis from affections of nerves or of the spinal cord. The atrophy which takes place is due to disuse of the muscles. Paralyses dependent on cerebral lesions are distinguished by the absence of a trophic disturbance of the affected muscles. The paralyzed muscles also, as a rule, respond to the excitation of electricity; that is, their electro-contractility is preserved. The temperature in hemiplegia becomes less on the paralyzed than on the opposite side; the pulse has less amplitude; and the veins sometimes show congestion. There may be œdema on the paralyzed side. Remote effects relate to the contraction of certain muscles. Permanent contraction of the flexor muscles, especially of the forearm, is frequently observed. It is in some cases due to a contraction sufficient to overcome antagonizing muscles, and in other cases to a greater degree of paralysis of the extensor muscles, the flexors contracting simply because they are not antagonized. In the latter case the flexed parts are restored with a little force; and in the former the contracted muscles offer resistance to efforts for extension. It is customary to distinguish a primary and a secondary contracture. The primary contracture appears a few days after the attack, and is attributed to reactive inflammation. It generally disappears. The secondary contracture appears several months after the attack, and is permanent. It is attributed by many to secondary degeneration of the spinal cord. It is a bad prognostic sign. Weir Mitchell has observed that the growth of the nails on the limbs of the affected side is arrested, and that a resumption of their growth is a forerunner of a return of power over the paralyzed muscles. There is a tendency to the formation of bed-sores, particularly on the nates and over the trochanter of the paralyzed side.

The mental condition in different cases of hemiplegia from cerebral hemorrhage presents great variation. The faculties of the mind are generally, if not invariably, more or less impaired. Patients are moved to tears or laughter by trivial circumstances. A marked change in character is frequently observed. Patients are liable to become impatient and irritable. They lose self-reliance, and are easily influenced by those around them. This fact sometimes has important medico-legal bearings. The tendency is to progressive impairment of the mental faculties, ending at last in imbecility. Cases differ much as regards the rapidity of progress toward this result. The mental deterioration doubtless often depends in no small measure on the deficiency of the exercise of the mental faculties after paralysis has

Aphasia has been already considered as incident to cerebral embolism and thrombosis. (Vide p. 594.) It occurs in a certain proportion of the cases of hemiplegia caused by cerebral hemorrhage. There may be either total loss or more or less impairment of speech, and the aphasia may be either ataxic or amnesic. As regards the dependence of this symptom on the situation of the clot, the facts stated in connection with Cerebral Embolism and Thrombosis are applicable. Recovery from the aphasia is less likely to take place when dependent on the presence of a clot than when it depends on occlusion of an artery. Aphasia is to be distinguished from the difficulty in articulation arising from paralysis of the tongue and lips.

CAUSATION.—The dependence of cerebral hemorrhage on conditions pertaining to the vessels within the brain has been considered in connection with the anatomical characters, and also its relation to disease of the heart. The local conditions are rarely present prior to the middle period of life; hence, apoplexy and hemiplegia, caused by cerebral hemorrhage, seldom occur in persons less than forty years of age. In the majority of cases the age is more than sixty. Cerebral hemorrhage is somewhat more frequent in males than in females. The various causes of arterio-sclerosis are remote causes of cerebral hemorrhage. Such causes are—alcoholism, syphilis, gout, and hereditary predisposition. As already stated, simple hypertrophy of the left ventricle of the heart may have a causative relation to cerebral hemorrhage by increasing arterial tension, assuming the existence of the lesions of the arteries of the brain which have been described. Hypertrophy associated with mitral stenosis or insufficiency or with aortic lesions has no causative agency. It is doubtful if venous congestion, incident to dilatation of the right side of the heart or other causes, ever has much agency in determining the occurrence of hemorrhage. Active congestion from causes other than simple hypertrophy of the heart may have this effect. Persons have been attacked when under mental excitement, as in public speaking or in a fit of anger. In two cases under my observation an apoplectic attack took place during sexual intercourse. Straining at stool, violent muscular exercise, the throes of labor, and drunkenness have in some cases appeared to produce an attack. All these are exciting causes. In the larger proportion of cases the hemorrhage takes place without any obvious exciting cause. In a considerable proportion of cases it occurs during sleep. I have known it to occur in a patient considerably reduced by prolonged menorrhagia, and to follow much loss of blood from hemorrhoids.

Formerly, much importance was attributed to a so-called *apoplectic constitution*, consisting of shortness of the neck, with considerable *embonpoint* and what is known as a full habit. An analysis of a considerable number of cases shows that no reliance is to be placed on these or any other external characters as denoting a predisposition to cerebral hemorrhage.

DIAGNOSIS.—Apoplexy from cerebral hemorrhage may be confounded with several morbid conditions which involve coma more or less complete. There is little risk of confounding apoplexy and syncope except for a short time, for syncope is of brief duration. It is characterized by death-like pallor, coldness, catching of the breath, and great feebleness or extinction of the pulse—symptoms which do not belong to the clinical history of cerebral hemorrhage. The coma which sometimes follows an epileptic paroxysm bears a resemblance to apoplexy. Knowledge of the fact that the comatose state has been preceded by violent convulsions, with difficult and noisy respiration from laryngeal spasm, will at once settle the character of the attack. Without this knowledge the foam or blood on the lips and the wounded tongue show that epileptic convulsions have occurred. The doubt can only arise when the

a stranger found in an unconscious state. The physician generally is able to ascertain that the patient is subject to epileptic fits. Epilepsy may act as an exciting cause of apoplexy. Hysteria; another condition which may suggest the existence of apoplexy, may be discriminated by the characteristic phenomena of hysteria having the comatose state; by convulsive movements in some cases, into which the patient enters more or less; and by the absence of stertor, the mobility of the patient, and the restoration of consciousness on resorting to the cold douche. The existence generally, in uræmic coma, of epileptiform convulsions if not coexist, suggests the probable existence of renal disease, and is found to contain either albumen or casts, or both.

Alcoholic intoxication may be mistaken for apoplectic coma. The differential points: The odor of spirits or of wine in matters noted in the breath of the patient; absence of hemiplegia; the pulse feeble or soft and increased in frequency, not diminished in frequency as it is usually in apoplexy; the pupils dilated. The patient can be roused sufficiently to exhibit some of the manifestations of consciousness in the manner of speaking. Pouring cold water upon the head to a considerable height is a ready mode of partially arousing the patient. It is important to make this discrimination. To call apoplexy drunkenness is an unfortunate error, and the reverse would be annoying to the patient.

In narcotism due to opium-poisoning the patient by vigorous efforts can be roused for an instant. The respirations are notably diminished in frequency, but there is no stertor. The pupils are contracted. There is no hemiplegia.

Uræmic coma is distinguished by low temperature, the thermometer registering 96° F. in the mouth, the chloroform-like odor of the breath, the presence of sugar in the urine, and sometimes by intense thirst.—H.]

Alcoholic coma caused by active hyperæmia (congestive apoplexy) and cerebral hemorrhage is excluded by the coexistence of hemiplegia. The diagnosis may generally be ascertained during the apoplectic state. The patient moves the extremities of one side, while those of the other side remain paralyzed. He may manifest sensibility only when the integument of one side is scratched or pricked. The face may be drawn to one side, especially if the effects of pain can be produced. The paralyzed members, when raised and allowed to drop, fall as if inanimate. The absence of the cremaster reflex on the paralyzed side, and its presence on the other side, may assist in determining the hemiplegic side during coma. On the other hand, meningeal hemorrhage and cerebral hyperæmia do not, as a rule, give rise to hemiplegia. The occurrence or otherwise of hemiplegia is of course readily ascertained after the patient emerges from the apoplectic state. The exclusion of embolism as a cause is more difficult and is not always practicable. For the differential diagnosis the reader is referred to the diagnosis of embolic apoplexy (p. 596). Hemiplegia without apoplexy may be caused by cerebral affections other than hemorrhage, embolism, and thrombosis—namely, by tumors and abscess of the brain.

These affections give rise to cerebral symptoms prior to the occurrence of hemiplegia, and not infrequently to paralysis limited to one or more cranial nerves. If the hemiplegia be not preceded by symptoms pointing to tumor or abscess, and if functional hemiplegia be excluded, the differential diagnosis lies between hemorrhage, embolism, and thrombosis. If the hemiplegia have occurred suddenly, thrombosis may be excluded. The points for discriminating embolic hemiplegia have been stated. The occasional occurrence of hemiplegia in rare instances is to be remembered in the diagnosis.

The importance of a careful examination of the head for the evidence of injury in cases of coma when nothing is known of the history may be here alluded to. A patient admitted into hospital in a comatose condition, without this precaution may be supposed to have apoplexy, when subsequently perhaps at the autopsy, fracture of the skull with meningeal hemorrhage may be found.

PROGNOSIS.—An attack of apoplexy from cerebral hemorrhage may prove fatal within a very short period, sometimes within a few moments. When it proves suddenly fatal, the coma is at once profound and accompanied by great disturbance of respiration and loss of deglutition, death taking place by apnoea. A fatal termination frequently takes place after the lapse of from twelve to twenty-four hours. The coma in these cases continues, and becomes more profound; the respiration is more and more embarrassed; tracheal râles occur; deglutition is gradually lost; the urine is retained or flows away involuntarily; involuntary dejections occur; and the mode of dying is chiefly by apnoea. If no improvement take place within ten or twelve hours, the coma remaining or becoming complete, disturbance of the respiration and deglutition being more marked, there is little room for the expectation of amendment, and the case will probably end fatally within a short period. In other cases life is prolonged for several days, the patient not emerging from the apoplectic state, but more or less improvement, as regards consciousness, taking place in some cases. The mode of dying in these cases is by apnoea and asthenia combined.

On the other hand, the apoplectic attack may pass off in a few moments or a few hours, hemiplegia remaining. The paralysis at first is generally complete, and the sensibility on the affected side, as well as the power of motion, is often lost. The former usually returns more or less speedily; and more gradually there is improvement as regards the power of motion. In most cases this improvement goes on progressively until a certain point is reached, and at this point, which varies much in different cases, the improvement stops. More or less of the paralysis remains permanently as a rule. It is impossible to judge beforehand of the degree of improvement which may be expected as regards the paralysis. The completeness of the paralysis at first is probably due to the shock or contusion of the parts of the brain in proximity to the extravasated blood. After recovery from this the amount of paralysis will depend on the extent of damage which the brain-substance has received.

The occurrence of cerebral hemorrhage involves liability to its recurrence. Of those who recover from a primary attack, a considerable proportion are again attacked after intervals of varying duration in different cases. As a rule, the hemorrhage in successive attacks is greater, rendering them more severe or dangerous. It is, however, to be borne in mind that recurrences do not always occur. Patients with hemiplegia resulting from a clot in the brain sometimes live for twenty years or longer, a second hemorrhage not taking place. In a recurrent attack the hemorrhage may be on the same side or in the other hemisphere, more frequently the former. Instances have occurred in which a hemorrhage occurred simultaneously in both hemispheres, causing double hemiplegia. The mental condition after the occurrence of hemorrhage has been already referred to.

TREATMENT.—To bleed or not to bleed is the first question which arises in the treatment of an attack of apoplexy from cerebral hemorrhage. The answer is neither affirmative nor negative as regards cases collectively, but it may be either according to the symptoms in individual cases.

If the apoplectic attack be accompanied by symptoms denoting determina-

tion of blood to the head and increased arterial tension—a flushed face and strong pulsation of the carotids—venesection is indicated, especially if the patient be robust or full-blooded and the action of the heart be abnormally strong. Under these circumstances it is fair to infer that the giving way of the cerebral artery was due in a measure to the hyperæmia or to the arterial tension as an accessory or exciting cause. Bleeding will not undo the mischief which has already taken place, but it may prevent an increase or a renewal of the hemorrhage. In a certain proportion of cases the symptoms are essentially different. The face may be pallid, the carotids do not beat strongly, and the pulse may be small and weak. Venesection under these circumstances is contraindicated. If the abstraction of blood be decided upon, it should be by venesection. It is important that the effect of the bleeding be produced promptly, and for this reason cups or leeches do not as well meet the indication. The amount of blood abstracted should be determined by the effect. A large bleeding is rarely indicated.

Generally, it is advisable to administer an active cathartic. Croton oil, from the facility with which it is administered, its efficiency and its quickness of operation, is to be preferred to any other cathartic. Three or four drops may be given at once and repeated in three or four hours if free purgation be not produced. Its operation may be promoted by large, stimulating enemata. An active cathartic should not be given if the pulse be notably small or feeble.

The patient should be placed in a cool, airy apartment; the head should be moderately raised; cold or evaporating lotions should be applied to the head, or, if the head be hot and flushed, the ice-cap; stimulating pediluvia may be employed if the extremities be cool; and everything constricting the neck and chest should be removed. Attention is to be directed to the bladder, and if required the use of the catheter is not to be delayed.

These are the measures to be pursued until it is decided whether the patient is to emerge from the apoplectic state. If after the lapse of several hours the symptoms denote a hopeless condition, the physician must content himself with measures which appear to contribute to the comfort of the patient, for he is, in fact, unconscious of suffering. Purgatives and other perturbing remedies under these circumstances will only tend to hasten the fatal termination. If, on the other hand, the attack pass off, the measures indicated are simply quietude and an unstimulating diet until symptoms denote inflammation around the clot. These do not call for active treatment. Cool applications to the head, a sinapism to the neck, saline laxatives, and perfect quietude are sufficient. The vital powers should not be impaired by active treatment. The recovery is effected by the disintegration and absorption of the clot, and this requires many weeks or months. The processes of disintegration and absorption are not promoted directly by any medicines. There is no ground for supposing that mercury, iodine, or other drugs have any direct influence over these processes. Blisters or other modes of counter-irritation are of no utility. Electricity applied to the brain is a doubtful measure, and is not without hazard of injury. As regards the clot, nothing can be done except by nourishing the patient well, avoiding stimulants, preventing as far as possible everything which disturbs body or mind, and meeting any symptomatic indications. The case is now one of hemiplegia dependent on the presence of the clot and the damage which it has occasioned.

A tendency to the formation of bed-sores is counteracted by observance of strict cleanliness and by not allowing continued pressure on susceptible parts.

Active treatment directed to the paralyzed muscles is contraindicated while the symptoms denote inflammation or irritation at the situation of the hemorrhage. Gentle rubbing of the paralyzed limbs and passive movements, how-

ever, may be resorted to with but little delay. More energetic measures are indicated after two or three months. The objects of treatment are the promotion of the circulation and nutrition in the paralyzed muscles, together with the increase, as far as possible, of their functional capacity. The means are massage or kneading, rubbing with stimulating liniments, passive movements, electricity, and volitional exercise. Kneading, rubbing, and passive movements should be systematically and perseveringly employed. If they do not occasion fatigue, they cannot be too much employed. It is to be borne in mind that paralyzed muscles do not of themselves resume at once their normal functional capacity, even after the conditions causative of the paralysis are removed; and having been for a considerable period paralyzed, they may remain so indefinitely if appropriate measures be not made for their restoration.

Electricity is a potential agent in promoting the objects stated, especially when the paralyzed muscles respond not at all or feebly to the will. It promotes circulation, nutrition, and is a substitute for the will as regards the functional exercise of the muscles. With respect to the choice between the two currents, the methods to be adopted, etc., the reader is referred to treatises on the practical use of electricity or to works devoted to nervous diseases. This agent is apt to be inefficiently employed. It may be injudiciously used, and it is potential for harm as well as good. When practicable, therefore, its employment should be under the direction of an experienced physician who has given special attention to electro-therapeutics.

When the paralysis is not complete, the most efficient measure for securing as much improvement as is compatible with the amount of damage which the brain has received is voluntary exercise of the paralyzed muscles. A patient who has been for some time a paralytic is in a condition not unlike that of the infant who has not learned to use the muscles. Persistent exercise in the one case, as in the other, is the means by which development and power are to be acquired. There is reason to believe that in not a few cases paralysis continues until it becomes fixed at a certain point, when persevering exercise in conjunction with other measures might have led to more or less improvement. It is often difficult to enforce this measure on account of its simplicity.

The liability to the recurrence of cerebral hemorrhage renders it important to observe all possible precautions by way of prophylaxis. Placing the system in the best possible condition by means of a well-regulated diet and regimen, and avoiding exciting causes, will afford all the security which can be obtained. It is not probable that any protection is afforded by reducing the powers of the system, and injury may thereby be produced. It is injudicious to adopt a diet which is insufficient for the wants of the system, or to resort to repeated bloodlettings, cathartics, or other lowering measures. In striving to avoid excesses and imprudences of all kinds care must be taken not to err in the opposite extreme. Mental occupation within certain limits is advisable.

A liability to hemorrhage if an attack have never occurred cannot be estimated with any degree of certainty. Apoplexy and paralysis are affections which many persons apprehend, and if certain cerebral symptoms be experienced, especially vertigo, the apprehension is often the source of much unhappiness. The suggestion by the physician that there is danger of these affections is an indiscretion which I have known to prove most calamitous. When apprehension is felt, the physician is warranted in giving assurances that vertigo and other cerebral symptoms are sufficiently common without being followed by apoplexy or paralysis, and that these affections are rarely preceded by obvious premonitions. Needless uneasiness may oftentimes be removed by these assurances.

The treatment of hemiplegia from cerebral hemorrhage is the same whether it occur with or without the occurrence of apoplexy.

In connection with the subject of cerebral hemorrhage the question arises, in the particular situation of the extravasated blood be ascertained by means of the symptoms? This question arises in respect to the particular situation of softening from embolism and thrombosis, and also with reference to the localization of circumscribed inflammation or abscess of the brain, cerebral tumors, and atrophy. In order to avoid repetitions, the facts at present known concerning the localization of cerebral diseases are concisely stated under a separate heading.

Topical Diagnosis of Cerebral Diseases.

In the present article will be considered the diagnosis of cerebral diseases according to the situation of the lesion. The possibility of the topical diagnosis of cerebral diseases is based upon the fact that certain parts of the brain are endowed with special functions, the excitation or the abolition of which gives rise to characteristic symptoms. Our knowledge of the localization of these functions is due partly to physiological, but chiefly, so far as man is concerned, to clinical and pathological observations. This knowledge is still very imperfect. In the present article only such facts will be considered as are reasonably certain.

The diseases of the brain are conveniently classified as *focal* or *local* diseases, in which the lesion is confined to a circumscribed part of the brain, and *diffused* or *general* diseases, in which a large part of the brain is affected. Examples of focal cerebral diseases are—circumscribed hemorrhages, foci of softening either embolic or thrombic, localized encephalitis, abscess, and tumors. Examples of diffuse diseases of the brain are—anaemia and hyperaemia, diffuse encephalitis, and the conditions produced by concussion and compression of the brain. It is of course only the local diseases of the brain which admit of a topical diagnosis.

The symptoms which may be produced by local diseases of the brain are either *direct* or *indirect*. The direct symptoms are those due to irritation or to destruction of the part of the brain which is the seat of the lesion. The indirect symptoms are those referable to the influence exerted by the lesion upon neighboring or remote parts of the brain. Direct symptoms caused by destruction of brain-substance are permanent, except so far as some other part of the brain may be capable of assuming vicariously the functions of the destroyed part. Indirect symptoms are to a great extent variable and inconstant, and in the case of many local lesions they disappear after an indefinite period, leaving only direct symptoms. Although certain symptoms, such as coma, and in most instances headache, delirium, and vomiting, may be recognized as indirect symptoms, yet it is in general impossible from their nature alone to distinguish the indirect from the direct symptoms. This distinction, however, can often be made in the course of time by noting that certain symptoms disappear, and are therefore probably indirect, whereas other symptoms remain permanently and are considered to be direct. For instance, a fresh hemorrhage in that part of the internal capsule occupied by the motor tracts may give rise, in addition to hemiplegia, to anaesthesia, paralysis, and strabismus, the last three symptoms being indirect, as they are referable not, like the hemiplegia, to destruction of the part named, but to influence exerted upon other parts by pressure, inflammatory oedema, etc. At a time anaesthesia and the other secondary or indirect symptoms disappear, and the hemiplegia remains as the direct symptom of the lesion. It

is evident that the fewer the indirect, and the more pronounced the direct symptoms, the greater the probability of making an accurate diagnosis of the seat of the lesion. Hence it follows that a topical diagnosis is often impossible in the early stage of cerebral hemorrhage or softening, but can frequently be made at a later stage, when the indirect symptoms have disappeared.

For various reasons mistakes are especially liable to be made in the topical diagnosis of tumors. Not only do tumors often grow in parts of the brain the function of which is very imperfectly understood, but they give rise to many diffuse and indirect symptoms, and by their slow development they frequently displace nerve-elements without destroying them.

Hughlings-Jackson has graphically designated as *discharging* lesions those which irritate nerve-elements, and as *destroying* lesions those which annul their function. A discharging lesion in a motor tract produces spasm—a destroying lesion, paralysis.

After these few remarks by way of introduction, the lesions situated in the different parts of the brain will be briefly considered with reference to their topical diagnosis.

1. *Cerebellum*.—Hemorrhage in the cerebellum occurs much less frequently than in the cerebrum. The proportion is variously estimated as from 1 to 12 to 1 to 35. Embolism of the cerebellar arteries is even more unusual. Other local diseases of the cerebellum are abscesses, encephalitis, tumors, and atrophy.

Lesions, often extensive, of the cerebellum may remain entirely latent during life. This is believed to be the case only when the lesion is localized in one cerebellar hemisphere, and when its influence does not extend beyond the seat of disease. In a remarkable case reported by Ebstein,¹ nearly the whole left hemisphere of the cerebellum was occupied by an osteoma which did not encroach upon surrounding parts. The patient died of a pulmonary affection, having manifested no symptom referable to the nervous system. Characteristic, although not pathognomonic of lesions of the cerebellum, are disturbances of co-ordination designated as cerebellar ataxia and drunkenness. These symptoms are believed to be the result of an affection of the vermiform process or middle lobe of the cerebellum, either directly when it is the seat of disease or indirectly by an encroaching lesion. The gait in cerebellar ataxia, which affects chiefly the lower extremities, resembles that of a drunken man, and not that of a patient affected with locomotor ataxia or posterior spinal sclerosis. The symptoms in the great class of cerebellar lesions, such as fresh hemorrhages and tumors which act upon adjoining parts, particularly upon the pons and medulla oblongata, are various, but they can sometimes be utilized in making the diagnosis. Of symptoms produced by cerebellar disease, but not directly referable to disturbances of function of the cerebellum itself, may be mentioned vomiting, amblyopia, and amaurosis; headache, most frequently in the occipital region; hemiplegia, either corresponding to the side of the lesion or to the opposite side; less often epileptiform convulsions and spasm; and sometimes irregular and infrequent action of the heart.

2. *Crura Cerebelli*.—No characteristic symptoms of lesions of the superior or of the inferior peduncles of the cerebellum have as yet been discovered. On the other hand, lesions of the middle peduncles, the *crura ad pontem*, have repeatedly been observed to be attended by so-called forced or compelled movements. These peculiar movements appear, according to Nothnagel, when the lesion acts as an irritant and does not completely sever the connection of the affected crus with the cerebellum. Recognized forms of

¹ *Virchow's Archiv*, Bd. 49, p. 145.

these compelled movements are rotary movements of the body around its long axis; the assumption of a compelled position upon one side, to which the patient instantly returns when moved; the tendency to fall to one side, accompanied with dizziness; and the deviation of the head and of the eyes, most characteristic when one eye is turned upward and the other downward. These movements may occur during coma, but they are more characteristic of disease of the crura cerebelli when present in the waking state. With the exception of the rotary or "circus" movements and the peculiar deviation of the eyes, similar compelled movements have been observed in diseases situated in other parts of the brain. The movements may be toward the side of the lesion or toward the opposite side.

3. *Pons Varolii*.—Hemorrhages occur in the pons with about the same frequency as in the cerebellum. Emboli rarely lodge in the basilar artery, because its size exceeds that of either vertebral artery, and because the latter is unfavorably placed for the reception of an embolus. On the other hand, thrombosis of the basilar artery in consequence of atheromatous degeneration, followed by softening in the pons, has been repeatedly observed. It is important to keep distinct from each other tumors of the pons and tumors exterior to the pons and situated at the base of the brain, although they may have many symptoms in common.

Fresh hemorrhages in the pons can be diagnosticated almost with certainty when *alternating* or *crossed paralysis* (that is, facial paralysis on the side of the lesion and paralysis of the extremities on the opposite side) can be made out; but in many cases, perhaps the majority, of fresh hemorrhage in the pons there are no characteristic symptoms present and the topical diagnosis is impossible. Often the symptoms are those of an ordinary apoplexy, such as follows hemorrhage in the internal capsule. When it is considered that through the pons pass the bundles of motor and of sensory fibres which connect the cerebrum with the spinal cord, that here are situated the roots of origin of the trigeminus, abducens, facial, and acoustic nerves, and taking into view the close relation of the pons to the medulla oblongata, it cannot occasion surprise to find that the symptoms of stationary lesions, such as of old hemorrhages and foci of softening, and particularly of slowly-progressive tumors, may present a variety and complexity somewhat diagnostic of affections of this part. It would be beyond the limits and scope of the present summary to enumerate the possible, or even many of the frequent, combinations of symptoms which may attend diseases of the pons. The most characteristic, and when occurring suddenly probably a pathognomonic, symptom is *crossed paralysis* (*paralyse alterne*). When this variety of paralysis is due to a stationary, non-encroaching lesion, this lesion will almost always be found in the lower half of the pons. In crossed paralysis, while the extremities are always paralyzed upon the side opposite to the lesion, there is paralysis of the facial, abducens, or hypoglossus nerves upon the side of the lesion. The facial paralysis of crossed hemiplegia resembles peripheral facial palsy; that is, all of the muscles supplied by the facial nerve (including the occipitofrontalis, corrugator supercilii, and orbicularis palpebrarum) are involved and the reaction of degeneration appears. Crossed hemianæsthesia may likewise occur, but less frequently than crossed hemiplegia.¹ It must not be inferred that the facial paralysis is necessarily on the side of the lesion in affections of the pons. It is sometimes on the same side as the body paralysis, in which case the hemiplegia is in no way characteristic of disease of the pons. In a remarkable case of tumor of the posterior portion of the pons, reported

¹ The manifold variations under which crossed paralyse of motion and of sensation may appear have been tabulated by Sigerson, *Dublin Med. Journ.*, Feb., 1878.

by Wernicke,¹ there existed paralysis only of cranial nerves, and not at all of the extremities. When crossed paralysis fails, it is from the grouping of the symptoms and by a careful analysis of individual symptoms that the diagnosis of a pons lesion is to be made, rather than by the presence of any one characteristic symptom. Bilateral paralysis is rare—in fact, much less frequently met with than was formerly assumed or would seem probable on theoretical grounds, if we except those extensive hemorrhages which lead to death during the stage of apoplectic coma.

4. *Medulla Oblongata*.—Hemorrhage into the medulla oblongata is not frequent. It leads almost invariably to death, either instantaneously or within a few hours, in consequence of injury to the centres of respiration and of circulation. Tumors occur in this situation, but they are rare, and their symptomatology is very imperfectly understood. The most interesting and carefully studied of the local diseases of the medulla oblongata is bulbar paralysis, the acute form of which is generally due to ischæmic softening or to inflammation, rarely to hemorrhage. Both the acute and the chronic forms of bulbar paralysis will be subsequently considered.

The nerves which originate in the medulla oblongata are the hypoglossal, the vagus, the spinal accessory, and the glosso-pharyngeal. The symptoms which are most characteristic of lesions of the medulla oblongata are difficulty of articulation, called dysarthria and anarthria, and difficulty in swallowing. Disturbances in the rhythm of respiration and of circulation are frequent. Lesions of the medulla oblongata are the only central lesions which can cause aphonia. Diabetes mellitus and diabetes insipidus have been occasionally observed to attend lesions (tumors) affecting the floor of the fourth ventricle. Lesions of the medulla can of course cause extensive paralysis of motion and of sensation, which may be either unilateral or bilateral according to the situation of the lesion, and which may exist without the coincidence of characteristic symptoms.

5. *Pedunculus Cerebri*.—Lesions confined to one of the peduncles are rare. Nevertheless, localized hemorrhages, foci of softening, and tumors, particularly tuberculous tumors, have been observed in this situation. It is, as a rule, only when the affections are situated in the basal portion of the peduncle near the pons that their effects are limited to this structure. The peduncles are composed essentially of centripetal and of centrifugal nerve-fibres connecting the cerebrum with the spinal cord. The motor fibres, constituting the so-called pyramidal tracts, occupy the middle third of the pes pedunculi; and the sensory fibres are situated in the tegmentum. The intimate relation between the inner border of the crus and the oculo-motor nerve is to be borne in mind. Characteristic of localized lesions of the crus cerebri are paralysis of motion and often of sensation of the side of the body opposite to the lesion, and paralysis of the third or oculo-motor nerve on the same side as the lesion; in other words, a variety of crossed paralysis. The symptoms of paralysis of the third nerve are ptosis, external strabismus, and dilatation of the pupil, often combined with double vision. It is only when the ocular paralysis and the crossed facial or body paralysis develop at the same time that it is safe to diagnosticate an affection of the crus. Lesions of the crus may produce simply hemiplegia or hemianæsthesia without ocular paralysis, in which case the topical diagnosis would be impossible.

6. *Corpora Quadrigemina*.—Of the anatomical facts bearing upon the functions of these bodies, the most important is the termination of a part of the fibres of the optic tracts in the anterior pair or the nates. Furthermore, it is to be considered the close relation between the terminations of the third and fourth cranial nerves and the corpora quadrigemina. Very little is known

¹ *Arch. f. Psych.*, Bd. 7, p. 513.

symptoms referable to disease of the corpora quadrigemina. Lesions of the anterior pair lead to diminution of vision or to blindness. If the lesion is confined to one of the anterior pair, it is probable that hemianopsia will result. Paralysis of the oculo-motorius, reflex immobility of the pupil, and disturbances of co-ordination resembling cerebellar ataxia have been observed in lesions, particularly of the posterior pair and of the cerebellar peduncles. None of these symptoms, however, is diagnostic of disease of the corpora quadrigemina, which, with our present knowledge, does not admit of positive diagnosis.

Optic Thalamus.—Although the optic thalamus is very often involved in age, softening, and other affections of the internal capsule and the internal capsule, it is rare that a lesion is confined exclusively to this body. From former views, it is now believed that lesions situated in the thalamus, their influence not extending beyond the seat of disease, do not produce paralysis either of motion or of sensation. The posterior part of the thalamus—namely, the pulvinar and the external geniculate body—derives fibres from the optic nerves, so that lesions of this part produce disturbances of vision, probably in the form of hemianopsia—a disturbance which, however, peculiar to lesions in this situation. Hemiplegic hemichorea has been observed with lesions of the thalamus, but whether as a direct or indirect symptom is uncertain. No lesion can render certain the topography of the optic thalamus.

Striatum (nucleus caudatus, nucleus lenticularis, and capsula interna).—This is the most frequent seat of disease and of softening. It is impossible to be familiar with the anatomical details of the parts here situated. The region of this region is shown in Fig. 1, which presents a horizontal section through the right cerebral hemisphere. The striatum is composed of the nucleus (NC in Fig. 1) or intralenticular nucleus, the lenticular nucleus, the extralenticular nucleus, and the internal capsule. The caudate and the lenticular masses of gray matter. The internal capsule is composed of white matter. The internal capsule is made up of an anterior division, situated between the nucleus and the lenticular nucleus, and a posterior division, between the thalamus and the lenticular

masses. The two divisions meet at a bend called the knee of the internal capsule. The destination of the fibres composing the anterior division of the internal capsule is not thoroughly understood. In the posterior division are the motor and the sensory tracts of nerve-fibres supplying the limbs of the body. The motor tract forms a compact mass of nerve-fibres. The sensory tract includes only the caudate nucleus in the corpus striatum.

FIG. 1.

Horizontal Section through the Right Cerebral Hemisphere (from Strümpell): NC, nucleus caudatus; NL, nucleus lenticularis; Th, thalamus opticus; CLa, anterior division of the capsula interna; CIp, posterior division of the capsula interna; Fa, fibres belonging to the facial nerve; P, pyramidal tract (motor); S, sensory tract; O, occipital lobe; F, frontal lobe.

fibres called the pyramidal tract (*P*), situated in the middle third of the posterior division of the internal capsule.¹ The fibres belonging to the facial nerve are probably situated in front of the pyramidal tract, nearer the knee of the capsule. The sensory tract occupies the posterior third of the posterior division of the internal capsule. The sensory tract includes both the nerves of ordinary sensation and the nerves of special sense.

The further course of the pyramidal tract is as follows: The tract is composed of motor fibres which originate in the motor cortical area—namely, the central convolutions and the paracentral lobule. (See Figs. 2 and 3, pp. 619, 620.) These fibres descend through the centrum ovale in the corona radiata, and are collected together into a compact mass in the middle third of the posterior division of the internal capsule. From the internal capsule the pyramidal tract is continued into the middle third of the pes pedunculi,² thence into the anterior half of the pons, where the fibres are scattered among the longitudinal bundles of the pons, and thence into the medulla oblongata, where they form the anterior pyramids. At the crossing of the pyramids a part of the pyramidal fibres usually remains uncrossed, and descends in the anterior columns of the spinal cord, while the larger part crosses and descends in the lateral columns of the cord.³ (See Fig. 5, p. 671.) Here the pyramidal tracts terminate in the ganglion-cells of the anterior horns, whence the anterior nerve-roots originate. The pyramidal tracts, therefore, transmit voluntary motor impulses directly from the motor cortical area to the motor ganglion-cells in the anterior horns of the spinal cord. In the pyramidal tracts of the brain are also included fibres belonging to the motor cranial nerves.

Destruction of the pyramidal tract of one half of the brain causes hemiplegia of the other half of the body. It is evident that the lesion must be very large to destroy all of the pyramidal fibres in the centrum ovale, whereas a small lesion in the posterior division of the internal capsule will cut across the entire tract. For reasons which have been previously stated, the internal capsule and the adjacent ganglia are the most frequent seats of hemorrhage and of softening. Hence the symptoms which attend these lesions in this situation are usually taken as the basis of the clinical history of cerebral hemorrhage and of cerebral embolism.

When the lesion involves the anterior two-thirds of the posterior division of the internal capsule, there is ordinary hemiplegia; that is, paralysis of motion of the opposite extremities and paralysis of the lower branches of the opposite facial nerve. The hypoglossal nerve is parietic. Secondary contracture of the paralyzed muscles in most cases ensues when life is sufficiently prolonged. The muscles undergo only slight atrophy from disuse, and preserve their normal electrical reactions.

Lesions involving the posterior third of the posterior division of the internal capsule are much less common. They cause hemianæsthesia or paralysis of sensation of the opposite half of the body. This hemianæsthesia is often complete, including not only ordinary sensation, but the special senses of sight, hearing, smell, and taste. The special senses may be only partially or

¹ The exact situation of the pyramidal tracts in the internal capsule varies somewhat with the level of the section, these tracts being nearer the knee in the superior part and nearer the posterior extremity in the inferior part of the internal capsule.

² Here, too, the situation varies somewhat with the height of the section, the tracts occupying the third quarter (reckoned from within outward) in the upper or anterior part of the peduncle.

³ Sometimes all of the pyramidal fibres cross to the opposite lateral column. It is believed that very rarely the pyramidal fibres do not decussate at the crossing of the pyramids, but descend in that half of the spinal cord which corresponds to the hemisphere in which they originate. In the latter case it has been claimed that a lesion in the brain would produce hemiplegia on the same side as the lesion.

at all involved. The affection of sight is probably in the form of hemiopia. Post-hemiplegic hemichorea (which was first described by Weylitchell) and athetosis have been observed especially with lesions in this situation.

No symptoms have been referred directly to lesions confined to the anterior division of the internal capsule, to the caudate nucleus, or to the lenticular nucleus. Lesions of these parts, however, are almost invariably accompanied by hemiplegia, but this is referable to involvement by pressure or otherwise of the neighboring pyramidal tracts of the posterior division of the internal capsule. If the pyramidal tracts be not directly involved, the hemiplegia is often temporary, disappearing when the effects of pressure or of collateral edema have been removed. The hemiplegia caused by destruction of the pyramidal tracts is permanent. The partial facial paralysis, however, seems to be an exception to this rule, as it is probable that one hemisphere may innervate the facial muscles of both sides.

FIG. 2.

Diagram showing Position of Motor-centres in the Cortex (after Eichhorst).

Centrum Ovale.—We know of no symptoms diagnostic of lesions situated in the centrum ovale of the cerebral hemispheres. Lesions involving the corona radiata, which connect centres in the cortex with peripheral centres, cause the same symptoms as lesions of the cortical centres themselves. Hence lesions affecting the fibres descending from the motor cortical centres, cause hemiplegia; if of small extent, monoplegia of the limbs. Lesions of fibres of the corona radiata coming from the visual cortex cause hemiopia. Lesions of fibres from the third convolution or from the first temporal convolution of the left side cause aphasia. Lesions in the frontal lobe, and less frequently in the parietal lobe, and in the other cerebral lobes, may give rise to no appreciable

Cerebri.—Since the publication of the

of their discovery of motor-centres in the cortex of the brain, much attention has been directed, and with fruitful result, to the clinical and pathological study of localized lesions of the cerebral cortex.

A. *Motor Area of the Cortex*.—In confirmation of physiological experiment, pathological observations have demonstrated that lesions of a certain region of the cerebral cortex are followed by motor disturbances. This region, designated as the motor cortical area, embraces the anterior central and the posterior central convolutions (also called respectively the ascending frontal and the ascending parietal convolutions) and the paracentral lobule. The results of experiment, as well as the symptoms following small circumscribed lesions in the motor area, justify the recognition of separate motor centres in this part, the locations of which are represented in the accompanying diagrams (Figs. 2 and 3).

The centre for the movements of the lower facial muscles (those supplied by the buccal, oral, and nasal branches of the facial nerve) of the opposite

FIG. 3.

Diagram of the Median Surface of the Cerebral Hemisphere, showing the Paracentral Lobule (*Lb. Paracentrl.*) (modified from Ecker). Abbreviations: *G.*, gyrus; *F.*, fissure; *C.*, corpus callosum; *Conv.*, convolution; *F. Rol.*, fissure of Rolando; *Sup.*, superior.

side is situated in the lower third of the central convolutions. Near this, and probably somewhat lower, is the centre for the movements of the tongue (*Hypogl.* in Fig. 2). The centre for the movements of the opposite arm occupies the middle third of the anterior central convolution. The centre for the movements of the opposite lower extremity is situated in the upper part of the central convolutions, especially in the paracentral lobule. (See Figs. 2 and 3.)

The motor cortical area receives its blood from the middle cerebral artery—a fact which explains the greater frequency of embolic and of thrombic softening in this district than in other parts of the cortex.

Lesions involving the entire motor area of the cortex are attended by the symptoms of an ordinary cerebral hemiplegia, and then, if the hemiplegia develop at once, it cannot usually be distinguished from lesions of the internal capsule or of the pyramidal tract in other situations. Such lesions in the cortex must be very extensive, and they are rare.

Less extensive lesions in the motor cortical area cause paralysis of only certain muscles of the opposite side. The term *monoplegia* is used to designate these localized paralyses. The following forms of monoplegia have been observed to attend localized cortical lesions: 1, oculo-motor monoplegia (isolated ptosis); 2, facial monoplegia, sometimes combined with paralysis of the hypoglossal nerve; 3, brachial monoplegia, or paralysis of the opposite arm; 4, crural monoplegia, or paralysis of the opposite leg; 5, brachio-facial monoplegia, or paralysis of the arm and face. It is evident, from the situation of the motor-centres, that while facial monoplegia and brachial monoplegia, and also brachial monoplegia and crural monoplegia, may be and often are combined, paralysis of the face and of the leg without involvement of the arm can scarcely be produced by a single cortical lesion, and in fact has never been observed. In progressive cortical lesions a paralysis at first confined to one arm or to the face may advance to total hemiplegia, the cortical localization being then characterized by the development of the hemiplegia out of successive monoplegias. Secondary contractures make their appearance almost invariably in the paralyzed muscles, but are of course not distinctive of cortical affections. As in other forms of cerebral paralysis, the electro-muscular reactions are normal or only quantitatively affected—a circumstance which distinguishes cortical monoplegias from most of those produced by lesions of the spinal cord and of peripheral nerves.

Of great value in the diagnosis of lesions of the motor cortical area are spasms affecting isolated groups of muscles (*mono-spasms*), such as spasms confined to the muscles of one side of the face or to the muscles of one of the opposite extremities. The spasms are both tonic and clonic, and they are sometimes designated as partial epilepsy of cortical origin. They may occur without paralysis, they may develop at the same time with paralysis, they may precede the paralysis, or they may attack muscles which have been paralyzed for a variable length of time. The latter two forms of development are especially characteristic of cortical lesions. Partial epilepsy of cortical origin is sometimes accompanied or followed by general epileptic convulsions, in which case the spasm begins regularly in the same group of muscles. In the most characteristic form of the disease consciousness is not lost at the onset of the paroxysm. The patient observes the progress of the convulsions from one group of muscles to another, and finally loses consciousness when the convulsions become general. When this variety of epilepsy is preceded by monoplegic paralysis, it may be considered as almost pathognomonic of a cortical lesion.

In most cases of cortical paralysis careful examination will show some sensory disturbances, but our knowledge of these is imperfect. It is believed that the nerves of ordinary and of muscular sensation terminate in the cortex of the motor area and in the cortex of the parietal lobe, but, thus far, it has not been possible to definitely fix centres for sensation.

B. Cortical Centres for Speech—These exist in the left inferior frontal (Broca's) convolution in its posterior part (or *pars opercularis*), and in the left superior temporal convolution. It is probable, although not definitely proven, that the left island of Reil also contains centres for speech. When the individual is left-handed or when the speech-centres of the left hemisphere are congenitally defective, the centres for speech may occupy the corresponding parts of the right hemisphere.

Ataxic or motor aphasia is due to difficulty in the co-ordination of the muscles used in speaking. It is caused by lesions of the left inferior frontal convolution. **Amnesic aphasia**, or loss of the memory of words, is probably the result of a lesion of the left superior temporal convolution. The disturbance of speech called by Wernicke sensory aphasia, and by Kussmaul word-

deafness and word-blindness, has been observed also to follow lesions of the first temporal convolution of the left side. Sensory aphasia is characterized by inability to understand spoken or written words. On superficial observation the patients are thought to be deaf. The various forms of aphasia are often combined with each other.

C. *Visual Area of the Cortex*.—It has been demonstrated that the occipital convolutions contain centres for vision. Although not absolutely proven, the view is widely accepted, that the fibres of the optic nerve which supply the outer or temporal half of the retina do not cross in the optic chiasm, but terminate in the occipital lobe of the same side, while the fibres which supply the inner or nasal half of the retina cross in the optic chiasm and terminate in the occipital lobe of the opposite side. The accompanying diagram (Fig. 4) illustrates this view of the semi-decussation of the optic nerves.

Diagram showing Semi-decussation of the Optic Nerves (after Landois).

Thus, the right occipital lobe contains the visual centres for the temporal half of the right retina and the nasal half of the left retina. Destruction of these centres in the right occipital lobe would therefore cause blindness of the temporal half of the right retina and of the nasal half of the left retina. In this case objects occupying the left half of the visual field would not be perceived. With an affection of the left occipital lobe of course the relations would be reversed. This form of disturbed vision is called *hemianopsia* or *hemipia* (strictly, lateral homonymous hemianopsia). As is indicated in the diagram, the hemianopsia is limited by a vertical line passing through the point of fixation (*macula lutea*), and not by a line dividing the retina into two equal parts. It is thus evident that the defect of vision in hemianopsia is greater in the retina opposite to the lesion.¹ Hemianopsia is likely to be overlooked unless a special examination of the vision be made.

Hemianopsia may be caused also by lesions of one optic tract, of the pulvinar and corpus geniculatum externum of the optic thalamus, of the posterior part of the internal capsule, of the medullary substance of the occipital lobe, and perhaps also by lesions of one of the anterior pair of the corpora quadrigemina.

Hemianopsia is the only symptom which has been directly referred to lesions of the occipital lobe. In many instances affections of the occipital lobe have given rise to no symptoms which attracted attention.

D. *Other Parts of the Cortex*.—Some physiological experiments render probable the existence of centres for hearing in the temporal lobe, but auditory disturbances other than the peculiar form called sensory aphasia are not positively known to result from cortical lesions.

Diseases of the frontal lobes are often latent. No distinctive symptoms have been assigned to lesions of the parietal lobes.

Meningeal Hemorrhage.

One of the most important varieties of meningeal hemorrhage is hæmatoma of the dura mater, due to pachymeningitis hæmorrhagica, under which head it will be subsequently considered.

¹ Hemianopsia is designated as right-sided or left-sided with reference to the defect in the visual field. Hence with lesions of the right occipital lobe, left hemianopsia occurs.

The extravasated blood in meningeal hemorrhage may be seated as follows : 1, between the dura mater and the skull ; 2, in the so-called arachnoid cavity ; 3, in the subarachnoid space or the meshes of the pia mater. When seated between the dura and the skull the most frequent cause is traumatism. In the majority of cases of traumatic meningeal hemorrhage, but not in all, there is fracture of the skull. The hemorrhage resulting from traumatism may be any of the three situations mentioned, as well as in the substance of the brain. It may be most abundant at the base or on the convexity. The study of this important variety of meningeal hemorrhage belongs to the domain of surgery. Another cause of meningeal hemorrhage is the rupture of aneurisms of the arteries of the base, most frequently of the basilar or the middle cerebral. The lodgment of calcareous emboli in the cerebral arteries may lead to aneurism and hemorrhage. The occasional occurrence of meningeal hemorrhage in consequence of thrombosis of the sinuses, and in consequence of an intracerebral hemorrhage bursting through the peripheral brain-substance, has already been mentioned. In a case given in a former edition of this work a hemorrhage was attributable to wounding of a vessel by needle-shaped iculæ of bone in the dura mater, without any injury of the skull. Hemorrhages, usually in the form of ecchymoses, are often observed in the meninges in infectious diseases. Larger hemorrhages occur in purpura and other diseases with a hemorrhagic diathesis. Meningeal hemorrhage has been known to follow a paroxysm in whooping cough, to occur during Bright's disease, and rarely under other conditions when no especial cause could be assigned. Meningeal hemorrhage is common in new-born infants, in whom it is sometimes, but not always, attributable to mechanical causes attending labor. Large meningeal hemorrhages are always fatal ; but small hemorrhages may be absorbed, leaving only a pigmented spot behind.

Meningeal hemorrhage, if the extravasation be considerable and rapid, may give rise to sudden coma or apoplexy, which is very rarely accompanied by hemiplegia. It may destroy life speedily. In a case reported in a previous edition of this work death took place two hours after the apoplectic seizure. Cases which prove fatal in the condition of coma cannot be differentiated by means of the symptomatology from cases of cerebral embolism or cerebral hemorrhage. The diagnosis is rendered probable by a traumatic causation. From congestive apoplexy it is distinguished by the absence of the symptoms which denote determination of blood to the head.

In the case referred to, in which the hemorrhage was caused by spiculæ of bone, epileptiform convulsions occurred. Symptoms of irritation, such as convulsions, are more frequent in meningeal than in cerebral hemorrhage. If the hemorrhage be not large it may give rise to no symptoms pointing to a grave affection. In the case of Daniel Webster the autopsy showed that slight meningeal hemorrhage had occurred some time prior to his fatal illness. The hemorrhage was connected with an injury which had not incapacitated him from subsequent intellectual efforts in which was manifested no diminution of his mental powers.

It follows, from what has just been stated in regard to the symptomatology and diagnosis, that the treatment is to be governed by symptomatic indications.

Insolation, or Sunstroke.

The terms *insolation* and *sunstroke* are applied to an affection—or perhaps more properly different affections—occasioned not exclusively by exposure to the sun's rays, as the terms signify, but by the action of great heat combined generally with other causative circumstances. The terms denote a

sudden attack in extremely hot weather after exposure to the direct rays of the sun or to great heat, the attack characterized by loss of consciousness, followed frequently by stertor and convulsions, and death taking place, in a considerable proportion of cases, within the space of a few minutes or a few hours. Now, in a certain proportion of these cases the morbid condition, as judged by the symptoms, is expressed by the term exhaustion. The vital powers are prostrated, the forces carrying on the circulation give way, and death takes place by syncope. In another class of cases the affection apparently is similar to congestive apoplexy. In still another class of cases the symptoms show a combination of apoplexy and exhaustion. The cases last referred to probably constitute the majority of the cases of so-called insolation or sunstroke. In other cases the condition is referable to the abnormally high temperature of the blood. Other names than insolation and sunstroke have been proposed—namely, solar asphyxia, heat-apoplexy, thermal or heat fever, etc.

Morbid appearances found after death are as follows: The blood is dark and imperfectly coagulated, often fluid, and collected in the large veins. The heart is usually firmly contracted, and the left ventricle is empty, the right containing a small amount of dark fluid or partly clotted blood. Ecchymoses, especially subserous hemorrhages, are, as a rule, present. Extravasations of blood into the sympathetic ganglia of the neck, about the vagus in the neck, and in the connective tissue are sometimes met with. The lungs are deeply congested; sometimes they contain hemorrhages, and they are often oedematous. A moderate amount of serous transudation into the pleural and pericardial sacs and into the ventricles of the brain is not uncommon. The spleen is sometimes swollen and soft. Parenchymatous degeneration or cloudy swelling of the kidney, liver, spleen, and heart-muscle has been described as a lesion of insolation. The larger veins of the pia and dura mater are usually distended; and injection of the smaller vessels of the membranes and of the cerebrum is occasionally but not constantly found. The consistence of the brain and cord is sometimes notably soft.

The premonitions are slight or wanting. Dr. Swift, in a report based on the observation of 60 cases in the New York Hospital, gives the following account of the attack: "The patients are suddenly seized, while in the performance of their labors, with pain in the head and a sense of fulness and oppression in the epigastrium, occasionally nausea and vomiting, general feeling of weakness, especially of the lower extremities, vertigo, dimness of vision, and insensibility. Surrounding objects appear of uniform color. In a great majority of cases this was, so far as could be ascertained, blue or purple. In one instance everything appeared red, in another green, and in another white."¹ It has been stated that irritability of the bladder precedes the attack. Pain in the head, although generally present, does not always precede unconsciousness. It was wanting in the case of a medical friend of the author who had a severe attack accompanied by violent convulsions.

The attack may consist of only a transient insensibility; but in severe cases the patient passes quickly into a comatose state. It is in this state that cases come under medical observation. The pupils are in some cases dilated, in some contracted, and sometimes the size is normal, but the responsiveness to light is lessened or lost. There may be contraction and dilatation at different periods in the same case. The pulse may be at first infrequent and full, but it often becomes frequent and feeble toward the fatal termination. I have observed death to take place purely by apnoea, the pulse having considerable force until after the cessation of breathing. The respirations in some cases are

¹ "Observations on Exhaustion from the Effects of Heat," by H. S. Swift, Resident Physician of the New York Hospital, *N. Y. Journal of Medicine*, July, 1854.

stertorous, and in other cases suspirious and accompanied by moaning. They are increased in frequency in the majority of cases. In most cases the temperature of the body is notably raised. The maximum rise in cases at Bellevue Hospital, in July, 1868, was $109\frac{1}{4}^{\circ}$ F., and the lowest observed was $99\frac{1}{4}^{\circ}$. In a case observed in July, 1872, the temperature in the axilla was $110\frac{1}{4}^{\circ}$. If the thermometer indicate a rise to 107° or more, a fatal termination is to be expected. In the case, however, just referred to, in which the temperature was $110\frac{1}{4}^{\circ}$, the patient recovered. Convulsions and rigidity of the muscles are of frequent occurrence. Vomiting frequently occurs, and toward the close of life there are involuntary evacuations from the bowels. The prognosis is rendered extremely unfavorable by the occurrence of vomiting and purging. The duration varies from a few minutes to several hours. The average duration in the fatal cases observed by Swift was four hours. If the patient emerge from the comatose state, convalescence is usually speedy. Of 20 cases observed by Pepper, in 3 insanity followed. This sequel did not once occur in more than 100 cases received at the New York Hospital. Temporary delirium succeeding the attack is occasionally observed. Paralysis is very rarely a concomitant or a sequel. I have, however, known of the occurrence of incomplete transient hemiplegia in one case after recovery from the attack, and in one case before recovery. In the latter case it lasted but a few hours.

As already stated, the pathological character of the affection in all cases of insolation is not uniform. Instances of sudden death from exhaustion or syncope produced by heat and over-exertion are reckoned among cases in which the morbid condition is quite different. In a certain proportion of cases the appearances after death, the character of the attack, and all the symptoms denote congestive apoplexy. In other cases, which probably constitute the majority, the pathological character is mixed; an apoplectic condition being combined with exhaustion. It is highly important to take cognizance of these differences as regards pathological character in treating the different cases which are grouped together under the name of insolation. The notably increased temperature of the body probably stands in a causative relation to certain of the phenomena. Regarded from this point of view, insolation is in a marked degree a febrile disease. That toxical changes in the blood play an important part in the pathology is probable. Vallin of Paris has reported a series of observations upon dogs and rabbits destroyed by insolation. These animals, placed upon the back, fastened in this position, and exposed to the direct rays of the sun in the months of July and August in the climate of Paris, presented phenomena analogous to insolation in man, and they died generally after an exposure of from half an hour to two hours. Examinations after death showed hyperæmia of the brain and lungs, the cavities of the heart, especially the left ventricular cavity, being empty. These experiments have been repeated by Prof. Horatio C. Wood. Vallin is led to attribute these conditions and death to coagulation of the liquid of the muscular tissue (*suc musculaire*, myosin) of the heart and diaphragm. He does not, however, apply this explanation to all the cases embraced under the name of insolation. In some cases he attributes the death to toxical changes in the blood, the action of the heart being arrested by a morbid agency operating through the pneumogastric nerve. In the latter cases the heart-cavities may be filled with blood.¹ The observations of Prof. Horatio C. Wood lead him to the conclusion that the contraction of the ventricles of the heart found after death, especially when autopsies are made within a short time after death, is in most cases of post-mortem, not of ante-mortem, occurrence.²

Excessive heat is the chief agency in causing insolation, but other circum-

¹ Vide *Archives de Médecine*, Feb., 1870.

² On *Thermic Fever, or Sunstroke*, Boylston Prize Essay, 1872.

stances co-operate in the causation. Muscular exertion, unduly great or prolonged, is a powerful auxiliary cause. Persons are generally attacked when engaged in labor, but there are exceptions to this rule. Dr. Swift states that of the cases which he observed a large proportion were attacked shortly after dinner. The concentration of innervation upon the processes of digestion, the distension of the stomach with food and liquids, the latter being frequently taken in large quantity, and perhaps, in some cases, the disengagement of gas from chemical changes arising from indigestion, will account for the fact stated by Swift. In most cases persons are attacked when exposed to the direct rays of the sun, but there are exceptions to this rule. Swift states that eleven patients were attacked on the same morning in the laundry of one of the largest hotels in this city, and several cases were brought to the hospital from a sugar-refinery. Soldiers are not infrequently attacked after they have retired to their tents.

Cases are more frequent by far in tropical than in cold or temperate latitudes, and in the latter they occur during the heated term of summer, when the weather is unusually and continuously hot. Atmospheric influences other than heat have been supposed to be involved in the causation—namely, an unusual accumulation of electricity, dryness and rarefaction of the air, but facts showing the importance of these influences are wanting. The number of cases in the same place in different years varies greatly. According to Dickson, more persons died in Charleston, S. C., from sunstroke in 1824 than in any twelve other years; and in the city of New York in the summer of 1853 there were 260 cases reported, whereas in no previous year had there been more than 36 cases.¹

The attack generally takes place at periods when the heat of the day is at its maximum. Of the 60 cases observed by Swift, 40 occurred between 11 A. M. and 4 P. M., 17 between 4 and 9 P. M., and 3 between 8 and 11 A. M.

The DIAGNOSIS is, in general, made without difficulty. The circumstances connected with the attack and the symptomatic phenomena are sufficiently distinctive. Apoplexy with extravasation of blood is to be distinguished by the existence of hemiplegia. Persons deeply intoxicated are not infrequently brought into hospitals as cases of sunstroke, but the characters of alcoholic coma suffice for its discrimination.

Exclusive of mild cases in which there is transient stupor or insensibility, the danger in cases of insolation is always very great. The death-rate ranges from 40 to 50 per cent. If, with deep coma, the breathing be stertorous, sighing, or moaning, the prognosis is extremely unfavorable. Great frequency and feebleness of the pulse, relaxation of the sphincters, tracheal râles, and complete immobility are forerunners of a fatal termination. Convulsions are extremely unfavorable, yet I have known recovery to take place after violent convulsions. In accordance with the difference in pathological character in different cases, the mode of dying is sometimes by rapid asthenia or syncope. This mode of dying is exemplified among the cases in which the death is notably sudden, taking place in the space of a few moments after the attack. The mode of dying in other cases is by apnœa, but in the larger proportion of cases by apnœa and asthenia combined.

The TREATMENT is to be adapted to the pathological character of the affection, as represented by the symptoms, in individual cases. Pursuing this course, therapeutical measures, so far from being the same, will be diametrically opposite in different cases. In cases of nervous exhaustion, the danger being of death by rapid asthenia or syncope, complete rest is of the first importance. The removal of patients to their homes or to hospitals in this condition may contribute in no small measure to a fatal result. Stimu-

ich calls for the treatment just stated are—frequency and feebleness
lse, weakness of the heart-sounds, with absence of stertor and the
sment of breathing indicative of cerebral compression.

l-marked apoplectic cases I believe bloodletting to be the measure
r indicated. The treatment called for is the same as in congestive
. The life of the patient may depend on the prompt employment
etting. The bowels should be freely opened with croton oil. Cold
s applied to the head, either by means of the ice-cap or the douche.
l should be elevated, and everything constricting the chest or neck
removed. Revulsive applications should be made to the extrem-
re symptoms representing the condition calling for these measures
ess of the pulse, slowness of the respiration, with perhaps stertor,
he surface, congestion of the face, and throbbing of the carotids
he temporal arteries.

estion as to the propriety of bloodletting in cases of insolation has
s to much discussion and difference of opinion. The doctrine which
o inculcate is, that to abstract blood is vastly important in some and
ctive in other cases. Never to employ bloodletting or to employ it
es would be alike injudicious. It is, of course, for the judgment of
itioner to discriminate between the cases in which bloodletting is
and the cases in which it will do harm. I have noted several cases
parently exemplify the importance of bloodletting.

majority of the cases of insolation symptoms denoting congestive
are combined in variable proportions with those denoting exhaus-
e importance of bloodletting in these cases is to be measured by the
ance of the apoplectic phenomena, and it is contraindicated if pre-
e of exhaustion be denoted by the frequency or the feebleness of
. The success of the treatment will depend on the judgment of the
er in deciding whether bloodletting be called for or otherwise, and if
ated, in determining the amount of blood to be taken. Discrimination
oportant in prescribing croton oil. If the danger be from exhaus-
ctive purgative is not indicated. Cold to the head is important in
n as the symptoms of cerebral congestion predominate. On the

was kept up for a period ranging from half an hour to several hours, the continuance being determined by the effect on the temperature, pulse, and other symptoms. The temperature of the body was reduced more or less, and sometimes several degrees. The measure was repeated as often as the temperature again rose. If the pulse were feeble, stimulants were given more or less freely during the application of the water. The good effect of this plan of treatment has been marked in some cases. A patient admitted at 2 P. M., unconscious, pupils contracted, pulse 150, breathing stertorous, the axillary temperature $110\frac{1}{2}^{\circ}$, and the body cyanosed, was at once placed in the wet sheet and sprinkled. At half-past 4 P. M. the temperature in the axilla had fallen to $104\frac{1}{2}^{\circ}$, the frequency of the pulse and the cyanosis persisting. He was taken out of the sheet, dry cups were applied to the chest, and at 5 o'clock the wet sheet was again applied, and continued until fifteen minutes after 7 P. M. The temperature then was $101\frac{1}{2}^{\circ}$ and the pulse 120. At 9.45 P. M. the temperature fell to $100\frac{1}{2}^{\circ}$. At midnight he became conscious. Progressive improvement followed, ending in recovery. The only additional measures employed up to the restoration of consciousness were an enema containing castor oil with a few drops of croton oil, and the hypodermic injection of ten minims of the tincture of digitalis, the latter having reference to the frequency and feebleness of the action of the heart.

The employment of cold water in the manner just described was resorted to only in the cases in which there was a considerable increase of axillary temperature— 104° and upward. When the temperature was less, sponging the body with cold water was employed. Observations since 1872 have confirmed the efficacy of this plan of treatment in cases characterized by notable increase of temperature. The same method of applying cold has also been found efficient in other affections in which antipyretic treatment is indicated.

Dry cups to the chest relieve symptoms dependent on pulmonary congestion—namely, embarrassed breathing and cyanosis. Applied over the spine, they are useful in relieving convulsions and muscular rigidity.

In some cases treated in Bellevue Hospital the Calabar bean has been given in doses of one grain by hypodermic injection, and repeated two or three times after intervals of from half an hour to an hour. This remedy was tried with reference to muscular rigidity and convulsive movements. It seemed to be useful, but the observations are too few to warrant any positive conclusions. Given in the dose just stated, it produced no marked effect upon the pupils.¹

Hyperæmia and Anæmia of the Spinal Cord and its Meninges.

As regards hyperæmia and anæmia, the spinal cord and its meninges are to be considered together. These pathological conditions are probably never limited to either the meninges or the cord separately. In treating of spinal paralysis occurring without symptoms which denote either inflammation or lesions of structure—that is, functional paralysis—the question will arise as to the existence of one or the other of these conditions. Exclusive of this connection, it is difficult, with our present knowledge, to form an opinion as to the importance of these conditions. It is customary to refer certain symptoms to hyperæmia or anæmia of the cord on conjectural grounds. Our present knowledge does not lead us far beyond conjecture as regards the frequency of these affections, their causation, and their symp-

¹ For a report of 55 cases treated in Bellevue Hospital, July and August, 1872, prepared, at my request, by Dr. Katzenbach, at that time house-physician, vide *New York Journal of Medicine*, Jan., 1873.

matic phenomena. Both conditions are probably not infrequent. They are attributable to various causes, and it is not irrational to refer to these certain symptoms.

Hyperæmia here, as in other situations, may be active or passive. Active hyperæmia may be caused by prolonged muscular exercise and sexual abuse or excess. Collateral fluxion is supposed to be causative in certain cases of suppression of the menses, the cessation of bleeding from hemorrhoids, and prolonged exposure to cold. Passive hyperæmia is incident to stasis of the venous or the portal system.

The SYMPTOMS referred to active hyperæmia are—lumbar pain and pain in limbs, increased cutaneous sensibility, formications, muscular twitchings, paresis of the muscles. On the other hand, numbness of the extremities and æsthesia point to passive hyperæmia.

The DIAGNOSIS requires absence of fever and of the local symptoms which are either spinal meningitis or myelitis. The existence of causative agents is to be taken into account.

The condition is without danger, except that it may be a factor in the production of hemorrhage.

Tapping over the spine, using dry or wet cups according to the local symptoms and the general condition of the patient, stimulating foot-baths, the application of cold to the back, and cathartics, are the therapeutical measures indicated. Ergot and belladonna are considered to be useful by causing contraction of the arteries. The patient should lie as much as possible on the side or face, and not on the back.

Spinal anæmia (ischæmia) is an effect of aortic obstruction above the point at which the lumbar arteries are given off (Stenson's experiment). Temporary paraplegia is produced by compression of the aorta above that point. A few cases of paraplegia due to anæmia of the lumbar part of the spinal cord in consequence of embolism or thrombosis of the abdominal aorta have been recorded. Spasm of the intraspinal arteries has been supposed to be a cause of anæmia of the cord, continuing long enough to lead to impairment of nutrition and giving rise to paraplegia. Doubtless the cord, like the brain and other organs, suffers functionally whenever the blood is notably impoverished. This local anæmic condition, which is incident to general anæmia, probably has a causative connection with neuralgia affecting the intercostal and other nerves, together with other effects pertaining to the so-called "spinal irritation." Exclusive of a conjectured causative connection with functional or so-called reflex paralysis, and of the participation of the spinal cord in the effects of anæmia as a blood lesion, the diagnosis of spinal anæmia is warrantable in the present state of knowledge.

Spinal Hemorrhage.

Hemorrhage within the spinal canal, not dependent on injuries of the cord, is an exceedingly rare event. Its infrequency is in striking contrast to intracranial hemorrhage. Spinal hemorrhage may be meningeal (hæmorrhachis), or it may be in the substance of the cord (hæmato-myelus). In cases of meningeal hemorrhage the extravasation may be between the periosm and the dura mater, between the latter and the arachnoid membrane (in the so-called arachnoid cavity), or in the meshes of the pia mater. In cases of intracranial meningeal hemorrhage the blood may flow down into the spinal canal. Hemorrhage into the substance of the cord may be either focal or in the form of a larger focus. It is most frequently situated in the gray matter, in which it may extend for some distance in a longitudinal direction. The same changes occur in the extravasated blood as in cerebral hemorrhage. Both medullary and meningeal hemorrhage may result

from traumatism, such as fractures and dislocations of the vertebræ, blows upon the back, etc. Most of the cases formerly considered as spontaneous spinal apoplexies are cases of hemorrhage resulting from a previous myelitis, the vessels sharing in the softening process (hæmato-myelitis); but there are very rare cases which can hardly be interpreted otherwise than as primary hemorrhage into the cord. Aneurisms of the aorta, after having occasioned erosion of the vertebræ, sometimes burst into the spinal canal.

Meningeal spinal hemorrhage causes paralysis, as a rule, so suddenly that the patient falls. Consciousness is retained. Severe pain may be felt at or near the site of the hemorrhage. Pain is also felt in the extremities. The cutaneous sensibility becomes impaired, and abnormal sensations are referred to the skin. The paralysis and anæsthesia are rarely complete. If the hemorrhage take place in the lumbar region, the lower limbs are paralyzed, together with the bladder and rectum. If the hemorrhage be in the upper part of the spinal canal, in addition to paralysis of the lower extremities paralysis and anæsthesia are present in the upper limbs, and these symptoms may be accompanied by difficulty in breathing and swallowing. Cramps, spasms, and tremor often occur in the upper or lower extremities according to the situation at which the hemorrhage takes place.

The SYMPTOMS are due to excitation of the spinal cord and the paralyzing effect of pressure. According to the rapidity of the hemorrhage, they occur abruptly or are developed more or less slowly. Their degree is determined by the amount and situation of the hemorrhage.

If the symptoms follow an injury of the spinal column, violent muscular exertions, or severe convulsive movements, these etiological relations render the diagnosis probable. The diagnosis is substantiated by the exclusion of spinal meningitis and myelitis. These diseases are excluded by the sudden or rapid development of the symptoms and by the absence of fever. Secondary fever may be developed after the lapse of several days.

If the hemorrhage take place at the upper part of the spinal canal, and if the amount be considerable, it may cause speedy death by disturbance of respiration (apnoea). A large extravasation in a lower situation, giving rise to complete paraplegia, with cystitis and bed-sores, is often fatal after a duration more or less protracted. Recovery may be expected, except in cases of injury of the spinal cord by fracture or dislocation of vertebræ. The removal of the coagulated blood by absorption is, however, a slow process, and recovery takes place after a considerable period, the improvement being very gradual.

The TREATMENT at the time of the attack has for its object the arrest of the hemorrhage. Absolute rest and cold applied to the spine are the most important of the measures for this object. Bloodletting is to be employed under the conditions which render this measure advisable in other connections.

The subsequent treatment has reference to the relief of symptoms, the absorption of the extravasated blood, the prevention of muscular atrophy, and the restoration of the functional activity of the paralyzed muscles. Iodine, mercury, and electricity are recommended as sorbefacients, but their usefulness in this way is open to scepticism. The treatment to be addressed to the muscles is the same as in cases of paralysis caused by other spinal affections.

Hemorrhage into the substance of the cord is preceded by symptoms denoting myelitis in a certain proportion of cases. These are wanting if the hemorrhage be occasioned by injury of the spine or violent muscular exertions. In either case there is sudden paralysis without loss of consciousness, accompanied by a localized pain in the spine. The paralysis will involve only the lower extremities, or in addition the upper extremities and muscles

of the trunk, according to the seat of the extravasation. The pain is temporary, and the symptoms of excitation—spasms, cramps, etc.—which characterize meningeal hemorrhage are wanting. Sensory paralysis below the seat of the hemorrhage is more or less marked, and it is often complete, as regards the sensibility to both tact and pain. The paralysis involves the bladder and rectum. Atrophy of the paralyzed muscles takes place rapidly. Bed-sores are produced speedily. Death may take place quickly by apnoea if the hemorrhage be into the upper portion of the cord. If the seat of the hemorrhage be in the lumbar region, the termination is generally fatal, after a shorter or longer duration, in consequence of sloughing of soft parts exposed to pressure, cystitis, etc.

A small clot in a lateral half of the upper part of the cord gives rise to spinal hemiplegia characterized by motor paralysis on the side of the lesion and sensory paralysis on the opposite side. This is very rare.

The points involved in the differentiation from meningeal hemorrhage have been mentioned. Myelitis with softening gives rise to paralysis more or less slowly. This affection is excluded if the paralysis occur suddenly without having been preceded by any symptoms of spinal disease. In hæmato-myelitis, however, the paralysis may develop with great rapidity; but myelitis generally precedes the hemorrhage if the latter be not produced traumatically. Sudden paralysis preceded by symptoms of myelitis renders hemorrhage probable. The affection generally known as the acute spinal paralysis of children (sometimes occurring in adults) is excluded by the absence of fever.

The objects of the TREATMENT are essentially the same as in cases of meningeal spinal hemorrhage

CHAPTER II.

INFLAMMATORY DISEASES OF THE MENINGES OF THE BRAIN AND OF THE SPINAL CORD.—HYDROCEPHALUS.—HYDRORRHACHIS.

Pachymeningitis and Hæmatoma of the Dura Mater.—Simple Acute Cerebral Meningitis: Anatomical Characters; Clinical History; Causation; Diagnosis; Prognosis; Treatment.—Chronic Cerebral Meningitis.—Tuberculous Meningitis.—Acute Spinal Meningitis.—Chronic Spinal Meningitis.—Cervical Hypertrophic Meningitis.—Cerebro-spinal Meningitis: Anatomical Characters; Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment.—Hydrocephalus.—Hydrorrhachis.—Syringo-myelus.

THE dura mater, which is composed of fibrous tissue, is the most external of the three membranes enveloping the brain. It consists of an external lamella, which serves as the internal periosteum of the cranium, and an internal lamella, the inner surface of which is lined with flat, polygonal endothelial cells. Most of the recent writers, discarding a parietal layer of the arachnoid, confine the name arachnoid membrane to that which was formerly described as its visceral layer. This is a thin connective-tissue membrane whose outer surface is smooth and covered with endothelium. The pia mater is the vascular membrane of the brain, the convolutions of which it follows and to which it closely adheres. It is connected with the arachnoid by interlacing bundles of connective tissue. The space between the arachnoid and the pia mater is known as the subarachnoid space, or sometimes as the meshes of the pia

mater. In it is contained the cerebro-spinal fluid. The space between the dura mater and the arachnoid, which is usually found empty at autopsies, is called the subdural space, or, according to the former nomenclature, the arachnoid cavity. The subdural and the subarachnoid cavities are to be regarded as lymph-spaces.

By the term meningitis is usually understood inflammation of the pia mater or of the pia mater and arachnoid, it being impracticable to distinguish the inflammation of one of these membranes from that of the other. In fact, both are generally involved in meningitis. Sometimes inflammation of the pia mater is denominated *leptomeningitis*, in distinction from *pachymeningitis*, which is inflammation of the dura mater.

Pachymeningitis—Hæmatoma of the Dura Mater.

Pachymeningitis is divided into *pachymeningitis externa* and *pachymeningitis interna*.

External pachymeningitis may be either acute or chronic. Acute pachymeningitis is always suppurative, and is chiefly of surgical interest. It follows injury and disease of the cranial bones. Purulent inflammation of the dura mater follows suppurative disease of the internal or middle ear (otitis interna or media), with consecutive caries of the petrous portion of the temporal bone. It is often combined with purulent thrombosis of the lateral or other sinuses of the dura mater. The purulent inflammation may extend to the pia mater and to the substance of the brain.

By chronic external pachymeningitis is understood the fibrous thickening of the dura mater, often combined with the formation of osteophytes, which occurs especially in old age. The thickened dura becomes adherent to the skull. This form of pachymeningitis is analogous to the ossifying periostitis of the long bones.

Internal hemorrhagic pachymeningitis is of greater medical interest. This affection is characterized by the formation of an adventitious membrane upon the inner surface of the dura mater, usually in circumscribed patches over the convexity, and either limited to one side or extending to both sides of the median line. At first the membrane is extremely thin, delicate, and hardly to be recognized, except as a reddish, yellow, or brown stain. If one of these membranes be stripped off and examined under the microscope, it is found to consist chiefly of capillary blood-vessels with wide lumina, often provided with varicosities and with thin embryonic walls. Between the vessels are a few round, stellate, or fusiform cells, but there is very little fibrillated connective tissue. A considerable number of extravasated red blood-corpuscles, which have escaped either by diapedesis or by rupture of the vessel-walls, and a greater or less quantity of blood-pigment in the form of reddish-brown granules or of ruby-red crystals of hæmatoidin, will also be found in these membranes. The newly-formed blood-vessels are in organic connection with the pre-existing vessels of the dura mater. In more advanced cases the new membrane is thicker and composed of several layers, of which the deeper—that is, those nearest the dura mater—resemble ordinary fibrillated connective tissue. In some cases extensive extravasations of blood occur from rupture of some of the thin-walled, newly-formed vessels, and then give rise to the symptoms of meningeal apoplexy. To the bloody tumors thus formed upon the inner surface of the dura mater the name hæmatoma is applied. Hemorrhages confined to the subdural space, and not of traumatic origin, in the great majority of cases are due to hemorrhagic pachymeningitis. This fact was first established by Virchow. Some recent writers advocate the view which prevailed before Virchow's investigations—namely, that the first stage in hemorrhagic

pachymeningitis is an extravasation of blood upon the inner surface of the dura mater, and that the development of blood-vessels and of new connective tissue is secondary. It is, however, admitted that when the extravasation is abundant (hæmatoma, properly speaking), an organized membrane has in the majority of cases already been formed. The more usually accepted view is that in the majority of cases the development of new blood-vessels upon the inner surface of the dura mater antedates the extravasation.

The symptomatic phenomena embrace those proceeding from the chronic inflammation of the dura mater and those caused by pressure upon the surface of the brain. Cerebral symptoms denoting inflammation are—cephalgia, which is often notably intense, vertigo, tinnitus aurium, vigilance, and disturbed sleep. Other symptoms are sensitiveness to light and, in a marked degree, contraction of the pupils. The hemorrhage may occur either rapidly or slowly. If rapid and considerable, it causes an apoplectic attack, which may prove speedily fatal, but in most cases the patient recovers. Successive apoplectic attacks occur after variable intervals. If the hemorrhage takes place slowly, it causes somnolence which continues for twenty-four or thirty hours, the mind on awaking being more or less disordered. Successive periods of somnolence mark repeated, slow, and small or moderate hemorrhages. Contraction of the pupils persists, and if the hæmatoma be limited to one hemisphere, the contraction is greater on that side. At a later period, however, the contraction of the pupils may cease. The pulse is slow and irregular, becoming frequent in fatal cases before death. Paralysis of the facial muscles and hemiplegia may occur, limited to one side, or occurring first on one and afterward on the other side. Muscular contractions, twitchings, and convulsive movements more or less marked are liable to occur on one side or on both sides. The convulsions sometimes have an epileptiform character. Strabismus and ptosis are wanting. The mental faculties are impaired in a greater or less degree.

The clinical history has so much diversity in respect to the events which occur, the order of their occurrence, their duration, etc. that there are few reliable typical characteristics. As regards its course, the affection may be either acute or chronic. Moreover, its phenomena are often obscured by the use of various other diseases with which it is often associated.

If death take place in a primary attack of apoplectic coma, a diagnostic basis may be based on the antecedent cerebral symptoms and certain etiological points. In the cases which have not this termination the diagnostic points pertaining to the clinical history are the occurrence of successive attacks of coma or sopor, lasting for many hours or even for days, and the occurrence of more or less of the symptoms which have been mentioned, these occurring in a way not significant of other cerebral affections. Diseases to be excluded are—simple cerebral meningitis, tuberculous meningitis, cerebral hemorrhage, embolism or thrombosis, and general cerebral paralysis. There are cases in which the affection gives rise to no morbid symptoms. The morbid condition is sometimes found after death when it had not been suspected during life.

Points relating to the etiology are of much account in the diagnosis. The affection rarely occurs at less than forty years of age, and of the different decades the largest proportion of cases is between seventy and eighty. It is rare in early life, but the percentage of cases is larger prior to ten than from ten to twenty years of age.¹ Men are affected much oftener than women. Persons in health are never affected, if traumatism be excepted. Of the various affections in connection with which it occurs intercurrently, those caused by alcoholism take precedence. Clinical observations show that it is a disease

¹ Vide Huguenin, in *Ziemssen's Cyc.*, Am. ed. vol. xii.

to which drunkards are especially liable, whatever may be the pathological explanation. It is incident to different chronic lesions of the brain, particularly to those belonging to general cerebral paralysis. In a considerable proportion of cases it is referable to injuries from blows, falls, etc. It occurs sometimes in diseases attended by a hemorrhagic diathesis, such as scurvy, purpura, leucocythæmia, and pernicious anæmia. Here doubtless the hemorrhage is primary.

The course of the disease varies from a day to a year or longer. Huguenin gives the following as the results of an analysis of all the carefully recorded cases which he could collect: The duration was from one day to five days in 34 per cent.;¹ from five to thirty days in 40 per cent.; from one month to six months in 18 per cent.; from six months to one year in 4 per cent.; and more than a year in 4 per cent.

The prognosis will depend on the extent of the hemorrhage if hæmatoma form. Patients have recovered who had presented symptoms supposed to be a sufficient warrant for the diagnosis. Coexisting diseases often contribute to a fatal ending.

Recovery is not to be expected as a result of any special medication. Impending danger from hemorrhage may be perhaps averted and death postponed by therapeutical measures. Measures are to be addressed to the inflammatory condition in proportion to the symptoms. Generally, cold applications to the head, counter-irritation to the neck, cathartics, and stimulating foot-baths suffice. Venesection or topical bleeding is rarely indicated. With reference to the limitation of hemorrhage, the bromides and ergot may be prescribed. It is doubtful if the iodide of potassium or mercury promotes absorption of the effused blood. Palliative remedies, according to symptomatic indications, and the anæsthetics, form part of the treatment.

Simple Acute Cerebral Meningitis.

The name acute cerebral meningitis denotes, conventionally, inflammation of the meninges of the brain exclusive of the dura mater; that is, inflammation affecting the arachnoid membrane and the pia mater. It is also called *leptomeningitis*. To distinguish it from tuberculous meningitis it is designated as simple meningitis. It is sometimes called acute meningitis of the convexity in consequence of its localization by preference upon this part.

ANATOMICAL CHARACTERS.—Inflammation here, as in other situations, is preceded and usually accompanied by hyperæmia. The inflammatory products are serum, fibrin, and pus in varying amount and in varying proportions. These products of inflammation are chiefly in the meshes of the pia mater (subarachnoid space), but in severe cases they may be present, to a certain extent, also upon the outer surface of the arachnoid (subdural space), and may extend into the cortical substance of the brain. The inflammation affects usually in the highest degree the pia mater covering the convexity of the hemispheres, but it may extend to the meninges of the base, or in rare instances be chiefly confined to the base. When death takes place soon after the onset of the inflammation, the exudation is found to consist chiefly of serum rendered somewhat turbid by the admixture of pus-cells. When death occurs later, as it does in the majority of cases, the exudation is more distinctly purulent. The greenish-yellow, opaque streaks of pus are found in

¹ Of course, in these short durations the affection is not a hemorrhagic pachymeningitis, which is necessarily chronic, but it must be a simple hemorrhage on the inner surface of the dura mater, it being Huguenin's view that this hemorrhage precedes the pachymeningitis.

greatest abundance in the furrows between the convolutions, especially in the track of the large veins of the pia mater. In severe cases of some duration a greenish-yellow layer may be found spread nearly uniformly over the convex surface of the brain. The exudation, examined microscopically, is found to consist of serum, pus-cells, fibrillated fibrin (sometimes in great, sometimes in small amount), together with a certain number of red blood-corpuscles. The amount of serum varies considerably in different cases. The pus-cells are doubtless emigrated white blood-corpuscles. Pus-cells are also found, sometimes in sufficient number to be visible to the naked eye, in the cortex cerebri, especially around the blood-vessels. Punctate hemorrhages are sometimes found both in the pia mater and in the cortex. The ventricles may contain a moderate quantity of serum, which is usually turbid, or they may be empty. It is to be borne in mind in examinations after death that increase in the amount of serum in the subarachnoid space is not evidence of inflammation; nor is mere opacity of the arachnoid to be mistaken for acute inflammation.

CLINICAL HISTORY.—Simple acute meningitis may be abrupt or gradual in its development. The premonitions are the symptoms of determination of blood or active hyperæmia. There is a marked variation in symptoms at different periods of the disease—namely, prior to and after a certain amount of sero-fibrinous exudation. The course is divisible into two stages, the division being based on the amount of the products of inflammation. The first stage extends to the period when, owing to the pressure of these products, a notable change in the symptoms occurs.

The first stage is called the stage of excitement. It is characterized by pain, usually intense, referred to the entire head, sometimes greatest in the anterior and sometimes in the posterior portion. The pain is the same as in active cerebral hyperæmia. Delirium frequently occurs, and the delirium in this stage is generally active or maniacal, or in some cases hilarious. Owing to the prominence of the delirium, patients are sometimes carried to insane institutions, the affection being mistaken for acute functional mania. Convulsions may occur, especially in young subjects. The senses of sight and hearing are abnormally acute. Light and sounds occasion distress and increase the cerebral excitement. There is photophobia, and the eyebrows are corrugated to shield the eyes from the light. The pupils are generally contracted. The face is flushed. The carotids and temporal arteries pulsate strongly. The head is hot. Vomiting generally occurs in this stage, and is often prominent as a symptom. The bowels are constipated. The urine is diminished in quantity, and is sometimes albuminous. The abdominal walls are depressed. Fever is more or less intense; the pulse is accelerated, strong, and full; and the axillary temperature may rise to or above 104° F. Exacerbations occur in which the delirium and cephalalgia are notably increased. The duration of this stage is short. It may continue but a few hours, and it rarely extends beyond two or three days.

The second stage is called the stage of oppression. The symptoms distinctive of this stage are those denoting pressure by the inflammatory products. The pain in the head is diminished. The morbid sensitiveness to light and sounds is lessened. The pupils may be dilated or contracted, and their responsency to light is diminished or lost. Strabismus and loss of vision may occur. Drowsiness succeeds the state of mental excitation. There is rigidity of the muscles of the back of the neck. The pulse is diminished in frequency, and is often irregular in force and rhythm. It becomes rapid and thready a few hours before death. The respirations are disordered in rhythm or suspicious. The Cheyne-Stokes respiration may be present. Paralysis

may occur, limited to the face or one extremity or extending over one side of the body. If the progress of the disease be unfavorable, coma is at length induced, and continues until death. Convulsions may occur in the second as well as the first stage.

CAUSATION.—Although acute simple cerebral meningitis often presents itself clinically as a primary or idiopathic affection, the evidence of post-mortem examination shows that it can very rarely be considered as a primary disease. The majority of the cases which are not secondary and which occur sporadically are instances of epidemic cerebro-spinal meningitis. In these cases an examination of the membranes of the spinal cord will usually show that these are inflamed. It is in accordance with modern views to suppose that in all cases of purulent meningitis a special infective agent has gained access to the inflamed membrane. This agent is causative of most of the cases in which the disease is primary. Very frequently simple cerebral meningitis is secondary to some other disease. Secondary meningitis may be caused by infection from some disease of a part contiguous to the cerebral membranes, or from some remote disease, whence the agent of infection is transported to the brain by the blood or the lymph-current, or from some blood disease.

Acute cerebral meningitis may be referable to injuries of the head involving wounds of the soft parts or fracture of the skull. In not a few instances it is secondary to inflammation of the middle ear, with or without caries of the petrous portion of the temporal bone. In these instances an acute circumscribed pachymeningitis usually, but not always, precedes the affection of the pia mater. Caries of the cranium in any situation may give rise to meningitis, either circumscribed or more or less diffused. Purulent inflammations in the upper part of the nasal cavities and in the orbits may be followed by meningitis. Abscesses of the brain which reach the surface lead to purulent meningitis.

Various infectious diseases form an important group of causes. A certain proportion of cases of acute lobar pneumonia, especially in drunkards, are complicated with acute cerebral meningitis. To this group of causes belong also acute ulcerative endocarditis, pyæmia, septicæmia, erysipelas, the eruptive fevers, typhoid fever, typhus fever, Bright's disease, purulent pleuritis and acute articular rheumatism. It is uncertain whether in these cases the meningitis be caused by the special virus of the disease or be due to some secondary infection. In the meningitis complicating lobar pneumonia the same organisms have been found in the exudation in the meninges as in the exudation in the lungs, so that here, at least, it is probable that the special cause of the pneumonia is also the cause of the meningitis. The weight of evidence is in favor of the view that acute cerebral meningitis may be caused by a variety of micro-organisms, including those of epidemic cerebro-spinal meningitis, the bacteria of suppuration, and the specific germs of many of the acute infectious diseases. The cerebral meninges are rendered more susceptible to the causes of acute purulent inflammation by the pre-existence of chronic meningitis, such as is often met with in drunkards, syphilitic patients, insane persons, and idiots.

Acute cerebral meningitis may occur at any age. It is more common in males than in females.

DIAGNOSIS.—Acute meningitis may be confounded with active cerebral congestion. If the inflammation go off by delitescence—that is, without passing into the second stage—it may be impossible to say after recovery whether the affection were meningitis or merely active congestion. In other

words, more or less of the symptoms belonging to the second stage are required for a positive diagnosis.

Cases of typhoid fever characterized by early and active delirium have heretofore not infrequently been considered as cases of acute meningitis. The points involved in this differential diagnosis are the following: The access or slow development of the fever; the distinctive events belonging to it—namely, diarrhoea, meteorism or tympanites, tenderness in the iliac regions, together with absence of morbid acuteness of the senses, and continuance of the delirium without the supervention of the phenomena of the second stage of meningitis; also the eruption and the characteristic rise of temperature during the first week. These points show the disease to be a fever, and not meningitis. In the somnolence of typhoid or typhus fever patients manifest no opposition to being aroused, to having their position changed, etc.; whereas in meningitis the patient is irritable when disturbed, and resists, perhaps with violence, efforts to give nourishment, to examine the pupils by raising the eyelids, or to interrupt in any way the somnolent condition.

Functional mania may be erroneously considered as denoting acute meningitis. The discrimination is to be based on the absence of morbid acuteness of the senses, together with the absence of febrile movement, and the continuance of the mania without the symptoms of compression.

Other diseases are more likely to be considered as acute meningitis than this is to be mistaken for other affections. In view of the infrequency of primary cerebral meningitis the ability of a practitioner to distinguish it from other affections may be suspected if he believe that he has met with many cases of it.

PROGNOSIS.—Acute meningitis involves much danger. It may destroy life quickly. Cases have terminated fatally in thirty-six hours. As a rule, the duration in fatal cases does not extend beyond eight or nine days. The symptoms denoting an unfavorable prognosis are—profound coma, notable disorder of respiration, difficulty of deglutition, general immobility and anæsthesia, feebleness of the pulse, etc. Strabismus, hemiplegia, and convulsions may be present in cases which recover. A few well-marked cases, presenting these symptoms, which have fallen under my observation have ended in recovery. Data are wanting for determining the ratio of cases which end fatally, but it is certain that the fatal cases greatly preponderate. The association with acute articular rheumatism is considered as rendering the prognosis extremely unfavorable. I have, however, observed a well-marked case, the symptoms denoting spinal as well as cerebral meningitis, which ended in recovery.

In cases which prove rapidly fatal death may be due chiefly to apnœa, but if life be prolonged for several days the mode of dying is by apnœa and asthenia combined.

TREATMENT.—The treatment must have reference to the stage of the disease. The objects in the first stage are to lessen the determination of blood to the head and to limit the amount of exudation. If the heart act with abnormal power, bloodletting in this stage is to be employed. As a measure of depletion and revulsion active purgation is indicated. Cold is to be applied to the head, either by means of the ice-cap, the cold douche, or constant ablution. Cutting the hair close to the head renders these applications more efficient.

Bloodletting in this disease is indicated in view of the promptness of its operation and the short duration frequently of the first stage. Bearing in mind that the chief source of danger is from the products of inflammation, it is important that the measures employed with the hope of limiting these

ould be resorted to more promptly and vigorously than in other acute inflammations—for example, pneumonitis—in which the products of inflammation generally do not give rise to serious results. Moreover, there is not the same necessity for guarding the vital forces as in other acute inflammations; for in this disease there is danger that life may be quickly destroyed by apnoea caused by the pressure of effused serum and lymph, whereas in most other acute inflammations the danger is that they will destroy life by asthenia. It is not, however, to be forgotten that asthenia enters into the mode of dying in cases of meningitis which do not pursue a rapid career, and hence blood-letting and other measures of depletion may be pushed too far. These measures are indicated only in the first stage of the disease. Perfect quietude, exclusion of light, elevation of the head, and the avoidance of everything which may tend to increase cerebral excitement by acting on the senses or the mind form an important part of the treatment of this stage. The bromides are useful for tranquillizing intense cerebral excitation. If these do not prove effective, codeia may be given or a salt of morphia, the latter administered hypodermically. Sinapisms to the neck and stimulating pediluvia have a certain measure of utility. Vomiting calls for palliative measures. The diet in this stage should be restricted to the blandest articles taken cold.

In the second stage the great object of treatment is to promote absorption of the morbid products, serum and lymph. Depletion is no longer admissible. Mercurialization is advised for this object, and although the efficiency of mercury as a sorbefacient has doubtless been much exaggerated, we are not warranted in saying that it has no effect in that way. If it exert never so small an effect, it is indicated in a disease like this, in which the object to be effected is of so much importance. Iodine is another remedy supposed to be useful as a sorbefacient. I have witnessed, as I think, the good effect of the iodide of potassium in several cases. Patients under my observation have recovered under the use of this remedy, mercury not having been employed. It may be given in doses of from five to ten grains four or five times daily, increasing the doses, if improvement do not take place, up to the limit of tolerance. A blister may be applied over the nucha. The propriety of blistering the scalp is questionable.

Another object of treatment in the second stage, if death do not take place by apnoea, is to support the powers of the system. Measures for this object are indicated in proportion as the tendency to death is by asthenia.

Attention to the bladder is important in the second stage.

Chronic Cerebral Meningitis.

Simple chronic cerebral meningitis—that is, meningitis not incident tuberculous or any prior cerebral affection—is infrequent, although it is rare than the acute form of the disease. The statement has reference to periods of life after infancy, but it holds good also with respect to the period. In a great majority of cases it is a subacute affection *ab initio*.

THE ANATOMICAL CHARACTERS are thickening and opacity of the pia and arachnoid caused by a new formation of connective tissue. The formation is usually circumscribed. The thickened and opaque membrane is abnormally adherent to the brain, and frequently adhesions of fibrous tissue are formed between the dura mater and the arachnoid. There may be considerable effusion into the ventricles. A certain degree of opacity of the pia-arachnoid, especially marked along the longitudinal fissure, cannot be considered as a pathological condition in old age.

This affection may be ranked among the “insidious diseases.”

not point to any cerebral affection or they are not distinctive of disease. The diagnosis is difficult. Pain in the head is usually as prominent as a symptom, but this is common to many affections. There may be little or no fever. Vomiting may be a prominent symptom, but it occurs in various pathological connections. Mental apathy, sometimes to stupidity, indisposition to either mental or physical exertion, and a notable change in disposition, characterize certain cases. Swellings of the face and hemiplegia sometimes occur, but they are effects of the disease. This statement also applies to epileptiform con-

known a case of chronic meningitis to be considered as a case of gastritis, vomiting being a prominent and persistent symptom. The patient fell into coma before death, but this was attributed to exhaustion. The disease was not suspected prior to the autopsy. In another case in which a correct diagnosis was not made, the patient dying suddenly without any extravasation, the case had been considered as one of latent or intermittent fever, chills occurring from time to time. A hospital record showed no symptoms referable to the head except mental inertia and border-
line mentality. He gradually fell into coma, and after death the case was found to be one of chronic meningitis.

ARDS DIAGNOSIS, close observation ought to lead to the conclusion that there exists a chronic cerebral affection. Paralysis is less likely to occur in the presence of tumors within the skull. The absence of paralysis is therefore of no account in the diagnosis. This statement will measurably apply to all cases. If cephalgia, impairment of the mental faculties, and gradually developed coma follow an injury of the head, chronic meningitis is

A traumatic cause is likely to give rise to inflammation. Chronic meningitis is developed in a small proportion of cases of the affections of the brain embraced under the name Bright's disease. The existence of renal disease is therefore of some account in the diagnosis; but in cases of renal disease cerebral symptoms referable to uræmia—namely, epileptiform convulsions, coma—are not to be considered as evidence of meningitis. The existence of syphilis is to be ascertained, inasmuch as this is a cause of meningitis.

TREATMENT consists of moderate counter-irritation, the iodide of potassium, perhaps mercurialization, quietude of mind and body, and the regulations appropriate to chronic affections generally.

Tuberculous Meningitis.

A distinctive feature of this variety is the presence of miliary tubercles in the brain matter in connection with meningeal inflammation. Hence the name *tuberculous* or *tubercular meningitis*. As the inflammation, in the majority of cases, is chiefly at the base of the brain, it is called by some *basilar meningitis*; but this name is not to be recommended, inasmuch as meningitis at the base is not necessarily tuberculous. An old name for the affection is *acute hydrocephalus*, as there is usually found a considerable accumulation in the ventricles. Tuberculous meningitis affects children more frequently than adults, and is treated of fully in works devoted to the diseases of childhood. It is of rare occurrence in the first year of life, occasionally after two and before seven years of age. It is not, however, unknown in childhood.

MEDICAL CHARACTERS.—Tuberculous meningitis attacks by preference the *lateral matter* covering the fossa Sylvii, the optic chiasm, the interpe-

duncular space, and the under surface of the cerebellum; but it is by no means confined to these situations, being often found on the convexity of the brain, although, as a rule, in a less degree than at the base. Tubercles may also be present in the choroid plexuses, and even in the substance of the brain. The tubercles appear as grayish-white or yellowish granulations in the coats of the small arteries of the pia mater. They are usually of about the size of a millet-seed, but nodules the size of a pea may be formed by the coalescence of many granulations. Some of the tubercles are so small as to be recognizable only by the aid of the microscope. While usually found with difficulty, they may be present in such a small number as to require careful search for their detection, and on the other hand their number may amount to thousands. A sero-fibrinous or a fibrino-purulent exudation is found, as a rule, at the base, and may be present upon the convexity of the brain. The amount of exudation varies much in different cases. Although there is reason to believe that tubercles precede the inflammatory exudation, there seems to be no necessary connection between the number of tubercles and the degree and extent of inflammation. Tubercles may be present in large numbers without any apparent inflammation, and, on the other hand, the inflammatory exudation may be abundant without the coincidence of many tubercles. It can serve, however, no useful purpose, from a clinical standpoint, to distinguish between miliary tuberculosis of the meninges (without apparent inflammation) and tuberculous meningitis, inasmuch as the former usually produces the same symptoms as the latter, and, in fact, is accompanied not infrequently by the microscopical evidences of inflammation. In the majority of cases of tuberculous meningitis (in 75 per cent., according to Seitz), the ventricles are found dilated and containing a large quantity of serous effusion, either clear or moderately turbid from pus-cells. When the ventricular effusion is abundant the surrounding brain-substance is often found greatly softened and sometimes almost diffuent. It is probable that this softening is cadaveric and without clinical significance. In proportion to the amount of fluid in the ventricles the convolutions are flattened and the sulci shallowed. Minute extravasations of blood are frequently found in the pia mater, sometimes in the substance of the brain.

The microscopical examination of the tubercles shows that they consist usually of a nodular accumulation, not always distinctly circumscribed by lymphoid and endothelial cells in the walls and perivascular sheaths of the small arteries of the pia mater, especially where they divide. The lumen of the artery will often be found compressed and thrombosed at the seat of tuberculous infiltration. The inflammatory products are serum, fibrin, and pus.

Tuberculous meningitis is due to the invasion of the blood-vessels of the meninges by tubercle bacilli. Sometimes, especially in children, the affection of the meninges is the sole manifestation of the tuberculous infection, more frequently, and almost without exception in adults, the meningeal tuberculosis is secondary to tuberculosis of some other part of the body. In children the primary tuberculosis is often of the cervical, bronchial, or mesenteric lymph-glands; in adults it is usually of the lungs; but a primary tuberculous focus may be in any part of the body subject to tuberculous infection, as in the genito-urinary apparatus, the serous membranes of the vertebræ, etc. Although it is probable that in these cases the tubercle bacilli are carried from the primary focus by the blood-current, it is a fact that the meninges are often involved without other evidence of the invasion of the blood by tubercle bacilli. Still, in not a few cases general miliary tuberculosis is likewise present. In cases of primary tuberculous meningitis it is not understood how the tubercle bacilli reach the meninges. In

of the apparently primary cases there will be found tuberculous disease of the middle ear. It has been suggested that sometimes the tubercle bacilli reach the cerebral meninges through the ethmoidal foramina from the upper nasal passages.

Tuberculous inflammation of the cerebral meninges is nearly always accompanied by a similar affection of the spinal meninges, so that the disease is in reality a tuberculous cerebro-spinal meningitis. The affection of the spinal meninges is usually less intense than that of the cerebral meninges, but it may give rise to characteristic symptoms.

CLINICAL HISTORY.—In the progress of this disease, as in simple meningitis, the symptoms undergo a marked change due to the pressure of the exudation and effused liquid; and this change will serve as the basis of a division into two stages. The development of the meningitis may be preceded by the symptoms and signs of pulmonary tuberculosis, or, less frequently, of tuberculosis in other situations, as in the lymphatic glands, serous membranes, and the genito-urinary apparatus. The meningeal affection, even when it does not distinctly supervene upon tuberculous disease of the lungs, is usually preceded by pallor, loss of weight, impaired appetite, irritability of temper, muscular debility, indisposition to exertion, and other general symptoms for a variable period; but in a certain proportion of cases the symptoms denoting the head affection appear suddenly, the previous health having been apparently good. When the meningitis occurs after a prodromic period extending, as it does in some cases, over several weeks and even months, during which the general health becomes considerably impaired, an antecedent tuberculous affection in other organs is to be inferred, or it may be that the miliary granulations within the skull existed for some time prior to the development of meningeal inflammation. The latter is probable if the prodromic period have been marked by cerebral symptoms. On the other hand, the meningitis, when it is developed abruptly—that is, without a prodromic period, the previous health having been apparently good—is usually incident to a primary tuberculous infection of the meninges.

The development of meningitis, as a rule, is denoted by pain in the head, referred generally to the forehead. Convulsions are less likely to occur at the onset than in simple acute meningitis. Vomiting in most cases is an early and sometimes a prominent symptom. More or less fever occurs. The axillary temperature is raised, but the rise is less than in simple acute meningitis. Notable diurnal remissions are likely to occur, the exacerbations taking place at night. These symptoms continue for several days. The cephalalgia is frequently severe. Lancinating pains occur from time to time, causing infants to give a sudden, sharp, and short cry, which has been known as the *cephalic cry*. A common exclamation is, "Oh my head!" The hands are often carried to the head. There is increased sensibility to light and sound. The expression is frowning. In children raising the lids and exposing the eyes to the light occasion crying. The conjunctiva is often suffused. The pupils in this stage are frequently contracted. The face may be flushed, and in some cases paroxysmal flushing of the face is a notable symptom. I have observed this to precede convulsions. During this stage vigilance is frequently a prominent symptom, and the sleep obtained is disturbed by dreams causing patients to awake suddenly in terror. It is important to note that vomiting and increased sensibility to light, although generally marked, may be wanting.

Drowsiness and somnolence mark the supervention of the second stage. Here is now less suffering from cephalalgia, but occasional lancinating pains may still occur. The pulse may fall below the average frequency

of health. It is not infrequently faltering. It fluctuates in frequency and may be irregular in rhythm. The respirations, which in the first stage may have been accompanied by sighing, are now often irregular in rhythm and may present the Cheyne-Stokes phenomena. In young children masticatory movements are common, and after dentition grinding of the teeth. Rolling the head or boring the pillow is a symptom in infants. The somnolence increases. The patients are reluctant to be aroused. If able to speak, they reply to questions slowly or in monosyllables, like a person half awakened from profound sleep. When aroused they have an expression of stupidity. Incoherence is common, and occasionally drowsiness alternates with paroxysms of delirium. The pupils become dilated, and not infrequently present disparity as regards size. They respond sluggishly to light. As the somnolency deepens the movements of the eyeballs are not in unison, strabismus frequently occurs, and oscillations of the balls are occasionally observed. The eyelids are but partially closed, the eyeballs being raised so that the cornea is partially covered by the upper lid, and in some cases the patients lie with the lids widely opened. Vision is gradually impaired, and frequently is lost. Various ophthalmoscopic appearances have been described, of which the most common are neuro-retinitis and a swelling of the optic papilla, called choked disc. [Tubercles may also be deposited in the choroid coat of the eye, in which situation they are distinctly visible with the ophthalmoscope. In all doubtful cases the eye-ground should be inspected, not once, but repeatedly, for tubercles may appear in the course of twenty-four hours in an eye-ground which had previously been found normal in every respect.—H.] Subsultus, carphologia, and fumbling with the bed-clothes are frequent symptoms. Convulsions frequently occur, especially in children. They are either limited or general, and they may be either severe or slight. Paralysis of one side of the face and incomplete hemiplegia are occasionally observed. Not infrequently the muscles of the posterior part of the neck become rigid, and the patient lies with the head drawn backward. Contraction of certain of the muscles of the limbs occurs in some cases. This is sometimes observed on one side, while the muscles of the opposite side are relaxed. Occasional vomiting is a symptom of the second stage. As a rule, there is complete anorexia, but in some cases which I have observed food has been taken with apparent relish. The teeth and lips often become covered with sordes. Constipation is the rule. In young children the dejections are sometimes greenish and resemble spinach in appearance. The abdomen is retracted. Retention of urine is not uncommon.

Sooner or later the patient becomes comatose; but in some cases before the occurrence of coma remissions occur, in which the improvement as regards intelligence and in other respects is such as to appear to the friends to afford ground for much encouragement in hoping for recovery. The occurrence of profound coma is followed by impairment and loss of deglutition, with more or less embarrassment of respiration. The pulse becomes frequent and feeble, and the mode of dying is by apnoea and asthenia combined.

The duration of the disease is variable. It rarely is less than a week. In the majority of cases it does not exceed two weeks. It rarely extends beyond three weeks, but exceptionally it may be prolonged considerably beyond this period. The termination is almost invariably fatal. In some of the cases of supposed recovery it is probable that the affection was simple meningitis.

DIAGNOSIS.—The diagnosis involves the discrimination from an essential fever. With the latter it is not infrequently confounded. In making the differential diagnosis, meningitis is to be excluded by the absence of sensibility.

ity to light, of the characteristic lancinating pains which belong to the first stage, and of the strabismus, affection of the pupils, and other symptoms belonging to the second stage. In fever, drowsiness and delirium are not preceded and accompanied by the symptoms just referred to. Moreover, in typhoid fever, diarrhœa, abdominal tympanites, and iliac tenderness are likely to be present—symptoms not belonging to the clinical history of tuberculous meningitis.

It is to be discriminated from the so-called *hydrencephaloid affection* incident in children to exhaustion from diarrhœa. With this affection it was formerly confounded. In this affection the symptoms denoting inflammation are wanting, and the drowsiness or stupor is not accompanied by strabismus, inequality of the pupils, embarrassment of respiration, irregularity of the pulse, and other symptoms, exclusive of the somnolence, which belong to the second stage of tuberculous meningitis.

To discriminate tuberculous from simple meningitis is by no means always easy. The gradual development of the former, the prodromic symptoms, the longer duration of the first stage, and the coexistence of pulmonary tuberculosis in a certain proportion of cases must serve as a basis of this differential diagnosis. The meningitis is probably simple if it can be distinctly traced to a traumatic origin. It is, however, to be borne in mind that in most cases it is possible to recall some injury of the head within a period of weeks or months prior to the occurrence of any disease in childhood; and it is customary to refer the affection to an injury often when there is not sufficient ground for such an opinion. Tubercles in the choroid coat are sometimes discovered by ophthalmoscopic examination. Their presence decides the differential diagnosis; but inasmuch as they are not always present in cases of tuberculous meningitis, their absence is not sufficient to exclude this affection.

PROGNOSIS AND TREATMENT.—If the diagnosis be positive, the encouragement for successful treatment is slight. It is difficult, of course, to decide upon measures which will be likely to be useful in a disease tending intrinsically, like this, to a fatal issue, and when in cases of apparent recovery we are obliged to distrust the correctness of the diagnosis. The chief source of encouragement for successful treatment, in fact, in a case which the practitioner supposes to be one of this disease, is the possibility that the diagnosis may be incorrect. With reference to this liability to error in diagnosis the measures indicated in simple meningitis are admissible. If, however, the practitioner be thoroughly convinced of the correctness of the diagnosis, he is hardly justified in resorting to bloodletting or measures which occasion suffering, such as blisters and frequent cathartics. Under these circumstances measures to palliate distress and prolong life are alone indicated. In this country the iodide of potassium is generally given largely in the second stage of the disease. Cases have been reported in which this remedy was apparently successful; but there is room for the supposition that in these cases either meningitis did not exist or the disease was simple meningitis. It is certain that in the immense majority of cases the remedy is unsuccessful. I do not, however, concur in the opinion held by most writers, that tuberculous meningitis is necessarily fatal. At least there seems to me ground for considering as probable recovery in some instances. I have reported an instance of apparent recovery in another work.¹ Recovery in no instance can be demonstrated, since it can always be said that the diagnosis may have been incorrect. Of course if recovery invalidate the diagnosis, the disease must be considered as always ending fatally.

¹ Vide *Clinical Medicine*, by the author.

Acute Spinal Meningitis.

It is doubtful whether acute inflammation of the spinal meninges ever occur as a primary or idiopathic affection. It has already been mentioned that tuberculous inflammation of the spinal meninges is usually present in greater or less degree in cases of tuberculous cerebral meningitis. Acute spinal meningitis is a prominent lesion in epidemic cerebro-spinal meningitis, an affection which may occur sporadically and will be subsequently described. Acute spinal meningitis, as well as acute cerebral meningitis, may occur although rarely, as a complication in various infectious diseases, such as lobar pneumonitis, pyæmia, septicæmia, typhoid fever, typhus fever, or exanthematous fevers, gangrene of the lungs, and purulent pleuritis. Finally acute inflammation of the spinal meninges may be secondary to disease of neighboring parts, in which case the inflammation is conducted to the membranes by continuity. Thus, acute spinal meningitis may be consecutive to acute myelitis or to diseases and injuries of the vertebræ, such as cancer, caries, and fracture, or to inflammations in the neighborhood of the vertebræ. In the latter case the inflammation may extend to the meninges through the intervertebral foramina without involving the vertebræ. When the inflammation is secondary to affections of the vertebræ or adjoining parts, there are generally both spinal pachymeningitis and leptomeningitis. In the other cases the pia-arachnoid membrane is the part chiefly inflamed. Although acute spinal meningitis has been often attributed to prolonged exposure to cold, it is doubtful whether this be ever an efficient cause of the disease.

The inflammatory products are fibrin, serum, and pus. In the ordinary form of the disease these products are accumulated in the subarachnoid spaces, chiefly upon the posterior surface of the spinal cord. When the inflammation is secondary to fractures and diseases of the vertebræ, the exudation is usually both upon the outer and upon the inner surface of the dura mater. Sometimes the exudation is very abundant between the dura mater and the bone (acute peripachymeningitis). With acute spinal leptomeningitis there is generally more or less inflammation of the adjacent parts of the spinal cord (meningo-myelitis).

The local SYMPTOMS of acute spinal meningitis are chiefly referable to effects manifested through the spinal nerves, and they correspond to the functions of the posterior and anterior roots of these nerves. More or less pain is felt in the spine, radiating therefrom to the extremities. The pain is increased, not so much by pressure over the spinal column as by movements of the body. The sensibility of the surface is morbidly increased (hyperæsthesia). These effects are manifested through the posterior roots of the spinal nerves. Other effects are manifested through the anterior roots or by reflex action through the posterior—namely, tonic contraction of the muscles of the extremities, clonic contractions in some cases, spasm of the muscles of the back so as to give rise to opisthotonos, and sometimes rigidity of the thoracic muscles, causing dyspnœa. As regards the muscular contractions or spasms, there are exacerbations and remissions. These symptomatic phenomena are attributable to a morbid excitation of the spinal nerves, and they belong to the early part of the affection. Subsequently, paralysis occurs as the effect of pressure upon the cord by the products of the inflammation. The paralysis may be limited to the lower extremities (paraplegia) or it may be general; that is, affecting both the upper and lower extremities. The paralysis is rarely complete. It is usually limited to motion, and with it, indeed, exaggerated sensibility or hyperæsthesia may persist, as well as tonic contraction of muscles. With these local symptoms there is more or less fever, together with anorexia and prostration. The pulse is sometimes abnormally infrequent, and this may

a striking contrast with the temperature of the body as determined by thermometer. In the course of the disease, however, the pulse becomes small and feeble. Profuse perspirations often occur. Reflex and electrical irritability are generally preserved.

Diagnostic features point to the spinal cord as the seat of the disease, and to it as an inflammatory and a grave affection. Hysterical opisthotonos, rigidity, evidences both of inflammation and of gravity. Moreover, various other and concomitant phenomena betoken the existence of hysteria, and differentiate it from tetanus, which is a very grave disease. The disease, however, is distinguished by the early occurrence of trismus and tonic rigidity, and the absence of local and general symptoms denoting inflammation, and the traumatic origin of the affection in the majority of cases. The points involved in discriminating acute spinal meningitis from chronic meningitis will be noticed in treating of the latter in the next chapter. However, we may remark here that acute spinal meningitis and acute tetanus very rarely occur independently of each other. The two affections are usually associated; but the inflammation may be primarily seated in the spinal cord, and it may predominate in one or the other.

Acute spinal meningitis often runs a rapid course, its duration not extending beyond a week. It ends fatally in a large proportion of cases. Life is often lost by apnoea in some cases in which the respiratory function is notably affected by either spasm or paralysis of the muscles concerned in respiration—an extension of the inflammation to the medulla oblongata. If the trismus, dysphagia is likely to be a symptom. In either case death is usually by intense dyspnoea, which, on a physical examination of the chest, does not proceed from any adequate pulmonary or cardiac complication. In some cases asthenia predominates in the mode of dying.

The prognosis is to be estimated by the extent of the diffusion of the inflammation, and the severity of the symptoms. The immediate danger depends on the extension of the inflammation upward so as to interfere with respiration. In cases of a moderate intensity of the disease recovery may take place wholly and completely. The disease may continue and become chronic, or it may take place, leaving as sequelæ more or less atrophy and paralysis of the muscles which had been affected.

Indications for TREATMENT are essentially the same as in acute cerebral meningitis. Considering the rapid course of the disease in severe cases, and the danger in the direction of apnoea, bloodletting, general or local, or leeches may be employed if contraindicating circumstances relating to the patient's blood, and the constitutional strength be not present. Mercurial treatment is warrantable, if not desirable. If employed, it should be rapidly discontinued for this end inunction may be added to the administration of opium at short intervals. Ergot and belladonna are supposed to diminish spasm by causing contraction of the small arteries, and in this way to relieve the symptoms.

When the symptoms denote the presence of the products of inflammation, the vesication successively of different sections of the spine, and the use of potassium in large doses, are indicated. Sustaining treatment is the course indicated in proportion as the duration of the disease is prolonged, and the symptoms show a tendency to death by asthenia. Retention of urine is to be prevented, and cystitis may claim appropriate treatment.

Chronic Spinal Meningitis.

It is now believed that chronic spinal meningitis with clinical manifestations is much less frequent an affection than was formerly supposed. This

teristic of chronic spinal meningitis are also produced by diseases of spinal cord and by diseases of peripheral nerves, and many of these diseases being recognized only by careful microscopical examination, may readily escape observation at post-mortem examinations. Some of these diseases have been discovered only within a comparatively few years. Among the lesions which have been considered as evidence of chronic spinal meningitis, such as thickening and opacity of the pia-arachnoid membrane, calcareous plates in this membrane, and adhesions between this membrane and the spinal cord on the one hand and the dura mater on the other hand, are extremely common, and are usually present without any evidence during life of a spinal affection. Chronic spinal meningitis is not infrequent as a secondary affection. It may follow epidemic cerebro-spinal meningitis or it may accompany chronic diseases of the spinal cord or of the vertebræ. In these cases, however, there are usually no distinctive symptoms referable to the affection of the meninges. But, although chronic spinal meningitis is doubtless an affection of much less clinical importance than was formerly supposed, and although the symptoms formerly referred to a primary chronic inflammation of the meninges are usually dependent upon some other affection, nevertheless, there remain certain cases which are still to be considered clinically as instances of chronic spinal meningitis.

The LESIONS of chronic spinal leptomeningitis are, thickening and opacity of the pia-arachnoid membrane, increased subarachnoid fluid, and adhesions between the pia mater and the spinal cord and between the arachnoid and the dura mater. As already mentioned, these lesions, as well as calcific plates in the arachnoid membrane, are common, especially in elderly persons, without any corresponding symptoms during life.

The CAUSES which have been assigned for chronic spinal meningitis are injury to the spinal column, exposure to cold, abuse of the sexual function, and chronic alcoholism.

The SYMPTOMS are similar to those of acute spinal meningitis, but they are of longer duration, less intense, and not accompanied by acute febrile reaction. The symptoms are pain and rigidity of the neck and back, pain in the extremities, hyperæsthesia, and muscular spasms. These symptoms of irritation gradually give place to symptoms of loss of function, such as anæsthesia, paresis of the extremities, incontinence or retention of urine, and incontinence of feces. There may be a sensation of constriction, as of a tight belt, around the body. If marked paralysis and anæsthesia exist, it may be assumed that the spinal cord is involved.

The following points are urged in distinguishing the paraplegia of myelitis from that of meningitis: The former is accompanied by less pain in the spine, limbs, and extremities; the paralysis is developed more rapidly, and is greater in degree; cutaneous anæsthesia and analgesia occur earlier, and are more marked; and the muscles sooner become atrophied.

In a considerable proportion of cases of paraplegia dependent upon chronic spinal meningitis the termination is unfavorable, but in general the prognosis is better than in myelitis.

In the TREATMENT of chronic spinal meningitis the indications for blood-letting, local or general, are rarely present. Dry cupping, blisters, sinapisms, and irritating liniments applied to the back are considered as highly useful while the inflammation continues. The application of the hot iron is recommended as an efficient method of counter-irritation. During this period the avoidance of exercise and of exposure to cold is important. When there is reason to think that inflammation no longer continues, it is an object of treatment to promote absorption of the inflammatory products. The iodide of potassium is supposed to be of use in this way. Mercury may be tried, with proper pre-

cautions to avoid ptialism. Nothing should be done to impair the general condition, and, if it be impaired, restorative remedies and hygienic measures are indicated. Tepid baths seem to be of use. The improvement sometimes derived from mineral waters, used either internally or externally, probably does not depend on any special efficacy, but to a greater or less extent on the hygienic advantages which are associated with their use.

As regards treatment addressed directly to the paralysis, the measures are the same as in all paralytic affections whenever the measures are not contra-indicated by conditions standing in a causative relation to the paralysis, the object being to maintain the nutrition and functional capacity of the affected muscles.

Cervical Hypertrophic Pachymeningitis.

This affection was first described by Charcot in 1871. It is a rare disease. It is characterized anatomically by the formation of layers of new connective tissue from the inner surface of the *dura mater*. This membrane thus becomes greatly thickened, and it is usually adherent to the pia-arachnoid membrane, which may also become thickened in a similar way. The cord lies imbedded in a mass of dense fibrous tissue, by which it is compressed. The cord may be simply anæmic, but frequently it is the seat of a chronic transverse myelitis. Below the myelitis the cord presents the lesions of a descending secondary degeneration. The nerve-roots which are surrounded by the new fibrous tissue are likewise compressed and atrophied. The disease is usually confined to the cervical region.

The causation is not known. Exposure to cold and the abuse of alcohol have been assigned as causes, but without sufficient proof.

The compression and irritation of the posterior roots of the cervical nerves give rise in an early stage of the disease to severe shooting pains in the back of the neck, extending to the occiput and to the arms. There is often complaint of formication and of numbness in the arms. At a subsequent period the compression of the anterior roots of the cervical nerves causes paralysis with atrophy of the muscles of the upper extremity, most marked, as a rule, in the muscles supplied by the ulnar and the median nerves. The atrophied muscles rapidly lose reaction to the faradic current. The hand may assume a position of exaggerated extension. There may now be anæsthesia of the upper extremities. In consequence of the cervical part of the spinal cord being involved, the motor nerves going to the lower extremities may lose their power of conduction; and then follows a spastic paralysis of the lower extremities. If there be a complete transverse myelitis, anæsthesia of the lower extremities and paralysis of the bladder and rectum follow. Bed-sores may form. The paralyzed muscles of the lower extremities do not undergo atrophy, as do those of the upper extremities.

Cervical hypertrophic pachymeningitis may be confounded with tumors pressing upon the cervical part of the spinal cord, with caries of the cervical vertebrae and with amyotrophic lateral sclerosis. The main points in diagnosis are the situation and the radiation of the pain and the characters of the paralysis in the upper and in the lower extremities. Amyotrophic lateral sclerosis is distinguished by the absence of sensory disturbances, by the preservation of the vesical functions, and by the frequent development of the symptoms of bulbar paralysis.

The disease is of long duration. The usual termination is in death, either by apnoea or by asthenia. The symptoms may, however, be arrested, at least for a long time, and cases have been reported in which recovery is said to have resulted.

It is not likely that any measures of treatment directly affect the lesion.

Iodide of potassium and electricity are the therapeutical agents usually employed. Counter-irritation to the back of the neck by means of the hot iron has been recommended.

Cerebro-spinal Meningitis.

The name cerebro-spinal meningitis denotes an inflammatory affection of the arachnoid and pia mater of both the brain and the spinal cord. A sporadic and purely local affection, it is considered rare, but of late years sporadic cases of cerebro-spinal meningitis are met with in New York very infrequently. The name is generally understood as designating an epidemic disease characterized by cerebral and spinal meningeal inflammation. In the latter application it denotes an infectious disease in the sense in which the term infectious is at present defined. Epidemic cerebro-spinal meningitis is a general not a local disease. Its appropriate nosological place is among the essential fevers. It is with propriety called by some writers cerebro-spinal fever. The evidence of its having existed prior to the present century is not clearly apparent in medical literature. Since the beginning of the nineteenth century epidemics have occurred at different periods in various parts of the Old World and in this country. It prevailed in New England between the years 1807 and 1816, and was then known as *spotted fever*. For a quarter of a century after that period this country was exempt from its visitations; but within the last forty years it has prevailed from time to time in different districts of the United States and in Canada. This article will have reference to cerebro-spinal meningitis as an epidemic disease, or to cerebro-spinal fever.

ANATOMICAL CHARACTERS.—In the majority of cases an exudation of a purulent character, similar to that in simple meningitis, is found in the meshes of the pia mater both of the brain and cord. The extent and the abundance of the exudation vary much in different cases. The inflammation affects the pia-arachnoid membrane both of the convexity and of the base of the brain, but it is usually most intense at the base, and it may be limited to this situation. Within the spinal canal the inflammatory exudation is limited chiefly to the posterior surface of the cord and to the membranous envelopes of the posterior nerve-roots. The purulent exudation, however, is rarely distributed uniformly over the posterior surface, but is most abundant in the lumbar, lower dorsal, and lower cervical regions of the cord, while it may fail in the rest of the cervical region or be present there only in scattered patches. The exudation consists predominantly of pus, together with serum and fibrin, mixed usually with a considerable number of extravasated red blood-corpuscles. In recent cases mucin may be present in considerable amount, so as to render the exudation gelatinous. The membranes as well as the substance of the brain and cord are generally hyperæmic, and frequently the seat of small hemorrhagic extravasations. The substance of the brain and cord has usually an abnormally soft consistence, which may be particularly marked at certain points. The sheaths of the blood-vessels which penetrate the brain and the spinal cord are infiltrated with pus-cells, which may accumulate in sufficient number to form small abscesses in the brain or in the cord. The ventricles usually contain an increased amount of fluid, somewhat turbid in appearance or rarely decidedly purulent. The central canal of the spinal cord may be distended with purulent fluid.

In cases terminating within a few hours (fulminant cerebro-spinal meningitis) the anatomical evidences of the disease may be slight. In such cases the exudation is mainly serous, although the microscope will show that emigration of white blood-corpuscles has already actively begun. In these fulminating cases the brain-substance will be found, as a rule, cedematous

and anæmic. In cases of prolonged duration the ventricles are usually found greatly distended with serum. The previously creamy, purulent exudation is perhaps now desiccated and caseous, or more frequently has nearly disappeared.

The following embrace the most important of the morbid changes existing in other parts of the body: The skin often presents herpetic vesicles and petechiæ. The voluntary muscles, especially of the neck and back, are darkened in color and often the seat of granular degeneration. As in other infectious diseases, parenchymatous degeneration of the heart, liver, and kidneys is usually found. The lungs present no constant changes, but are frequently the seat of bronchitis, atelectasis, lobular pneumonia, and hypostatic congestion. The spleen, in the majority of cases, is not much enlarged, but is of lax consistence. Sometimes the spleen is found greatly swollen and softened. A moderate enlargement of Peyer's patches and of the solitary follicles is common. Abscesses in the joints and elsewhere have been occasionally observed. Endocarditis and inflammation of serous membranes are rarer complications. Suppurative inflammation of the middle and internal ear, choroiditis, and iritis are to be mentioned as occasional concomitants or sequelæ.

CLINICAL HISTORY.—The characteristic features of epidemic cerebro-spinal meningitis are remarkably distinctive. In many cases the disease begins with a sudden attack, the patient being at once stricken down with grave symptoms; but the access may be more or less gradual, the development occupying from one to eleven days. The prodromic symptoms, enumerated in the order of their relative frequency, are—cephalgia, chills without rigor or chilliness, nausea and vomiting, pain in the spine and limbs, vertigo, and diarrhœa. Cephalgia is usually the most prominent symptom when the disease is developed. The pain is intense, lancinating, and accompanied with a sense of tension. It is referred either to the frontal region, the occiput, or the whole head. The pain persists without intermissions. It is increased by light, sounds, and movements of the body. Pain referable to the spine, or rachialgia, is generally added to the cephalgia. The pain may extend over the whole of the spine, or it may be referred to either the lumbar, dorsal, or cervical portion. The extent and situation of the spinal pain probably correspond with the extent and situation of the spinal meningitis. The rachialgia is wanting if the disease prove fatal without inflammation extending to the spinal membrane. The spinal pain is not always increased by pressure over the vertebral column, but notably by movements of the body. Pain is frequently felt in different parts of the body, especially in the lower extremities. The pain in situations other than the head and spine is often intense. Hyperæsthesia of the surface of the body is often a marked symptom, rendering the slightest contact a source of suffering. Not infrequently vomiting accompanies the cephalgia at the outset of the disease.

Delirium in some cases quickly supervenes, but in other cases it occurs after a variable period. Sooner or later it occurs in a large proportion of the cases which are not quickly fatal. It varies much in character and intensity. At first there is simply difficulty in collecting ideas, but after a time the patient either remains taciturn, making no response to questions, or replies incoherently or becomes actively delirious, shouting and struggling against restraint. The latter form of delirium occurs in paroxysms, with calm intervals. The paroxysms occur especially at night. They are accompanied by hallucinations in some cases, and insane delusions. Occasionally the delirium is hilarious. The mind is usually desponding and apprehensive if the intelligence be preserved. Loquacity and erotic desires with priapism have been observed. Repeated seminal emissions occurred in a case which came under my observation. In a certain proportion of cases the patient becomes quickly somnolent

and falls into coma, which may be of temporary duration or continue until the disease ends fatally. More or less stupor, frequently amounting to coma, occurs not infrequently on the first day of the disease. The vision is rarely lost; double vision sometimes occurs; the pupils are frequently dilated, but sometimes contracted; the conjunctiva is often injected; and temporary deafness is an occasional symptom. In one of the cases of sporadic cerebro-spinal meningitis which I have observed lateral and vertical oscillation of the eyeballs was a notable symptom. The coma in some cases is without stertor and resembles that of hysteria. The patients seem to be in a quiet sleep, crying out if any attempt be made to alter the position of the body. A patient in one case which came under my observation had remained in precisely the same position for forty-eight hours, and in another case for three days. Mobility of the iris may remain, although the patient is in this comatose or deeply somnolent state.

Important symptoms relate to the muscles. Tonic contraction of the muscles of the neck and back is of frequent occurrence, giving rise to retraction of the head and opisthotonos in a greater or less degree. Trismus sometimes occurs, and in rare instances pleurosthotonos. Contractions of muscles of the extremities are not infrequently observed. Pain in the muscles of the legs and thighs, the spinal muscles, and those of the neck is a source of suffering if the patient be conscious. Muscular tremor is an occasional and strabismus not an infrequent, symptom. Subsultus and carphologia occur in cases in which the disease is protracted. Convulsions are not of frequent occurrence. Paralysis is also infrequent. Hemiplegic paresis and ptosis have been observed.

Nausea and vomiting are more or less prominent throughout the disease in a minority of cases. Constipation is the rule. The appetite is generally lost. However, a desire for food is sometimes expressed, although convalescence is not near at hand. The tongue is frequently large and flabby, showing indentations made by the pressure of the teeth. It becomes coated, and in the progress of the disease dry and dark. The teeth and lips frequently present sordes.

The respirations are sometimes suspicious. They are usually increased in frequency even when no pulmonary complication exists, and they are sometimes irregular. Stertor is rare. The pulse in the early stages of the disease is generally not more frequent, and is often less frequent, than in health. In the progress of the disease it becomes moderately accelerated, rarely exceeding 100 per minute, until toward a fatal termination, when it is frequent and small. Fluctuations in frequency at different periods of the day constitute a striking feature in some cases. Palpitations are occasionally observed. The quantity of urine may be greater than in health, and the urates are deposited in abundance. In some cases there is slight albuminuria, and exceptionally glycosuria has been observed. In a fatal case among those which I have observed there was hæmaturia, the hemorrhage being abundant and not occurring in any other situation.

The temperature of the skin varies in different cases and at different periods in the progress of the disease. At the beginning the temperature rarely exceeds, and often falls below, that of health. Notable heat of the surface is very rarely observed; the thermometer, however, shows the heat of the body to be more or less raised. Thermometric examinations in the axilla were made by Githens in 44 cases at 6 A. M., at 12 M., and at 6 P. M. daily, with the following results: The maximum of increase was 105° F., and in only 2 cases was this height reached. The maximum in 15 cases was between 104° and 105°; in 7 cases, between 102° and 103°; in 6 cases, between 101° and 102°; and in 2 cases it was below 100°. The difference between the morning and evening temperature was less than in most of the

fevers. "A rapid fall was the sure precursor of collapse."¹ As dryness and moisture, cases vary on different days and at different of the same day. Sweating is rare except in some cases shortly after death. The face is often suffused and of a dusky hue.

Rosy spots are frequently observed, but they are by no means common. They appear to be of more frequent occurrence in some epidemics than others. They vary in size from that of a pin's head to spaces of an inch in breadth or even larger. They are evidently due to an extravasation of blood or of blood-coloring matter, such as occurs in scorbutus, in some cases of continued fever, and occasionally in other fevers. They are hardly entitled to be called an eruption. A rose-colored eruption resembling that of typhoid fever has been occasionally observed.

Herpes of the face occurs often in some, and rarely in other epidemics. As herpes occurs very rarely, if ever, in other forms of meningitis, its presence may be of diagnostic importance. Urticaria, erythema, and vesicles have been observed, but their occurrence is evidently accidental; that is, they do not belong to the clinical history of the disease. In some of the cases which I have observed sudamina were abundant.

One of the features of the clinical history of this affection, exclusive of the cases in which death quickly ensues in apoplectic coma, shows a correspondence with the symptoms of acute cerebral meningitis, and the addition of those due to inflammation of the meninges of the spinal cord. The duration of the disease is very variable. Of fatal cases, the minimum duration is stated by Tourdes to be twenty hours. Ames states the minimum to be fifteen hours. The minimum duration in fatal cases is stated by Tourdes to be one hundred hours, and by Ames more than forty days. Of the cases analyzed by Ames, 16 died fatally on the second or third, and 19 on the fourth day.² Of 160 cases analyzed by Dr. S. B. Hunt, 12, or 1 in 13, died within the first twenty-four hours; 92, or more than half, died before the close of the fifth day; 14, or 1 in 10, died before the close of the tenth day; 4, or 1 in 40, before the close of the fifteenth day; and 18 survived for various periods thereafter.³

In some cases the duration varied between thirty-six hours and six weeks.⁴ In the majority of fatal cases the disease runs a rapid course, ending within the fifth day. In cases which end in recovery the convalescence is tedious and the patient remains for a long period in feeble health. Relapses have not been observed.

It is not easy to divide the career of the disease into well-marked stages, or to arrange cases into different classes, such as inflammatory, tubercular, malignant, etc., is not attended by any practical advantage. The symptoms are stated to occur by different observers. They vary as regards their occurrence, their duration, and the degree of amelioration and remissions. Not infrequently the improvement for a few hours, and sometimes for a day or so, is so marked as to give encouragement to hope that recovery is about to take place. These remissions are most likely to occur on the second or third day. In a case under my observation the temperature became normal, the intelligence returned, and for twenty hours the patient seemed convalescent; the symptoms, however, returned and the case terminated fatally.

LOGICAL CHARACTER.—All at present known of the pathological

³by Dr. Hunt in the medical volume of the *Sanitary Memoirs of the War*.

⁴See *Cerebro-spinal Meningitis in the Camps in and around Newbern in 1862-63*, by Dr. J. M. D., Boston, 1863.

character of epidemic cerebro-spinal meningitis is embraced in the statement that it is an infectious disease and belongs among the essential fevers. The inflammation of the pia mater of the brain and cord is a local manifestation or an effect of an underlying general morbid condition. It is reasonable to suppose that the specific infectious agent is a micro-organism, but with the exception of a few observations of micrococci in the exudation nothing is positively known concerning such an organism. It must be admitted that the phenomena of the disease are largely symptomatic of the cerebro-spinal inflammation.

CAUSATION.—The prevalence of the disease as an epidemic implies the existence of a special cause. With respect to the source of the special cause and the circumstances concerned in its production we have no positive knowledge. Nearly all who have observed the disease concur in the belief that the causation does not involve a contagium. The disease has prevailed in situations in which periodical fevers rarely occur. It is, however, not improbable that in malarial districts the special cause may be combined with that giving rise to periodical fevers, and that the phenomena of the latter are sometimes associated with those of cerebro-spinal meningitis.

In France the disease has been observed to prevail especially among soldiers, and particularly among new recruits. In this country it has prevailed among troops stationed at several different points. It attacks persons in all conditions and at all periods of life. Infants are not exempt, but the liability is increased after seven years of age. In a series of cases the larger number are between the ages of twenty and thirty years. Of the persons attacked, the larger proportion are males. The difference, however, is not great. The statistics of Sanderson, cited by Hunt, show 164 cases among males, and 154 among females.

Epidemics occur much oftener in the winter and spring than during the summer months. Of the epidemics which have occurred in this country nearly all were in the spring and winter months. Of 182 epidemics in Europe analyzed with reference to this point by Dr. John Simon, 10 were in August and September; 24 were in October and November; 46 were in December and January; 48 were in February and March; 30 were in April and May; and 24 were in June and July. The disease, as stated by Hunt, who cites the foregoing statistics, "has its favorite habitat in prisons and barracks. 'In the four or five years following 1837 it invaded nearly all the crowded barracks in France. It has appeared frequently among the galley-slaves of Toulon.'"

Facts pertaining to the localization of epidemics and the occasional occurrence of sporadic cases show conclusively that auxiliary causes which pertain to overcrowding, defective ventilation of dwellings, poisoning of the atmosphere by sewer emanations, etc. have a potent causative influence in association with the special cause; and it is an important fact that these auxiliary causes are by no means always confined to the habitations of the poor.

DIAGNOSIS.—Difficulty in making the diagnosis of cerebro-spinal meningitis relates chiefly to sporadic cases and to those in which the disease aborts or is unusually mild. Abortive cases sometimes occur, and the disease is sometimes so mild that its usual diagnostic features are not marked.

The disease need never be confounded with typhoid fever. The suddenness of the attack in many cases, the intensity of the cephalalgia, and the occurrence of symptoms denoting inflammation of the meninges of the brain and cord, distinguish it alike from typhoid and typhus fever. The characteristic abdominal symptoms of typhoid fever are wanting—namely, diarrhoea,

meteorism, and iliac tenderness. Absence of the latter symptoms does not exclude typhus, but other diagnostic points belonging to the latter disease are wanting. The characteristic eruption of typhus, often copious, appearing on the third or fourth day after taking to the bed, does not occur in cerebro-spinal meningitis. The spots of ecchymosis on which the name spotted fever is based cannot be confounded with the eruption of typhus. Tonic contraction of the muscles of the neck and back, rachialgia, convulsions, and furious delirium, which occur in cases of cerebro-spinal meningitis, are very rare in cases of either typhoid or typhus fever.

In the cases in which the patient falls quickly into coma and dies after the lapse of a few hours the affection resembles, in this fact, a paroxysm of pernicious intermittent fever. In general, however, the latter does not destroy life in the first paroxysm, and the occurrence of a paroxysm from which the patient has emerged suffices to establish the diagnosis. It is of course only in districts in which periodical fevers exist that the practitioner is called upon to make this differential diagnosis.

The occurrence of trismus and opisthotonos may suggest tetanus; but in tetanus the cerebral symptoms which belong to cerebro-spinal meningitis are wanting. Moreover, tetanus in other than tropical climates is exceedingly rare save as a traumatic affection, and it never prevails as an epidemic.

PROGNOSIS.—There are few epidemic diseases so destructive to life as cerebro-spinal meningitis. In the epidemic observed by Tourdes the proportion of deaths was 60 per cent. Ames gives the same proportion of fatal cases in the epidemic which prevailed in Alabama in 1848. In an epidemic observed by Lefèvre four-fifths died at the beginning, and two-thirds toward the end of the epidemic. Of 366 cases analyzed by Dr. S. B. Hunt, the deaths were 243 and the recoveries 123, making the percentage of fatal cases 70. Stillé states that ten epidemics between 1838 and 1848 gave an average mortality of 70 per cent., and a similar number of epidemics between 1855 and 1865 gave an average of about 36 per cent. He cites these statistics as showing a gradual decline of power in the epidemic cause. All observers agree as regards a large death-rate in cases of this disease. Mild cases, however, may occur during the prevalence of an epidemic, but even in these cases the physician should be cautious in giving a prognosis. The prognosis in all cases in which severe symptoms occur, such as notable delirium, coma, convulsions, and muscular contraction, is exceedingly grave. The disease is most likely to prove fatal in infants and in persons in middle and advanced life. It is stated that the proportion of fatal cases is greater among females than among males. The mode of dying, in the cases in which coma and death take place speedily, may be by apnoea, but in the majority of cases it is chiefly by asthenia.

Deafness and blindness are not very rare sequels of this disease. In the large majority of cases the deafness is bilateral. The blindness may be in both eyes, but oftener it is unilateral. The blindness is due to purulent choroiditis or to optic neuritis, and the deafness to purulent inflammation of the labyrinth of the ear.¹

TREATMENT.—As might be expected in a disease so severe and fatal as this, various potent therapeutical agents have been employed. No reliable abortive or curative treatment has as yet been discovered. Experience has, however, shown the utility of certain measures in the employment of which the physician is to be governed by the rational and symptomatic indications present in individual cases.

¹Vide article by Dr. H. Knapp in the *New York Medical Record*, Aug. 15, 1872.

Great severity of symptoms, the patient having been attacked in full health and the pulse being strong or hard, renders bloodletting appropriate. Wet cups may be applied to the neck or leeches behind the ears in lieu of venesection when the indications for bloodletting are less clear. The abstraction of blood is contraindicated if the cerebro-spinal symptoms be not severe, if the pulse be readily compressed, and if the patient were anæmic or feeble when attacked.

Quinia in large doses has appeared in some cases to be useful. Its apparent success is perhaps, in a measure, to be accounted for by supposing that pernicious intermittent fever may have been mistaken for the disease, and by the fact that malarial effects may be associated with the latter. The utility of this remedy may sometimes be due to its antipyretic operation. For the reduction of a high temperature in this disease sponging the body and the wet sheet are preferable. These measures are indicated by intensity of fever.

The testimony in behalf of opium in large doses is discrepant. As regards its utility, however, there is very general agreement among physicians of large experience. Prof. Stillé recommends one grain of opium every hour in grave cases, and every two hours in cases of moderate severity. This recommendation is based on the study of about 120 hospital cases. He has not known any approach to narcotism in the cases thus treated. The hypodermic administration of morphia is to be preferred. It is important to avoid narcotism. The bromides, given in large doses, are regarded with favor by many physicians with whose practice I have become acquainted through professional intercourse.

The utility of cold applications to the head and back is conceded by all physicians. The extent to which this measure is to be carried is to be determined by the sensations of the patient and the effect upon the symptoms.

The foregoing remarks relate to the treatment when the symptoms denote cerebro-spinal excitation. When the symptoms are those of oppression, the objects of treatment are the same as in cases of simple cerebral and spinal meningitis—namely, limitation of morbid products and their removal by absorption. The iodide of potassium, given in doses as large as are well tolerated, is indicated. Mercury, internally, and by inunction, may do something toward effecting the objects just stated, and if so it is desirable to secure its usefulness, however small it may be.

Support by alcoholics and nutritious alimentation is indicated in proportion as the symptoms denote asthenia.

Whenever an epidemic or a sporadic case of this disease occurs, local auxiliary causes should be sought and removed. Removal of residents to places without the area of the infected situation, if practicable, is to be recommended.

Hydrocephalus—Hydrorrhachis—Syringomyelia.

By the term hydrocephalus or hydrocephalus internus is understood an excessive accumulation of serous fluid in the ventricles of the brain, particularly the lateral ventricles. The name hydrocephalus externus is sometimes applied to great increase of fluid in the subarachnoid space. The serous effusion of hydrocephalus may be due to a variety of different processes such as venous congestion, atrophy of the brain, changes in the walls of the blood-vessels, and inflammation of the lining membrane of the ventricles or of the pia mater. In some, especially the congenital, forms of hydrocephalus we are unable to determine the cause of the disease. There is but little tendency to dropsical effusions within the cranium in cases of general dropsy.

hydrocephalus occurs either as a congenital affection or in early infancy, leading in some cases to an enormous enlargement of the cranium and giving rise to a characteristic deformity of the head. The reader is referred to works on the diseases of children for an account of this affection.

The name hydrocephalus *ex vacuo* is given to an effusion of serum into the ventricles as a result of wasting or atrophy of the brain-substance, such as occurs in old age. Under these circumstances, as the effused serum simply fills an unoccupied space, the brain does not suffer from compression. An abundant serous effusion is an important element in certain cases of tuberculous meningitis (acute hydrocephalus), and sometimes in other forms of meningitis. The exudation of fibrin and pus in some cases is very small, and the amount of effused serum large; but these are not properly cases of hydrocephalus. It was formerly thought that serous effusion sometimes occurs suddenly in sufficient quantity to occasion apoplexy (serous apoplexy). This was the theory in certain cases which are now explained by our knowledge of thrombosis, embolism, and uræmia.

Serous effusion into the lateral ventricles may occur in consequence of pressure upon the veins carrying the blood from the ventricles into the sinuses (venæ Galeni), as from a tumor of the pineal gland, solitary tubercles of the cerebellum, etc. A chronic accumulation of serum in the lateral ventricles, combined with a granular condition of the ependyma, has been described under the names *granular ependymitis* and *chronic ependymitis*. It occurs especially in cases of chronic alcoholism and in old age. A similar serous accumulation may be present in chronic cerebral meningitis with or without granular ependyma. The growth and coalescence of the granulations may cause obliteration of portions of the ventricles—for example, the anterior horns of the lateral ventricles—or may lead to the formation of bands of adhesion between the ventricular walls.

Extensive serous accumulation within the spinal canal is called *hydrorhachis*. The effusion may be in the central canal of the spinal cord (hydrorhachis interna or hydromyelus) or in the subarachnoid or subdural space (hydrorhachis externa). These affections, when congenital, are often combined with deficiency of portions of the vertebral column, constituting the affection commonly known as *spina bifida*. In this affection a tumor consisting of the serous accumulation with its enveloping membranes (hydro-myelocoele) protrudes through the fissure, most frequently in the sacral or dorsal regions. The affection is treated of in works on the diseases of children and on surgery. An accumulation of fluid in the central canal of the cord attends some cases of myelitis.

[The term *syringomyelia* is used to designate an affection characterized anatomically by the presence of cystic cavities in the cord independent of the normal cavity of the central canal. Dilatation of the latter is now called hydromyelia—a term first applied by Virchow to cavities of every kind in the spinal cord. The fact of the existence of these lacunæ in the medulla has long been recognized, but it is only of late years that we have learned to associate them with distinct clinical phenomena. Formerly, they were regarded as mere pathological curiosities. The most constant site of this cystic degeneration is the cervical and upper dorsal region of the medulla, but in extreme cases the cavity may extend throughout its entire length. It is formed, as a rule, at the expense of the gray substance, but on examining the cord by numerous transverse sections at short intervals it may be seen to deviate into the lateral or posterior columns. These anatomical alterations in strict accord with the clinical phenomena, which are for the most part *vary*, but may be combined in greater or less degree with the symptoms of lateral sclerosis and tabes dorsalis. The signs of muscular atrophy so

commonly present are due to an involvement of the anterior cornua in the destructive process. The cystic cavities are often separated by tracts of gliomatous tissue, and consequently they are regarded by pathologists as the "product of a true gliomatosis."

The statement contained in the last edition of this work, that the diagnosis of syringomyelia cannot be made during life, is no longer tenable. The clinical manifestations of well-marked cases of the disease are recognizable, and in numerous instances the diagnosis of syringomyelia has been verified by an autopsy. J. H. Lloyd and Wharton Sinkler of Philadelphia have quite recently reported cases¹ in which their diagnosis of the affection was confirmed by post-mortem examination.

As above stated, the principal symptoms are sensory, and the one that is most characteristic is the so-called "dissociation symptom;" i. e. preservation of tactile sensibility and of the muscular sense with insensibility to heat and pain—thermo-anæsthesia and analgesia. This dissociation of cutaneous sensibility is, however, observed also in anæsthetic leprosy and occasionally in peripheral nervous affections.

Motor symptoms are invariably present in well-marked cases, and consist of progressive muscular atrophy of the Duchenne-Aran type; or, if the pyramidal tracts are involved, the muscular wasting may be attended with the spastic symptoms of amyotrophic lateral sclerosis. Trophic disorders are as common as the symptoms above mentioned, and manifest themselves by hyperidrosis, herpetic and bullous eruptions, ulcerations, and panaritius which may proceed with little or no pain to complete destruction of one or more phalanges. These painless and destructive whitlows have been until quite recently regarded as pathognomonic of a disease described by Morvan, a physician of Brittany, and hence known as Morvan's disease, but the tendency at present is to regard the latter affection and syringomyelia as practically identical. Another form of trophic disturbance frequently observed is an arthropathy precisely similar to the "*arthropathie tabétique*" first described by Charcot.

Lateral curvature of the spine—scoliosis—is present in a large proportion of the cases, and is sometimes combined with posterior curvature—kyphoscoliosis. It is a symptom of muscular weakness and atrophy. The most common grouping of the symptoms of syringomyelia is muscular atrophy, most marked in the arms and shoulders, with the peculiar "dissociation symptom" above mentioned, and trophic disorders of various kinds.

Inasmuch as the lesions of syringomyelia are destructive of important nerve-centres and conducting tracts, its prognosis is hopeless. Life may, however, be protracted for an indefinite period, the patients generally succumbing to some intercurrent affection.—H.]

CHAPTER III.

INFLAMMATORY AND STRUCTURAL DISEASES OF THE BRAIN.

Encephalitis.—Abscess of the Brain.—Inflammatory Softening of the Brain.—Diffuse Sclerosis of the Brain.—Cerebral Paralysis of Children.—Infantile Spastic Hemiplegia.—Chronic Bulbar Paralysis.—Acute Bulbar Paralysis.—Intracranial Tumors.—Cerebral Syphilis.

Encephalitis—Abscess of the Brain.

THE terms encephalitis and cerebritis denote inflammation of the substance of the brain. It has already been mentioned that in cerebral meningitis the inflammation frequently extends more or less from the pia mater into the substance of the brain.

Encephalitis may present itself—1, as inflammatory softening; 2, as abscess; 3, as sclerosis or induration of the brain. In the present article abscess of the brain will be considered, and afterward the other forms of encephalitis.

Suppurative encephalitis may occur in any part of the brain. It is most common in the cerebral hemispheres and in the cerebellum. It is rare in other parts of the brain. Recent abscesses have a shaggy wall of softened cerebral tissue. Old abscesses are usually invested by a fibrous capsule. In the majority of cases the abscess is single, but sometimes there are several distinct abscesses, which are then usually small in size. Abscesses have been described which involve nearly a whole cerebral hemisphere, but in the majority of cases the size varies between that of a pigeon's egg and that of a hen's egg. Abscesses may perforate into one of the ventricles or may burst upon the exterior of the brain. The pus is sometimes fetid, especially when the abscess is secondary to putrid affections of the lungs. The pus may be gelatinous in consistence, and it is sometimes acid in reaction.

The most frequent cause of cerebral abscess is injury to the head attended by wound of the soft parts or fracture of the skull. Sometimes the abscess follows injury without wound or fracture. Suppurative inflammation of the brain is often secondary to caries of the cranial bones and to disease of the middle or internal ear, and less frequently to disease of the orbit or of the nose. It may be secondary to empyema, to gangrene of the lungs, and to bronchiectases with putrid secretion. In these cases, as well as in cerebral abscesses complicating pyæmia and acute ulcerative endocarditis, the abscess is probably due to infectious emboli lodging in the cerebral arteries. Other acute infectious diseases, such as typhoid fever and the exanthematous fevers, are very rarely followed by cerebral abscess.

Cerebral abscess may occur as an apparently primary or idiopathic disease. In a certain number of these cases it has been suggested that the abscess is the result of infection with the special poison of cerebro-spinal meningitis.

Cerebral abscess is more common in males than in females, and during the period from twenty to forty years of age than before or after this time. It is very rare after sixty years of age.

Even large abscesses of the brain, particularly of the primary variety, may remain latent for a long time, and they are sometimes discovered accidentally at autopsies. When the abscess is secondary to severe injury to the head or

to middle-ear disease, it is generally difficult to distinguish the affection from acute cerebral meningitis, which, in fact, is often also present. In these cases the course of the disease is generally acute.

Cerebral abscess often pursues a chronic course, and then more or less characteristic symptoms are present. Some of these symptoms are referable to the abscess *per se*; others are dependent upon its situation. Of the first group of symptoms the most important are—headache, which may be severe or of a dull character, vertigo, vomiting, rigors, and fever. These symptoms are not always present. Rigors are not common. Fever, if present, is usually not high and is of an irregular type, with remissions or intermissions. The symptoms which are dependent upon the situation of the abscess are manifold. If the motor regions be involved, muscular spasms occur, followed by paralysis (which may be complete or incomplete) in the form of hemiplegia or of monoplegia. Epileptiform convulsions are often present if the motor cortical zone be affected. Abscess seated in the occipital lobe may give rise to hemianopsia, and seated in the temporal lobe or involving the third frontal convolution on the left side, to aphasia. Disturbances of the pupils and of vision are common. (For further points which bear upon the localization of cerebral abscess, the reader is referred to the article on Topical Diagnosis, p. 613.)

Abscess of the brain may give rise to somnolence deepening into coma. The coma may develop suddenly, so as to give rise to the suspicion of hemorrhage or of embolism.

The DURATION of cerebral abscess is variable. The acute form may terminate fatally within a few days following the onset of the disease. The chronic form generally lasts for several months, and it may be for years.

The DIAGNOSIS involves especially the discrimination from cerebral meningitis, tumor of the brain, and thrombic softening. As already mentioned, the diagnosis of acute cerebral abscess, following traumatism and disease of the middle ear, from cerebral meningitis is difficult and often impossible. The main points to be considered are that in meningitis the cephalalgia, delirium, and fever are usually more intense, whereas in abscess symptoms dependent upon a local affection of the brain, such as hemiplegia, monoplegia, hemiopia, etc., are more common than in meningitis.

A capital point in the discrimination of abscess from tumor of the brain is the causation. When the symptoms follow injury to the head, ear disease, pulmonary disease, and the other causes of abscess which have been mentioned, the probability is in favor of abscess. The existence of rigors and of fever is in favor of abscess. Choked disc is rare in abscess and is common in tumor. When the diagnosis is doubtful, especially when none of the causes of abscess can be determined, the probabilities are in favor of tumor, inasmuch as tumor is much more frequent than primary abscess. Cerebral embolism and thrombosis can often be excluded by attention to the causation. Coma resulting from abscess is generally preceded by marked cerebral symptoms, which are absent or less prominent in embolism or thrombosis.

Cerebral abscess in nearly all cases ends fatally after a variable period. The immediate cause of death may be general oedema of the brain, producing coma, or rupture of the abscess either into one of the ventricles or upon the surface of the brain. The abscess may become encapsulated, and remain stationary for an indefinite time.

The TREATMENT is generally to be directed to symptoms. Depletory and debilitating measures are to be avoided. Tonic remedies, a nutritious diet, repose of the mental faculties, and stimulants if the patient be in danger from depression of the vital powers, should constitute the treatment.

The only possibility of effecting recovery is to trephine the skull and make an incision into the abscess. The operation is justifiable if the diagnosis be

reasonably certain and if it be probable that the abscess is in an accessible location. These conditions are not likely to be fulfilled except when the abscess is the result of injury or of disease of the bones or of the middle ear. Surgical works are to be consulted for the operative treatment. Several successful operations have been recorded.

Inflammatory Softening of the Brain.

Formerly, nearly all varieties of cerebral softening were considered to be inflammatory in their origin. It is now known that the majority of cases of softening are not inflammatory, but the result of suspended nutrition (necrosis), attributable either to embolism or to thrombosis. There remain, however, rare cases of primary softening the cause of which cannot be found in changes in the blood-vessels, that are still classified as inflammatory, although our knowledge is very imperfect as to their genesis and their distinctive pathological characters. It is possible that in these cases the softening is analogous to that present in many cases of myelitis. This encephalitic softening is generally reddish in color, and hence is called inflammatory red softening. The affected part of the brain, which may be either the white or the gray matter, is softened, somewhat swollen, of a diffuse reddish-yellow color, and frequently dotted with red points of capillary blood-extravasations. The region of inflammatory softening is not distinctly circumscribed, but is surrounded by a zone of œdematous brain-tissue. The microscopical examination reveals hyperæmia, blood-extravasations, broken-up nerve-fibres, fatty and disintegrating ganglion-cells, pus-cells in greater or less number, compound granular corpuscles, and sometimes pigment-granules. The histological characters do not suffice to distinguish inflammatory from non-inflammatory softening. The lesion has nothing to do with abscess, which, in the brain as well as elsewhere, is due to some specific infection. Whether this form of softening can terminate in resolution or complete restitution of the normal structure is unknown, but such a termination does not seem probable.

The SYMPTOMS resemble those of thrombic softening, and of course are various according to the situation of the disease. They do not enable us to make a diagnosis of inflammatory softening.

The cases which are designated popularly as softening of the brain are often cases of thrombic softening. The term "softening of the brain," however, is often used in a vague sense to designate mental weakness, which may be dependent upon a variety of morbid conditions.

As is evident, the TREATMENT of encephalitic softening must be directed to symptoms, and it does not differ from that applicable to softening from thrombosis. The general health of the patient should be maintained so far as possible. The phosphide of zinc, chloride of ammonium, and bromide of potassium have been recommended.

It is customary to include also under the term encephalitis certain cases in which cerebral symptoms, such as paresis of one or more of the extremities of the face, muscular spasms, disturbances of speech, appear, and then after a variable period, usually of some weeks or months, wholly or in great part disappear. The pathogeny of these temporary forms of cerebral disorder is not understood, but they cannot depend upon severe structural lesions.

Diffuse Sclerosis of the Brain.

Sclerosis of the brain is characterized by an increase of the neuroglia. Sclerosis may affect the whole or the greater part of the brain, when it is

called diffuse cerebral sclerosis, or it may occur in isolated, disseminated patches, and it is then distinguished as multiple or insular sclerosis. Multiple cerebral sclerosis is generally accompanied by a similar lesion of the spinal cord. The disease is then called cerebro-spinal sclerosis, which is a well-characterized affection, and will receive consideration in a subsequent article. At present only the diffuse form of cerebral sclerosis will be considered.

In diffuse cerebral sclerosis the brain presents an abnormally firm consistence. The brain is usually more or less atrophied, and the ventricles are frequently dilated. The microscopical changes are often less marked than the gross appearances would lead one to suspect. When these changes are marked, the lesion is found to be an increase of the neuroglia, usually, but not always, with atrophy of the nerve-elements. The centrum ovale is generally most affected, but the cortex may also be sclerotic.

Diffuse cerebral sclerosis is most common in the brains of idiots, old epileptics, and patients affected with the general paralysis of the insane. A certain amount of diffuse sclerosis with dilatation of the ventricles is not uncommon in the brains of those dying from chronic alcoholism. Diffuse cerebral sclerosis occurs in children as well as in very old persons.

The SYMPTOMS vary according to the extent and the intensity of the lesion. There is generally mental impairment which may amount to dementia. Epileptic convulsions are common. Rhythmical muscular spasms or chorea may be present. There is frequently hemiplegia, and when both hemispheres are affected there may be paresis on both sides of the body. The paralysis is often of a spastic nature. Speech is frequently disordered. The cutaneous sensibility is usually but little or not at all affected. Defective vision and deafness are not uncommon.

The COURSE of the disease is chronic. The duration is long, extending often over many years.

The TREATMENT relates only to symptomatic indications.

Spastic Cerebral Paralysis of Children.—Infantile Spastic Hemiplegia.

In the present article will be considered a peculiar form of hemiplegia occurring in children which resembles in many particulars the so-called spinal paralysis of children. As the latter affection is caused by a special form of myelitis involving the ganglion-cells of the anterior horns of the spinal cord, so the disease under consideration is the result of a special form of encephalitis involving the motor region of the cerebral cortex.

No post-mortem examination has as yet been made in an early stage of the disease, but the symptoms render it probable that the lesion is primarily an acute encephalitis of the motor cortex. In cases of long standing there have been found atrophy and sclerosis of the central convolutions in whole or in part. The affected convolutions are shrunken and are firm in consistence. The microscope shows increase of neuroglia and atrophy of the ganglion-cells, especially of the large pyramidal ganglion-cells. The disease may be either unilateral or bilateral, but is generally more marked in one hemisphere than in the other. Secondary degenerations are found in the pyramidal tracts.

The disease seems to be confined to children and begins usually within the first four years of life. The onset is generally acute and marked by fever, and often by convulsions. The existence of paralysis is not usually detected until after the febrile paroxysm, which is ordinarily of only a few days' duration, has subsided. The arm and the leg are paralyzed upon the side opposite to the lesion. The face is less frequently affected. The paralysis may be in

the form of a monoplegia. The paralysis is accompanied with more or less muscular rigidity and contractures, [causing a flexed position of the upper extremity, so that the arm is held against the thorax, the forearm flexed at a right angle, and the hand and fingers strongly flexed. Contractures are equally common in the lower extremity, and lead to various forms of talipes.—H.] The paralyzed muscles, although atrophied, do not present the reaction of degeneration to be subsequently described. Spasms of the paretic muscles, particularly in the form of athetosis or of chorea, are common. The children may become epileptic. Sensation is not affected. The tendon reflexes are usually increased. Temporary aphasia is common with right-sided hemiplegia.

Infantile spastic hemiplegia is distinguished from the spinal paralysis of children by the hemiplegic form of the paralysis, by the absence of the reaction of degeneration, and by the increased tendon reflexes.

There may be some improvement in the degree and extent of the paralysis soon after it first appears. The paralysis which remains after this early improvement is permanent. The paralyzed members are less developed than the others. The mental development may be normal, but it is often defective. [If before the attack the child had acquired the faculty of speech, this will be lost, at least temporarily, if the paralysis is on the right side of the body. In cases such as this in which speech is gradually regained while the other symptoms persist, it is supposed that the right cerebral hemisphere gradually assumes the work, so far as speech is concerned, of the left.—H.]

The TREATMENT at the onset of the disease consists in cold applications to the head and in the administration of mild purgatives. For the subsequent paralysis electricity and massage are of benefit. Bromide of potassium is useful if epileptic convulsions occur.

Chronic Bulbar Paralysis—Glosso-labio-laryngeal Paralysis.

This form of paralysis was described first by Duchenne in 1860 under the name "progressive muscular paralysis of the tongue, the palate, and the lips." Since that date a variety of names have been proposed, among which may be mentioned chronic progressive bulbar paralysis, progressive bulbo-nuclear paralysis, progressive atrophic bulbar paralysis, and glosso-labio-laryngeal paralysis. The disease is characterized by progressive paralysis and atrophy of the muscles of the lips, tongue, soft palate, pharynx, and larynx. The symptoms and the anatomical lesions are analogous to those of progressive muscular atrophy, with which, in fact, chronic bulbar paralysis is not infrequently combined. Chronic bulbar paralysis is also often associated with amyotrophic lateral sclerosis. The anatomical basis of chronic bulbar paralysis is to be found in an atrophy of ganglion-cells belonging to the nuclei of origin of certain motor nerves of the medulla oblongata. While there is no doubt that the essential change is an atrophy and disappearance of motor ganglion-cells, it is not certain whether the morbid process consists in a primary atrophy of these cells or in a primary interstitial myelitis with secondary degeneration of the nerve-cells. The medulla oblongata may present no distinct alterations to the naked eye, or perhaps there may be detected a few ill-defined gray and atrophic spots near the floor of the fourth ventricle. Microscopical examination is required for an accurate localization and study of the lesions. Atrophy and disappearance of the ganglion-cells have been found in the main and accessory nuclei of the hypoglossal nerves, in the motor (anterior) nuclei of the pneumogastric, spinal accessory, and glosso-pharyngeal nerves, in the nucleus of the facial, and in the motor (mastica-

tory) nucleus of the trigeminal nerves. The changes are bilateral. Of these nuclei the main nucleus of the hypoglossus seems to be earliest and most extensively involved. Sometimes it possesses not a single ganglion-cell. Some of the above-named nuclei may escape—for example, the motor nucleus of the fifth nerve. In the process of atrophy the ganglion-cells become rounded, devoid of processes, filled with pigment and diminished in size, and finally they disappear. In the nuclei of origin, some increase of the neuroglia (interstitial myelitis), corpora amylacea, and granular corpuscles usually attend the degenerative changes in the ganglion-cells. The degenerated spots are most readily recognized on microscopical sections stained with carmine by their red color, which is deeper than that of the normal parts. The nerve-fibres in the roots and trunks of the nerves whose centres of origin are affected undergo, to a greater or less extent, degeneration and atrophy. Although the muscular fibres in the tongue are atrophied, the organ may preserve nearly its normal dimensions in consequence of a formation of fat-cells in the interstitial tissue—a change recognized by the yellow color on section. The atrophy which takes place in the muscular fibres in this affection is of the same nature as that to be described for progressive muscular atrophy.

Clinically, the disease is characterized by progressive diminution of voluntary power over the tongue, the muscles of the palate, and the lips. The disease begins insidiously. The paralytic effects are bilateral and symmetrical. The loss of power, at first slight, gradually increases. After a time there is much difficulty in articulation. The patient is unable to pronounce words and the letters of the alphabet, especially the consonants requiring for their enunciation movements of the tongue and lips. Speech at length is impossible, and the only means of communication is by signs or writing. The paralysis of the orbicularis oris renders the lips immovable during emotions of grief or mirthfulness. The mouth is elongated and gives to the face an expression as if about to weep. The saliva is increased and dribbles over the lips. Food collects between the teeth and cheeks, and the fingers are required to dislodge it. The ability to protrude the tongue or to curl the tip upward is lost. Fibrillary contractions of the muscles of the tongue and of the lips can usually be observed. When the paralysis of the tongue and orbicular muscles of the mouth has increased to a certain extent or even from the outset and before the paralysis has extended to the lips, the muscles of the palate are affected. Deglutition then is more or less difficult, food and drink being often returned through the nostrils. The laryngeal muscles become paralyzed, causing aphonia, with either diminution or cessation of the respiratory movements of the glottis. Paresis of the muscles of respiration may follow. The acts of respiration are feeble, and the power of coughing is impaired.

Portions of food and drink and the salivary fluids are often drawn into the larynx, and are with difficulty expelled, owing to the inability to cough effectively. For this reason, if the patient be attacked with bronchitis, there is danger from the accumulation of mucus in the bronchial tubes. Paralysis may occur in other parts of the body and may extend more or less over the voluntary muscles. The progress of the affection is unattended by fever. The affection advances steadily, but more or less gradually, toward a fatal termination. Death may be caused by apnoea from impaired ability to carry on respiration, and from accumulations of foreign material in the bronchial tubes and air-cells, causing bronchitis, aspiration-pneumonia, or pulmonary gangrene; or the mode of dying is by asthenia or starvation, in consequence of inability to ingest an amount of aliment sufficient to sustain life. At an advanced period the action of the heart may be notably disturbed. Parox-

isms of feeble, irregular action, together with cyanosis, sometimes occur, and death may take place by syncope.

The intelligence remains unaffected. Although the paralyzed muscular fibres present the reaction of degeneration, this is generally difficult to determine on account of the preservation of a certain number of fibres with normal electrical excitability. Reflex excitability is generally lost, but in some instances it is retained, and in rare instances is increased. The paralyzed muscles are atrophied. The general sensibility of the mouth, tongue, and pharynx is not affected; the gustatory sense and the other special senses are preserved; and the appetite and digestion may be unimpaired.

The affection is readily distinguished from double facial paralysis (*diplegia facialis*) by the fact that the orbicular muscles of the eye and the muscles of the face, other than the orbicularis oris, are not affected. In its progressive character and the occurrence of paralysis in other situations, it bears a resemblance to general cerebral paralysis, in which the muscles concerned in speech are often the first affected. It differs from the latter affection in the fact that the intellect remains unaffected; and paralysis of other muscles than those of the tongue, mouth, pharynx, and larynx occurs incidentally in only a certain proportion of cases. The group of symptoms which characterize bulbar paralysis may occur in the course of progressive muscular atrophy. In the latter disease, however, the muscles of the extremities or trunk are also affected. In other words, spinal disease accompanies that of the medulla oblongata. Chronic bulbar paralysis may be preceded or followed by progressive muscular atrophy. In like manner the spinal diseases, called *amyotrophic lateral sclerosis* and *disseminated sclerosis of the cord*, may involve by extension the medulla oblongata, and give rise secondarily to the symptoms which belong to the history of bulbar paralysis. Embolism or thrombosis of the vertebral arteries, occluding the branches going to the medulla oblongata, and hemorrhage limited to the latter, have been known to cause the group of phenomena which characterizes bulbar paralysis. The differential points pertaining to thrombosis and hemorrhage are, the sudden occurrence of the paralysis of the tongue, lips, and pharynx, and the occurrence simultaneously of paralysis either unilateral or bilateral of the limbs. The name acute bulbar paralysis has been applied to these cases. (See next article.) Tumors in the medulla oblongata, in connection with the symptoms of bulbar paralysis, give rise to those denoting cerebral disturbance and to ophthalmoscopic appearances which are wanting in the latter disease.

With reference to CAUSATION, the fairest statement is a confession of ignorance. The disease very rarely occurs before forty years of age, and the male is more liable to it than the female. Occupation and station in life have no causative influence. Beyond these facts nothing can be positively affirmed in regard to the etiology. It is, however, reasonable to suppose that exposure to cold, excesses of all kinds, over-exertion, either physical or mental, and, perhaps, syphilis, have more or less agency in the development and progress of the disease.

In chronic bulbar paralysis involving irremediable anatomical changes in the medulla oblongata, all that can be hoped for is that the disease will cease to be progressive, or, next to this, if the progress continue, that this will be slow. The extreme limit of the duration of the disease is five years. The prognostics which show the fatal termination to be not far distant are, complete dysphagia, great debility from inanition, embarrassment of respiration, and disturbances of the heart's action from syncope.

The objects of TREATMENT are, *first*, the arrest of the progress of the disease, and, *second*, if this object be unattainable, retardation of its progress. With reference to these objects, the patient should, as far as possible, be withdrawn

from every agency which may be supposed to have a causative operation. All unsanitary influences pertaining to body and mind are to be removed. The system should be well nourished, and measures are to be employed for restoration of the general health if this be in any way impaired. These injunctions embody, perhaps, the most important part of the treatment, with our present knowledge. It is not certain that any remedies have a special influence on the disease. An able observer (Erb) warns against the administration of strychnia and phosphorus; yet the latter is undoubtedly useful in some cases of a similar disease seated in the spinal cord—namely, progressive muscular atrophy—and also in multiple sclerosis. It is doubtful if much benefit be derived from the nitrate of silver, the iodide of potassium, ergot, and belladonna, but it is proper to make trial of these remedies. There is very little ground for expecting benefit from counter-irritation. Most neurologists attach importance, *par excellence*, to electricity, but it does not seem, thus far, to have effected great results. Persistent trial of this agent, however, is not to be omitted.

When deglutition becomes difficult, nourishment should be introduced into the stomach by means of the œsophageal tube, and rectal alimentation may be resorted to. In order to avoid the danger of foreign substances entering the bronchi, it is well not to delay too long before resorting to the use of the œsophageal tube.

Acute Bulbar Paralysis.

Various lesions of the medulla oblongata may give rise to the group of symptoms which has received the name of apoplectiform or acute bulbar paralysis. Such lesions are hemorrhage, softening from embolism or thrombosis of the vertebral and basilar arteries, acutely developed compression of the medulla oblongata, and acute inflammation. In three cases of acute bulbar paralysis examined by Leyden there were found in the medulla oblongata a number of small foci of inflammatory softening. These foci may be discoverable only upon microscopical examination. The term acute bulbar paralysis is sometimes limited to the inflammatory variety, which will be taken as the basis of the following description of the symptomatology.

The SYMPTOMS develop acutely, and often rather suddenly. The disease may be ushered in by pain in the head and back of the neck, vomiting, and dizziness. The characteristic bulbar symptoms soon appear. These are difficulty in swallowing, difficulty in articulation producing the disturbances of speech called dysarthria and anarthria, and often irregularity in the rhythm of respiration and of the pulse, which is frequent, small, and intermittent. There is often, but not always, elevation of temperature. The extremities may or may not be paretic. Not infrequently there is paralysis of facial and of ocular muscles. Paralysis of the diaphragm has been repeatedly observed.

The DURATION of the disease is from four days to two or three weeks. The termination appears to be always fatal, and is generally due to paralysis of respiration.

No measures of TREATMENT have thus far been attended with success. Counter-irritants to the back of the neck may be employed. The indications are essentially the same as in acute myelitis.

Tumors within the Cranium.

Most of the tumors which have been found in other parts of the body also develop within the brain. Among the most frequent and characteristic of cerebral tumors is *glioma*. It develops from the cerebral substance,

from the membranes. It is met with elsewhere only in the spinal cord and retina. It is the sarcoma of the brain, differing from ordinary sarcomata by the presence of that finely-fibrillated and molecular connective substance called neuroglia. A peculiarity of glioma is that it often appears more as a diffuse infiltration than as a circumscribed growth. The consistence of the tumor may be either hard or soft. The hard variety may be mistaken for cerebral sclerosis, and the soft for cerebral softening. The tumor is often very vascular, and may be the seat of hemorrhages. Sometimes the hemorrhage is so great as to destroy the larger part of the tumor and to present the appearance of a primary cerebral hemorrhage. In such a case the microscopical examination of the tissue immediately surrounding the hemorrhage will usually reveal gliomatous structure. In some cases of glioma there can be demonstrated large numbers of the branching cells, called brush-cells and spider-cells, which characterize the normal neuroglia. In other cases the tumor seems to consist chiefly of small round cells imbedded in a finely-fibrillated granular matrix. In the latter cases proper methods of demonstration will often reveal the characteristic branching cells. Glioma is often combined with sarcoma, constituting the so-called *glio-sarcoma*. All varieties of *sarcoma* may develop in the brain, either as primary or as secondary growths. They originate more frequently in the membranes than in the brain-substance. *Gummata* are among the most important of cerebral tumors. They take their origin almost invariably from the membranes, but not infrequently grow from the pia mater into the brain-substance. They also form in many cases fused growths. They are usually combined with chronic inflammatory changes (gummatous meningitis). They usually present spots of cheesy degeneration. *Solitary tubercles* consist of nodules, varying in size from a pea to an apple, which present a cheesy centre and a periphery of connective tissue rich in small round cells. In the peripheral zone there are sometimes solitary tubercles containing endothelioid cells and giant-cells. The tubercular bacilli have been found in solitary tubercles. Tubercles may be present in other parts of the body. Solitary tubercles may occur in any part of the brain. They are found with especial frequency in the cerebellum. The brain and its meninges may be the seat of secondary *carcinoma*. Tumors presenting a structure very similar to carcinoma may develop primarily in the membranes. They probably take their origin from endothelium in the perivascular sheaths (endothelioma). The tumor called *cholesteatoma* is misnamed, as by no means always contains cholesterin. The appearance of cholesterin is afforded by the presence of flat epithelial-like cells, often arranged in concentric masses. *Psammoma* derives its name from the presence of little calcareous granules resembling particles of sand. The calcareous masses often present a concentric arrangement. They appear to be connected with the blood-vessels. The last two varieties of tumor grow from the membranes, especially from the dura mater. Of other intracranial tumors may simply be mentioned fibroma, myxoma, lipoma, lymphoma, osteoma, angioma, neurinoma, papilloma, and tumors of the pituitary body. In this connection may be mentioned the occurrence in the brain of the parasites *cysticercus cellulosae* and *echinococcus*. The cerebral arteries are occasionally the seat of *neurism*, aside from those distinguished as miliary. Aneurismal tumors are generally connected with arteries at the base of the brain, the basilar, the internal carotid, the middle cerebral, and the circle of Willis. Generally the tumors are small, but they are sometimes of the size of a pullet's egg. The different tumors produce morbid effects by pressure on the brain, and their effects, thus produced, other things being equal, are proportionate to the size of the tumor and the rapidity of its growth. Special morbid effects result from the situation of the tumor. They cause additional injury to

the brain, either by exciting circumscribed cerebritis, and thereby inducing softening of the brain-substance surrounding them, or by interfering with nutrition, and thus leading to non-inflammatory softening; and as a result of the softening hemorrhagic extravasation is not uncommon. These morbid effects are produced alike by different tumors; that is to say, the morbid effects have no relation to the particular kind of tumor. Hence the kind of tumor in any case cannot be determined by the symptoms which it occasions. For this reason the several tumors are considered collectively, instead of receiving each a separate consideration.

Of the SYMPTOMS which accompany tumors within the skull, cephalalgia is usually prominent. The pain is frequently limited to a circumscribed space which sometimes, but not always, corresponds to the site of the tumor. Pain is prominent as a symptom in proportion as the tumor gives rise to circumscribed meningitis or increases the intracranial pressure. Other cerebral symptoms more or less prominent are—vertigo, difficulty in preserving an equilibrium in walking, momentary loss of consciousness, tinnitus aurium, the feeling of formication, numbness in different parts of the body, and scintillations; hyperæsthesia of the surface followed by blunted sensibility; mental irritability, to which succeed dulness and progressive impairment of the faculties of the mind; sometimes active delirium, and frequently epileptiform convulsions. The so-called compelled movements, either backward, forward, or rotatory, or in a circle (circus movements), are sometimes, although rarely, observed. Vomiting may be a prominent symptom, occurring irrespective of the ingesta and not accompanied by symptoms denoting gastritis. This symptom is likely to be prominent in the cases in which cephalalgia and vertigo are unusually marked. The pulse is often slower than normal. Constipation is the rule. Polyuria and glycosuria have been noted, especially in tumors pressing on the pons or medulla oblongata.

Paralysis more or less extensive, affecting the special senses and voluntary muscles, occurs sooner or later. Hemiplegia, generally incomplete, is a frequent form of the paralysis. The hemiplegia is often developed from successive monoplegias. In some cases the two sides are successively affected, constituting double hemiplegia. The hemiplegia may have been preceded by facial paralysis, and if the latter do not precede it may either accompany or follow the hemiplegia. The tumor may be so situated as to press upon certain of the cranial nerves exterior to the brain. The paralysis of the parts supplied by these nerves will then be on the same side as the tumor and opposite to the hemiplegia, whereas if the paralysis be due to pressure of the tumor within the substance of the brain the cranial nerves affected are those on the same side as the hemiplegia and the side opposite to the hemisphere in which the tumor is situated. The paralysis caused by pressure upon nerves beyond their central connections has the distinctive characteristics of a peripheral paralysis. The affected muscles atrophy and speedily lose electrical excitability. The paralyzes may be limited to the seventh or portio dura nerve, or other cranial nerves may be involved. Loss or impairment of vision in one or both eyes occurs when the tumor either involves destruction of the optic nerve or interrupts its function by pressure. [Amaurosis is also a symptom of tumors of the cerebellum and of those of the corpora quadrigemina.—H.] Neuralgia and paralysis of sensation on one side of the face result from similar effects upon the fifth nerve. The third and fourth nerves may be involved, and not infrequently the paralysis affects, separately or collectively, the senses of hearing, smell, and taste.

The differences in different cases, as regards the parts affected with paralysis, of course depend on the seat of tumors, their size, and the direction in

which they extend. With reference to the differential diagnosis of tumors and inflammatory softening or other lesions, the extension of the paralysis to different parts in succession after variable intervals is a highly significant fact. The paralysis affecting successively parts supplied by different cranial nerves, the members in some cases becoming affected first on one side and then on the other side, and the continued increase of the degree of the paralysis of different parts, point with significance to tumors, because such a history is in correspondence with their continued growth and the progressively increasing amount of pressure and of destruction of cerebral substance. Aphasia in some cases is an effect of tumors, and this symptom renders it probable that they affect the posterior part of the inferior convolution of the left frontal lobe. [Cases of cerebral tumor vary greatly with reference to the degree in which the psychical functions are affected. In some the intelligence remains unaffected throughout the disease, or, at the most, some loss of memory may be apparent, while in others the patient gradually becomes completely demented.—H.] The ophthalmoscope is useful in determining the existence of intracranial tumors. Morbid changes in the optic discs, either congestive, inflammatory, or atrophic, are found in a very large proportion of cases, even though vision be not appreciably affected. The ophthalmoscope may be, therefore, of much value in the diagnosis, even before there are any subjective symptoms referable to the eye. Swelling of the optic papilla, producing the appearance called choked disc, is a result of intracranial pressure, and this may occur wherever be the seat of the tumor. Choked disc is an important aid in diagnosis. There may be descending optic neuritis. Atrophy of the optic nerve may be either secondary to the foregoing or a direct effect of the pressure of the tumor on the optic tract. The pupils are often dilated, and not infrequently they differ in size and respond feebly to light. With reference to the localization of tumors the reader is referred to the article on the topical diagnosis of cerebral lesions. (Vide p. 613.) It cannot be claimed, on the basis of clinical experience, that, by means of the so-called topical symptoms, tumors or other lesions can be always accurately localized. Aside from the imperfections of our present knowledge of the functions of the different parts of the brain, their relations with each other are such that a lesion in a particular situation may affect other situations more or less remote, and the parts thus secondarily affected may give rise to prominent symptoms. Nevertheless, experimental physiology and clinical observations have furnished facts which have led to some approximation to accuracy in localization.

As regards DIAGNOSIS, abscess of the brain may present a series of clinical events which render it difficult thereby to differentiate this affection from tumor. If the affection have speedily followed injury of the head, if it be connected with otitis, or if there be caries of the skull in any situation, the affection is probably abscess. If these etiological relations be wanting, tumor is more probable than abscess. Cerebral hemorrhage and softening from thrombosis or embolism are distinguished by this fact—namely, paralysis with or without an apoplectic seizure occurs suddenly without prodromes, whereas paralytic and other marked effects of tumor occur in succession and after prodromic symptoms which have existed for a longer or shorter period. In cases of hemiplegia from the affections just named nerves of the special senses and other cranial nerves are rarely involved, as they often are in cases of hemiplegic paralysis from tumor. Paralysis of the face on one side and of the limbs on the other side (alternate paralysis) is more likely to occur from tumor than from hemorrhage or softening.

With respect to the character of the tumor in individual cases, carcinoma

is probable if the patient be of middle or advanced age, if cancer be hereditary, and if it exist elsewhere. The evidence afforded by the symptoms of a rapid growth of the tumor is in favor of the conclusion that it is carcinomatous. The tuberculous character of the tumor is to be inferred from the existence of tuberculous disease in the lungs and other organs, and from the youth of the patient. Tumors of this kind rarely occur after puberty or at less than three years of age. The syphilitic character of the tumor is rendered probable by the fact that the patient has had syphilis and by the absence of evidence of carcinoma and tubercle. Aneurismal tumors rarely occur except in persons between fifty and sixty years of age. Where no data exist as to the variety of tumor, glioma is to be inferred, as being the most common form of cerebral tumor not referable to syphilis or to tuberculosis. Cerebral tumors are more common in males than in females.

As regards digestion, nutrition, and the functions of the body in general, cases differ. Patients may retain their weight and an aspect of health for a considerable period after the occurrence of paralysis and other symptoms referable to the brain. In other cases debility and emaciation occur early. The general condition will be likely to deteriorate speedily in the cases in which the tumor is either carcinomatous or tuberculous, parts other than the brain being the seat of the disease. It is to be added that the tumors within the skull may remain latent, as regards both local and general symptoms, until they have attained a considerable size. The slowness of their growth favors their latency. On the other hand, local morbid conditions incident to the growth of the tumors—namely, inflammation and softening of the surrounding brain-substance, congestions, circumscribed meningitis, and extravasation of blood—give rise not only to paralysis affecting different parts in succession and progressively increasing in degree, but to exacerbations of pain and other cerebral symptoms varying much in frequency and intensity in different cases—to somnolency or coma in some cases, either of transient duration or lasting for several days, and occasionally to active delirium.

The termination in most cases of tumor within the skull is, sooner or later, fatal, the duration of life varying much in different cases according to the nature of the tumor, the rapidity of its growth, and the incidental local morbid conditions. In some cases death takes place after a few months, and in other cases not until after many years. An exception to this statement is to be made in behalf of syphilitic tumors. These are amenable to curative treatment if they have not attained to much size and have not led to damage of the cerebral substance in proximity to them. Death may take place after gradual exhaustion; it may occur suddenly from cerebral hemorrhage; epileptiform convulsions sometimes determine the fatal termination; and patients sometimes die from secondary meningitis.

Syphilitic tumors offer much encouragement in the way of successful medicinal treatment. Cases in which are presented hemiplegia, paralysis of cranial nerves, aphasia, epileptiform convulsions, and delirium are by no means hopeless if the affection be traced to syphilis. I have met with instances successfully treated in which these symptoms were present. It is very important to resort to antisymphilitic treatment in all cases in which there is any ground for suspecting the previous existence of syphilitic disease.

The indications for the treatment of non-syphilitic tumors relate to the palliation of symptoms and the prolongation of life by analeptic and supporting measures. It is not certain that any known remedies have a beneficial influence upon the tumors themselves or the brain lesions which they produce. It is, however, claimed that certain remedies—namely, the iodide of potassium, the bichloride of mercury, and arsenic—do have such an influence.

some cases. Trial may be made of these remedies, taking proper precautions as regards a deleterious effect upon the general condition of the patient.

Cerebral Syphilis.

Although in previous articles mention has been made of various syphilitic affections of the brain, nevertheless, for the sake of clearness and in view of the frequency and importance of these affections, it is thought best to bring them together in a separate article.

Cerebral syphilis may be a manifestation of congenital or of acquired syphilis. In the majority of cases it is one of the late, tertiary lesions, occurring sometimes ten to twenty years after the primary infection. Cerebral syphilis in the secondary stage of syphilis is rare.

The two leading syphilitic lesions of the brain are gummata and obliterating endarteritis.

Intracranial gummata originate usually either in the dura mater or in the pia mater. They may develop in the cranial bones. Gummata originating in the substance of the brain are very rare. They then develop primarily in the walls of the blood-vessels. At first a gumma is composed simply of soft, grayish granulation-tissue, but in a short time central caseation and fibroid metamorphosis occur, producing a mass of firm consistence and opaque yellowish color. The gumma may develop as a circumscribed nodular tumor or as a diffuse growth. In either case there is usually more or less diffuse inflammatory thickening of the adjacent membranes, so that the term syphilitic or gummatous meningitis appropriately describes the lesion. There may be a single gumma or many gummata in the membranes. It is important to note that gummata, although almost invariably starting in the cerebral membranes, frequently grow into the substance of the brain, which they compress and destroy.

Obliterating endarteritis of the cerebral arteries is a common syphilitic lesion, but it is not peculiar to syphilis. The arteries at the base of the brain are the ones oftenest affected. The affected arteries are hard, of an opaque whitish color, and thickened. The change consists in a thickening of the intima due to a new growth of connective tissue. The thickening may affect the circumference of the artery symmetrically or be most marked at one point in the circumference. The artery may become entirely obliterated, either by the continued growth of the new connective tissue or by thrombosis. Small gummata are frequently found in the media and the adventitia of arteries which are the seat of syphilitic endarteritis. Small aneurisms may form as the result of the arterial disease. The occlusion of the arteries, especially of those of the base which belong to the terminal arterial system, leads to softening of the region of the brain supplied by the obstructed vessel.

Finally, it may be mentioned that syphilitic disease of the arch of the aorta, or syphilitic endocarditis or myocarditis attended by the formation of thrombi, may give rise to embolic cerebral softening. Cases of cerebral syphilis without any coarse lesions in the brain have been described, but here it is probable that the small arteries are diseased.

From this description of the syphilitic lesions of the brain it is evident that the symptoms are manifold and variable in individual cases, so that it is possible to give a clinical description applicable to all cases. The following may be mentioned as some of the common types.

The grouping of symptoms in cases of gumma may be that of other forms of cerebral tumor. When the gumma is seated at the base of the brain, there

are affections of various cranial nerves, such as facial paralysis, neuralgia and paralysis of the trigeminus, paralysis and twitching of the eye-muscles; disorders of vision, such as diplopia, hemianopsia, amaurosis, irregularity of the pupils; sometimes impairment of hearing, of smell, or of taste; and rarely paralysis of the hypoglossal nerve. Involvement of the crus cerebri causes hemiplegia. Choked disc is the rule. A gumma involving the motor cortical zone causes monoplegia or hemiplegia, usually accompanied with motor spasms and frequently with epileptic convulsions. When the centres for speech are affected there is aphasia. (The previous article may be consulted for other symptoms of syphilitic cerebral tumor.)

In a second group of cases the symptoms are referable to softening of the brain caused by occlusion of one of the cerebral arteries. These symptoms do not differ from those of ordinary thrombic softening.

In a large group of cases the symptoms are not those of a focal disease, as in cases of tumor and of softening, but belong to some chronic diffuse disorder of the brain. Here the clinical history may resemble that of chronic cerebral meningitis, of multiple cerebral sclerosis, of chronic insanity, or, in women, of hysteria.

The DIAGNOSIS cannot be made from the cerebral symptoms alone, although the transitory nature of many of the symptoms, their rapid development, and amelioration are in a certain degree characteristic. The diagnosis must be based upon a syphilitic history and the recognition of manifestations of syphilis in other parts of the body. The ophthalmoscopic examination may aid in the diagnosis, as, in addition to choked disc, a syphilitic choroiditis has been observed in some cases of cerebral syphilis.

Cerebral syphilis is often markedly amenable to TREATMENT. If, however, parts of the brain have been seriously impaired in their structure by syphilitic lesions, it cannot be expected that these parts will be restored, so that in a considerable number of cases the termination is unfavorable.

The treatment consists in the use of mercury and of iodide of potassium, according to the recognized principles of antisymphilitic therapeutics.

CHAPTER IV.

INFLAMMATORY AND STRUCTURAL DISEASES OF THE SPINAL CORD.

General Considerations relating to Inflammatory and Structural Diseases of the Spinal Cord.—Myelitis, Acute and Chronic.—Cerebro-spinal Sclerosis.—Locomotor Ataxia, or Posterior Spinal Sclerosis.—Hereditary Ataxia.—Acute Anterior Poliomyelitis.—Acute Anterior Poliomyelitis in the Adult.—Subacute and Chronic Anterior Poliomyelitis.—Progressive Muscular Atrophy.—Spastic Spinal Paralysis.—Amyotrophic Lateral Sclerosis.—Compression of the Spinal Cord.—Intraspinal Tumors.—Pseudo-hypertrophic (or Myosclerotic) Paralysis.

General Considerations Relating to Inflammatory and Structural Diseases of the Spinal Cord.

IN order to understand the localization of certain of the diseases of the spinal cord which are to be described in this chapter, it is necessary to

know the situation of certain bundles of nerve-fibres entering into the composition of the white columns of the cord. The accompanying diagram (Fig. 5) represents these bundles upon a transverse section of the cord at the level of the sixth cervical nerve.

In the anterior column of each half of the spinal cord adjacent to the anterior median fissure is a narrow tract of nerve-fibres, marked *p. a.* in the diagram, called the pyramidal fasciculi or pyramidal tracts of the anterior column. These bundles are called also the uncrossed or direct pyramidal tracts and the columns of Türek. They may be absent in normal cords. In the posterior part of the lateral column are situated the pyramidal fasciculi of the lateral columns or the crossed pyramidal tracts, marked *p. l.* in the diagram. The pyramidal tracts are composed of motor-fibres which originate in the central convolutions of the brain, descend through the centrum ovale (see p. 617), pass thence through the pes pedunculi, the pons, and the anterior pyramids of the medulla oblongata to the crossing of the pyramids, where the majority of the motor-fibres cross over and descend in the pyramidal tracts of the lateral columns of the cord, while a smaller but variable portion remains uncrossed and descends in the pyramidal tracts of the anterior columns of the spinal cord. The latter pyramidal tracts cross in their course through the spinal cord, so that eventually all of the motor-fibres of the pyramidal tracts which originate in one cerebral hemisphere cross to the opposite half of the spinal cord. The fibres of the pyramidal tracts are connected with the ganglion-cells of the anterior horns of the spinal cord. From these ganglion-cells originate the anterior nerve-roots. When the pyramidal tracts are destroyed in any part of their course, as by a hemorrhage in the posterior division of the internal capsule, they become the seat of a descending degeneration which can be traced from the seat of the lesion downward to the termination of the tracts.

Between the pyramidal tracts of the lateral columns and the periphery of the cord are seated the direct cerebellar fasciculi, marked *d. c.* The remaining parts of the anterior and of the lateral columns are called the fundamental fasciculi of the antero-lateral column or the anterior root-zone (*f.* in the diagram).

Two divisions are recognized in the posterior columns—namely, the triangular columns on each side of the posterior median fissure, called the funiculi graciles, or columns of Goll (*G.* in the diagram), and the wedge-shaped columns between these and the posterior horns, called the funiculi cuneati, or columns of Burdach (*B.* in the diagram).

The columns of Goll and the direct cerebellar fasciculi contain centripetal nerve-fibres, and are the seat of an ascending degeneration above any lesion which destroys their continuity.

The pyramidal tracts diminish in size from above downward, and in the lower dorsal region the uncrossed pyramidal tracts disappear. In the lumbar and the lower dorsal regions the division of the posterior columns into the columns of Goll and the columns of Burdach cannot be made out. The direct cerebellar fibres make their first appearance in the lumbar enlargement, and increase in size from below upward.

The divisions of the white columns of the cord which have been described are based chiefly upon the study of embryonic cords and of the secondary degenerations of the cord. These divisions are of importance, because each

Fig. 5.

After Eichhorst.

one represents a group of functionally distinct nerve-fibres, which may be the seat of some special disease.

Two great classes of diseases of the spinal cord are recognized—namely, the *systemic diseases* or *system-diseases*, and the *unsystemic, mixed, or diffuse diseases*.

The *system-diseases* of the spinal cord are characterized by the fact that the pathological lesions are confined to certain definite tracts or parts of the cord which represent distinct physiological systems or groups of nerve-fibres or of ganglion-cells. To the category of *system-diseases* belong the affection of ganglion-cells in the anterior horns, called *poliomyelitis anterior*; the sclerosis of the posterior columns constituting the essential lesion of *locomotor ataxia*; the degeneration of the pyramidal tracts, either alone as in *secondary descending degenerations*, or in combination with anterior poliomyelitis in *amyotrophic lateral sclerosis*; and the secondary ascending degenerations of the columns of Goll and of the direct cerebellar fibres. We must assume that in the *system-diseases* the special cause of the disease acts primarily upon the nerve-elements, and that the interstitial tissue is secondarily involved.

In contrast with the *system-diseases*, the lesions in the *unsystemic or diffuse diseases* are not confined to any definite group of nerve-elements, but affect irregularly either a large or a small part of the spinal cord. To this second class of diseases belong hemorrhages, tumors, the transverse, the diffuse, and the disseminated forms of myelitis, embolic or thrombic softening, and other affections.

Before considering the individual diseases of the spinal cord it will save repetition and assist in a clearer understanding of these diseases if the important symptoms of various affections of the cord be first considered with reference to certain peculiarities, and especially to their topical diagnosis.

An important distinction is made between two kinds of paralysis. In one variety of paralysis the paralyzed muscles rapidly undergo atrophy and assume the so-called reaction of degeneration. This variety may be called *atrophic paralysis*. In the second kind of paralysis the paralyzed muscles waste only after a long period from disuse, and they retain their electrical excitability as long as muscular substance is preserved.

The *atrophic form of paralysis*, attended with the reaction of degeneration, is always due either to disease of the ganglion-cells in the anterior horns of the spinal cord or to an interruption of the connection between these ganglion-cells and the muscles; that is, to diseases of the peripheral nerves. If the paralysis be due to any lesion of the motor tracts from their origin in the cerebral cortex to their termination in the ganglion-cells of the anterior horns of the spinal cord, there will be no rapid atrophy of the paralyzed muscles and no reaction of degeneration. The explanation of this difference is found in the fact that the ganglion-cells of the anterior horns exert some unexplained trophic influence upon the muscles with which they are in connection. A peculiarity in cases of paralysis due to disease of these ganglion-cells or to disease of the peripheral nerves is that the affected nerves from the seat of lesion and the paralyzed muscles undergo rapid degeneration; a degeneration, however, which may be recovered from if the primary lesion be repaired before the degeneration has advanced too far.

Another important difference is, whether the paralyzed muscles be relaxed and flabby or in a rigid, spastic condition. *Spastic paralysis* is generally associated with increased reflex action, and it occurs when certain inhibitory fibres which come from the brain and run in the lateral columns are interrupted by some lesion in their continuity. It is assumed by many that these

hibitory fibres are identical with those in the pyramidal tracts of the cord; it this view is not proven. For the production of spastic paralysis it is necessary also that the nerve-fibres and ganglion-cells which conduct and originate impulses for reflex action of the paralyzed muscles should not be destroyed. The conditions for spastic paralysis are present in many cases of cerebral paralysis, in most cases of transverse myelitis or compression myelitis the upper dorsal and the cervical regions, and in sclerosis of the lateral columns of the cord. Spastic paralysis does not occur when the centripetal flex fibres in the posterior nerve-roots, posterior columns, and gray matter, the ganglion-cells of the anterior horns which transmit reflex impulses, and the centrifugal reflex fibres of the anterior nerve-roots are diseased so as to rest their functions.¹

Loss of sensation is a symptom of spinal disease when the function of the sensory fibres in the cord is destroyed or impaired. The sensory fibres enter the cord by the posterior nerve-roots, from which a part enter directly into the posterior horns and a part pass into the posterior columns. The sensory fibres of the posterior columns probably also enter the posterior horns at some point distant from the entrance of the corresponding nerve-roots. Unlike the majority of the motor fibres, the sensory fibres decussate in the spinal cord. Loss of sensation dependent upon spinal affections, therefore, results to some disease of the posterior columns or of the posterior horns of gray matter, more particularly to disease of the latter. It is an interesting fact that tactile sensation may be lost while the sense of pain is preserved, and, *vice versa*, tactile sensation may be preserved while the sense of pain is lost (see article on Syringomyelia).—H.] The loss of sensation to pain is called analgesia. If a lesion destroy only one-half of the spinal cord—which is a very rare occurrence—the paralysis of motion will be on the side of the lesion, and the paralysis of sensation (tactile and for pain) will be on the opposite side.

Conditions affecting *reflex action* have already been mentioned in connection with spastic paralysis. Reflex action is increased if the connection between the reflex centres and the brain be interrupted. The reflex centres are situated in the gray matter of the cord. Destruction of the gray matter, therefore, abolishes the reflex action of those muscles which are in nervous connection with the diseased part of the gray matter. A similar effect is produced by disease of centripetal nerve-fibres which carry impressions from the periphery to these centres, as in the case of disease of the posterior columns and posterior horns of gray matter in locomotor ataxia. The two most important forms of reflexes for diagnostic consideration are cutaneous reflexes and tendon reflexes. *Cutaneous reflex* is generally studied by noting the contraction of the muscles of one of the lower extremities upon tickling the sole of the foot. Other cutaneous reflexes which may be examined are the contraction of abdominal muscles upon passing the finger along the skin of the abdomen or the contraction of the cremaster muscle upon passing the finger along the upper part of the inside of the thigh.

Tendon reflexes are examined at the knee and at the ankle. In most healthy individuals a vigorous contraction of the quadriceps extensor mus-

¹ It is the rule, therefore, that disease of the posterior columns and of the gray matter extending over a considerable longitudinal extent of the spinal cord prevents the occurrence of spastic paralysis. An apparent exception is amyotrophic lateral sclerosis; but it must be assumed that at the time of spastic paralysis the ganglion-cells of the anterior horns are not diseased sufficiently to prevent the transmission of reflex impulses. In the explanation of spastic paralysis some writers lay more stress upon irritation of certain nerve-fibres and ganglion-cells than upon the abolition of inhibitory impulses. It is probable that both irritative lesions and the withdrawal of inhibitory influence of the brain may cause spastic paralysis with increased reflexes.

cle is produced by striking quickly with the ulnar side of the hand or with a percussion hammer the ligamentum patellæ when the leg is flexed and the muscles are relaxed. This contraction, called the *knee-jerk* or *patellar reflex*,¹ may be increased or may be diminished or abolished in certain diseases of the spinal cord. The patellar reflex may be impaired even when cutaneous reflexes are intact. The centre for the patellar reflex is in the gray matter of the lumbar portion of the spinal cord. Diseases of the gray matter in this situation, and also disease of the centripetal nerve-fibres in the posterior columns of the lumbar enlargement cause the patellar reflex to disappear. In the various conditions causing spastic paralysis the patellar reflex is increased.

The so-called *foot-clonus*, *ankle-clonus*, or foot-phenomenon is produced by making passively a vigorous dorsal flexion of the foot, when, if the clonus be marked, the foot, upon relaxation of the flexion, will assume a position of extension in consequence of contraction of the gastrocnemius muscle. There may follow repeated movements of flexion and of extension, so that there is a continuous rapid vibration of the foot from one position to the other. This reflex, produced by irritation of the tendo Achillis, is more frequently absent in health than the knee-jerk, but in spastic paralysis it is often a marked phenomenon.

The use of *electricity* has become not only a valuable therapeutical agent, but also a most important aid in the diagnosis and the prognosis of various forms of paralysis. For diagnostic purposes it is necessary to make use of both the induced (or faradic) current and the constant (or galvanic) current. The polar method of application of the electric current is the most exact. In this, one electrode is placed over the nerve or the muscle to be irritated, and the other electrode at some distant part of the body, as the sternum or the nape of the neck. The galvanic battery should be supplied with a commutator, so that either electrode can be made positive or negative at will.

In order to understand the electrical reactions in disease it is necessary to be familiar with the so-called *law of contraction* for motor nerves and muscles in health. This law relates to the responses to the constant current applied by the polar method. This current produces muscular contractions only when the circuit is opened or is closed. The occurrence and the strength of these contractions depend upon the direction and the strength of the electrical current. If the constant current be very weak, no contraction is produced. If the strength of the current be gradually increased, the first contraction appears upon closing the descending current; and this is called the cathodal closure-contraction (C. C. C.), the cathode or negative pole being applied to the nerve or muscle when the circuit is closed. If the strength of the current be still further increased, the next contractions appear upon closing and upon opening the ascending current, sometimes one and sometimes the other causing the first response. These contractions are the anodal closure-contraction (A. C. C.) and the anodal opening contraction (A. O. C.), the anode or positive pole being applied to the nerve or muscle. Contraction upon opening the descending current or cathodal opening contraction (C. O. C.) appears last, and not until the current is so strong as to cause tetanic cathodal closure-contractions. The galvanic current therefore causes contractions in the following order: 1, C. C. C.; 2 and 3, A. C. C. and A. O. C., sometimes one coming first, and sometimes the other; 4, C. O. C. The main points to remember are that in health the C. C. C. exceeds the A. C. C., and the A. O. C. exceeds the C. O. C. The contractions occur in the same order whether the electrode be applied to the nerve or to the muscle.

The faradic current applied to nerve or to muscle in health causes tetani

¹ It is assumed that the knee-jerk is a reflex phenomenon, although this view is not proven.

spasm of the muscle, the intensity of the spasm being in proportion to the rapidity of the interruptions and the strength of the current.

The changes in electrical reactions in disease may be quantitative or qualitative. The *quantitative changes* consist in simple increase or simple diminution of electrical response. Simple increased electrical excitability is common in the early stages of various forms of paralysis; but when unaccompanied with qualitative changes in electrical reaction it is not of much diagnostic importance. So, too, diminished electrical response, when of diagnostic import, is generally, although not necessarily, accompanied with qualitative changes in muscular excitability.

Far more important than the simple quantitative changes are the combined quantitative and qualitative changes in the electrical excitability of nerve and of muscle which constitute the *reaction of degeneration*. This reaction is so called because it occurs only when the nerve or the muscle (or usually both) has undergone degeneration. The degeneration of the nerve is indicated by a diminution, and finally a disappearance, of its excitability both to the faradic and the galvanic currents. In cases of peripheral paralysis the electrical excitability of the nerve may be completely lost in from one to two weeks, so that it is impossible by electrical excitation of the nerve to produce any muscular contraction. During this time the reaction of the muscle to the direct application of the faradic current also diminishes, and finally disappears. This is due to degeneration of the intramuscular nerve-fibres. The reaction of the muscle to the direct polar application of the galvanic current undergoes important alterations, which indicate degeneration of the muscle, going on at the same time as nerve-degeneration. At an early stage of the degeneration there may be slight diminution in the galvanic excitability of the muscle, but this soon gives place to a decided and characteristic increase in the response to the galvanic current when directly applied to the muscle. This increased response is attended by certain noteworthy peculiarities. The first peculiarity is, that the anodal closure-contraction (A. C. C.) increases, so that after a while it equals, or even exceeds, the cathodal closure-contraction (C. C. C.), thus reversing the conditions in health. The cathodal opening contraction is also often increased, so that it may equal or exceed the anodal opening contraction. A second peculiarity is, that the muscular contractions, instead of being immediate in their appearance and short, are sluggish and prolonged, sometimes continuing during the entire duration of the current, instead of only at the opening or the closing of the circuit.

If the degeneration go on to complete destruction of the muscular structure, the increased galvanic excitability of the muscle gives place to diminution and final disappearance of all electrical excitability, the last to disappear being the anodal closure-contraction.

If repair of the degenerated muscular and nervous tissue occur, the exaggerated and altered galvanic muscular reaction gives place to the normal reaction, faradic excitability of the muscle returns, as well as the galvanic and the faradic reaction of the nerve. The nerve becomes capable of transmitting the impulses of the will, causing volitional contractions, before the normal faradic and galvanic excitability is restored.

Usually, both the nerve and the muscle simultaneously undergo degeneration. If the nerve be alone degenerated, there will be simple diminution or loss of its faradic and galvanic excitability and diminution or loss of the faradic muscular excitability, without qualitative change in the galvanic muscular excitability. If the muscle be alone degenerated, the faradic and the galvanic excitability of the nerve and the faradic excitability of the muscle will be preserved, while the above-described characteristic changes following

direct galvanic excitation of the muscle are present. The latter reaction is sometimes called partial reaction of degeneration.

The reaction of degeneration is present only in paralysis due to disease of the peripheral nerves and in that due to disease of the ganglion-cells in the anterior horns of the spinal cord. It is absent in all forms of cerebral paralysis, in all spinal paralyzes due to disease of the white matter of the cord, and in functional paralyzes. If paralysis be due to disease involving a segment of the gray matter of the spinal cord, as in transverse myelitis, the reaction of degeneration is present only in the nerves and muscles which are connected with that segment, while it is absent in the paralyzed muscles whose nerves originate below the diseased segment. It is thus apparent that the study of the electrical phenomena of nerve and of muscle in cases of paralysis affords most important information as to the seat of disease. The reactions to electricity also indicate the pathological condition of a nerve or of a muscle; and this may prove of great assistance in forming a judgment as to the possibility of recovery.¹

Myelitis.

Inflammation of the substance of the cord is called *myelitis*. Myelitis appears as an *acute* and as a *chronic* affection. These two forms, however, cannot be sharply discriminated in all cases, since acute myelitis often passes into the chronic form. Other divisions are based upon the extent of the inflammation and the part of the cord involved. Thus the inflammatory changes may be either circumscribed, diffuse, or disseminated; the white matter, the gray matter, or both, may be affected; or the disease may tend to extend transversely or in a longitudinal direction. When both white and gray matter of the greater portion of the cord are inflamed, the process is called *diffuse myelitis*; when the inflammation affects only or chiefly the gray matter, the disease is *central myelitis*; and when confined to the anterior horns of gray matter, it is *anterior poliomyelitis* or *anterior cornual myelitis*. In *transverse myelitis* the whole thickness of the cord over a circumscribed space is involved. *Cortical myelitis* or *meningo-myelitis* is the name given to inflammation of the peripheral portion of the cord, the inflammation being consecutive to spinal meningitis. When a number of separate foci of inflammation exist in the cord the change is designated as *disseminated myelitis*. Myelitis extending from below upward is called *ascending*, and extending from above downward it is called *descending*.

As regards the tissue primarily affected, Charcot, following Virchow's classification, distinguishes two varieties of myelitis—namely, *interstitial* and *parenchymatous myelitis*. In interstitial myelitis the connective tissue or neuroglia is first inflamed, and the nerve-elements suffer secondarily; and in the parenchymatous form the ganglion-cells and nerve-fibres are primarily involved, and the interstitial changes are secondary. The final result in both cases is the same.

The gray substance of the cord, on account of its greater vascularity and functional importance, is more frequently the seat of primary myelitis than is the white matter. Inflammation of the gray matter is particularly prone to extend in the vertical direction (central myelitis).

Acute myelitis, in the majority of cases, appears under the form of softening of the cord. Chronic myelitis, on the other hand, appears as induration or sclerosis. The changes which characterize acute myelitis will be described first, and

¹ For further information on this subject consult the excellent work of A. Hughes Bennett, *A Practical Treatise on Electro-diagnosis in Diseases of the Nervous System*, London, 1882.

therefore, which distinguish myelitis from spinal meningitis especially claim attention.

Disorders of sensation are often the first local symptoms. These are pain in the back, the sensation of a girdle around the trunk, and tenderness over certain of the vertebræ. Preceding paralysis the muscles which are to be paralyzed are sometimes affected with tremor or spasms.

The early occurrence of paralysis is a distinguishing feature. It occurs within a day or two, and sometimes within a few hours, after the symptoms have pointed to a spinal affection. In most instances the form of the paralysis is paraplegic, showing the seat of the affection to be in the dorsal or in the lumbar portion of the cord. According to the seat at the outset or the subsequent extension of the inflammation upward (ascending myelitis), the muscles of respiration and of the upper extremities may be affected. The speedy occurrence of paralysis is evidence that the cord has been primarily affected. Sudden and complete paralysis denotes that the myelitis is central and accompanied by hemorrhage (hæmato-myelitis).

Paralysis affecting the bladder and rectum is more constant and occurs earlier in myelitis than in spinal meningitis. Loss of cutaneous sensibility is more frequent in the former than in the latter. It is rare for sensory paralysis to be wanting. Its absence shows that the myelitis does not involve the posterior columns or the posterior cornua of the cord. Sensation may not be lost, but is more or less diminished, and it may be characterized by retarded transmission of sensory impressions. Exceptionally, there is cutaneous hyperæsthesia, this being attributable to complicating meningitis. Priapism is a symptom of not infrequent occurrence. Symptoms relating to reflex movements are of significance as regards the localization and the extent of the lesions. The continuance or increase of the reflex movements shows either that disorganizing changes have not taken place, or that the disorganization has not extended to the lower end of the spinal cord. On the other hand, loss of reflex excitability is an effect of destruction of the gray matter in the lower part of the cord. This extension is shown by the loss of reflex excitability after the occurrence of the motor paralysis.

Spasm of the muscles of the lower extremities, constituting the so-called spinal epilepsy of Brown-Séquard, is a prominent symptom in some cases of transverse myelitis not involving the lower lumbar region.

Notable wasting of the paralyzed muscles is indicative of destruction of the gray matter; and in this case the reaction of degeneration appears in the muscles the nerves of which originate in the diseased gray matter. Hence this reaction is absent in the muscles of the lower extremities in dorsal and cervical myelitis, and is present in lumbar myelitis involving the anterior horns.

In myelitis, earlier and in a greater degree than in spinal meningitis, the parts exposed to pressure—sacrum and trochanter—take on gangrenous inflammation. Not infrequently this occurs within a few days after the attack. The urine is retained and within a short period it becomes alkaline. The presence of muco-pus shows the existence of cystitis.

Fever in cases of acute myelitis is rarely high, and is generally of a low grade. The propriety of the term acute in this connection has reference to the rapid development of grave symptoms, rather than to the elevation of temperature and other evidence of constitutional disturbance. Fever symptomatic of gangrenous inflammation (septic fever) and of cystitis occurs in the progress of the disease.

Acute myelitis may run a rapid course, destroying life in a few days, or death may take place as a result of gangrenous inflammation or of cystitis after the lapse of several weeks. Complete recovery is rare. In a certain

and when the myelitic focus does not reach the lower extremity of the cord descending. The ascending degeneration occupies the columns of Goll and the direct cerebellar fasciculi; and the descending degeneration follows the course of the pyramidal fasciculi of the anterior and of the lateral columns. These tracts, when degenerated, appear gray and are finally atrophied, the process consisting in a gradual atrophy of the nerve-fibres combined with increase of the neuroglia and the appearance of granular corpuscles. When the myelitis occupies the whole thickness of the cord the degenerations are bilateral. Myelitis confined to one-half of the cord is very rare.

Chronic myelitis includes, according to common usage, the processes also called sclerosis and gray degeneration. It is characterized by proliferation of the neuroglia-elements, resulting in the production of fibrillated connective tissue and the atrophy of nerve-elements. Granular corpuscles and corpora amylacea may also be present. The consistence of the affected part is usually firm, its size is diminished rather than increased, and its color is gray. Sometimes there are no morbid changes visible to the naked eye. As regards their clinical history, certain cases of slowly-developing softening of the cord are to be referred to chronic myelitis, although Leyden considers all instances of inflammatory softening of the cord as acute in their origin.

Chronic myelitis embraces affections of the cord which vary greatly as to the situation, extent, and nature of the pathological process. Certain forms have an exact localization, and follow the course of certain definite groups of nerve-fibres and of nerve-cells. Others are characterized by irregularity in distribution and extent. Of the forms which have more or less of an exact localization may be mentioned posterior spinal sclerosis or locomotor ataxia, amyotrophic lateral sclerosis, and anterior poliomyelitis. These will each receive separate consideration. The secondary degenerations of Türk, although regarded by many writers as the result of chronic myelitis, are primarily degenerative. The name *funicular sclerosis* is given to sclerosis following certain definite columns of the cord, such as lateral and posterior spinal sclerosis. It is probable that in these cases the primary change is in the nerve-fibres. Otherwise it would be difficult to understand why inflammation should be confined to the course of definite nerve-tracts. The most important examples of chronic myelitis with irregular distribution are—chronic transverse myelitis, circumscribed sclerosis, and disseminated or multiple sclerosis. Multiple sclerosis will be considered separately, as it has a well-defined clinical history. Myelitis resulting from slow compression (angular curvature resulting from Pott's disease, cancer of the vertebra, or intraspinal tumors) is usually of the ordinary transverse variety and accompanied by secondary degenerations.

The CLINICAL HISTORY of *acute myelitis* presents variations corresponding to those which belong to the anatomical characters of the disease. The latter furnish the interpretation of the former, and from the symptoms the seat of the inflammation, its extent, and the particular parts of the cord which are involved may be inferred with considerable accuracy. Certain symptoms belong alike to acute spinal meningitis and to acute myelitis. In many if not in most cases these two affections are associated. In meningitis the inflammation extends from the membranes to the cord, and in myelitis the membranes are likely to be secondarily involved. Practically, at the bedside, having diagnosticated an acute intraspinal inflammation exclusive of intracranial inflammatory diseases, the diagnostic problem which remains is to differentiate myelitis from meningitis; that is, to decide that the inflammation has its origin in and is predominant in the cord. The symptoms,

of the cord, multiple cerebro-spinal sclerosis, sclerosis of the lateral columns, anterior poliomyelitis, and progressive muscular atrophy. These will be considered in this chapter under separate headings. Exclusive of these affections, the term chronic myelitis denotes an inflammatory affection localized in a segment, or sometimes in more than one segment, and extending transversely more or less throughout the cord (transverse myelitis). The form of paralysis resulting therefrom is generally paraplegia; but if the cervical portion of the cord be the seat of the affection, general spinal paralysis is the result. In cases of the disease as thus restricted the clinical problem is similar to that in cases of the acute form—namely, to differentiate chronic myelitis from chronic spinal meningitis. Here, too, it is to be considered that in the latter affection the inflammation extends more or less from the meninges to the cord, and that in the former affection inflammation of the cord generally involves the meninges. The antecedent history is to be taken into account. Both chronic myelitis and chronic spinal meningitis may have been preceded by an acute form of disease, and of course the chronic has the same primary seat as the acute. If, therefore, the previous history show the acute disease to have been acute myelitis, the existing affection is chronic myelitis.

As regards the symptoms, they point to myelitis, instead of meningitis, in proportion as they represent more or less disorganization of the cord. Hence, completeness of the paralysis, sensory as well as motor paralysis, paralysis of the bladder and rectum, cystitis, wasting of the paralyzed muscles, and a tendency to gangrenous ulceration are diagnostic of myelitis rather than of spinal meningitis.

The practical importance of making this discrimination relates chiefly to the prognosis. The prospect of improvement and recovery is far better in cases of spinal meningitis than in cases of myelitis. In proportion as the symptoms denote disorganization of the cord (softening and secondary atrophy) the prognosis is unfavorable. As already stated, however, destruction of the cord, causing complete motor and sensory paralysis of the lower limbs, is not incompatible with long life and good general health. In the preceding editions of this work a case is cited in which complete paraplegia followed a fall of forty feet, and after death there was found atrophy of the cord below the twelfth dorsal vertebra. This patient lived more than fifty years after the accident, married, and had six children, amassed a little fortune by his industry, and finally died with double pneumonia. In another case, reported by Dr. Purple,¹ there was complete loss of motion and sensation below the fifth dorsal vertebra following an injury. In this case the patient, finding his lower limbs burthensome, persuaded a surgeon to amputate them near the hip-joint. The operation was wholly without pain and the stumps healed readily.

The measures of TREATMENT indicated in cases of chronic myelitis are rest as long as the symptoms denote an inflammatory condition, and moderate counter-irritation over the spine. Remedies given with a view to promote the absorption of morbid products—namely, the iodide of potassium and mercury—are not indicated; and severe counter-irritation—by the moxa, issues, setons, etc.—is of no use. Electricity may be useful in retarding atrophy of the paralyzed muscles. The application of water to the spine by sponging and compresses is to be recommended, but cold affusions and hydropathic packing are hurtful. Experience has shown the hurtfulness of thermal baths. Attention to the bladder is important. Indications pertaining to the general condition of the patient are to be met. If the patient be confined to the bed, precautions are to be taken against the effects of pressure.

¹ *New York Medical Journal*, 1853.

proportion of cases the disease becomes chronic. It may end in more or less complete atrophy of the cord, and patients may live indefinitely with a permanent paraplegia, the general health being good.

In the foregoing account of the symptomatology of acute myelitis reference has been had especially to the points involved in the differentiation from acute spinal meningitis. These points have been already referred to in the account given of the latter disease. (Vide p. 643.) The affection to be noticed in connection with the functional affections of the spinal cord, called acute ascending paralysis (vide Chapter V.), closely resembles acute ascending myelitis; but in the latter affection disturbances of sensation and bladder and rectal symptoms are generally not marked. The symptoms which relate to reflex and electrical excitability, to the paralysis of the bladder and rectum, and to the occurrence of cystitis and of bed-sores at an early period, are sufficiently characteristic of acute myelitis as contrasted with so-called reflex and functional paralysis. Acute myelitis, the inflammation limited to the anterior horns of the gray matter of the cord (anterior poliomyelitis), constituting the affection known as infantile paralysis and an analogous affection in adults, will be considered separately in this chapter.

Acute myelitis is a rare disease, especially if cases of traumatic origin be excluded. Aside from injuries of the cord from fractures, contusions, penetrating wounds, etc., prolonged exposure to cold, as in sleeping upon damp ground, seems to be the only cause clearly apparent. The adequateness of other agencies supposed to be causative, such as muscular efforts, excessive venery, and exposure to a high temperature, is problematical. Acute myelitis is occasionally observed as a sequel of diphtheria and of other infectious diseases. The disease occurs when it cannot be traced to any causative agency.

The TREATMENT in the early stage of acute myelitis has for its objects diminution of the intensity of inflammation and the prevention of disorganization resulting therefrom. Dry cupping over the spine, and in full-blooded subjects the local abstraction of blood by cups or leeches, are indicated. The application of the ice-bag to the spine is recommended. Ergot and belladonna have been supposed to be useful by causing contraction of the arteries of the cord. Mercurialization, by giving calomel and also by inunction, is to be advocated in view of the danger and the frequently rapid progress of this disease, on the ground that the notions formerly held in regard to the anti-phlogistic effect of mercury are not without some foundation, and that the evils of the remedy are of little moment, provided it have a favorable influence upon the inflammatory process, however small this influence may be.

It will often happen that the acute stage is too brief to afford much time for treatment with reference to the objects just stated. This may be inferred when complete paralysis has taken place. Revulsive applications to the spine may be employed, but, considering the liability to gangrenous inflammation, they should not be made in situations exposed to pressure. To obviate the effects of pressure is an important part of the treatment. Relieving the bladder of an accumulation of urine is important, as well as proper attention to the early symptoms of cystitis.

Absolute rest is an important part of the treatment. Brown-Séquard advises recumbency on the abdomen, but the continuance of this decubitus is hardly practicable. There is no difference of opinion as to the impropriety of the employment of electricity in acute myelitis. Strychnia is contra-indicated.

Chronic myelitis, in the most comprehensive sense of the term, include several distinct affections, among which are sclerosis of the posterior column

of the cord, multiple cerebro-spinal sclerosis, sclerosis of the lateral columns, anterior poliomyelitis, and progressive muscular atrophy. These will be considered in this chapter under separate headings. Exclusive of these affections, the term chronic myelitis denotes an inflammatory affection localized in a segment, or sometimes in more than one segment, and extending transversely more or less throughout the cord (transverse myelitis). The form of paralysis resulting therefrom is generally paraplegia; but if the cervical portion of the cord be the seat of the affection, general spinal paralysis is the result. In cases of the disease as thus restricted the clinical problem is similar to that in cases of the acute form—namely, to differentiate chronic myelitis from chronic spinal meningitis. Here, too, it is to be considered that in the latter affection the inflammation extends more or less from the meninges to the cord, and that in the former affection inflammation of the cord generally involves the meninges. The antecedent history is to be taken into account. Both chronic myelitis and chronic spinal meningitis may have been preceded by an acute form of disease, and of course the chronic has the same primary seat as the acute. If, therefore, the previous history show the acute disease to have been acute myelitis, the existing affection is chronic myelitis.

As regards the symptoms, they point to myelitis, instead of meningitis, in proportion as they represent more or less disorganization of the cord. Hence, completeness of the paralysis, sensory as well as motor paralysis, paralysis of the bladder and rectum, cystitis, wasting of the paralyzed muscles, and tendency to gangrenous ulceration are diagnostic of myelitis rather than of spinal meningitis.

The practical importance of making this discrimination relates chiefly to the prognosis. The prospect of improvement and recovery is far better in cases of spinal meningitis than in cases of myelitis. In proportion as the symptoms denote disorganization of the cord (softening and secondary atrophy) the prognosis is unfavorable. As already stated, however, destruction of the cord, causing complete motor and sensory paralysis of the lower limbs, is not incompatible with long life and good general health. In the preceding editions of this work a case is cited in which complete paraplegia followed a fall of forty feet, and after death there was found atrophy of the cord below the twelfth dorsal vertebra. This patient lived more than fifty years after the accident, married, and had six children, amassed a little fortune by his industry, and finally died with double pneumonia. In another case, reported by Dr. Purple,¹ there was complete loss of motion and sensation below the fifth dorsal vertebra following an injury. In this case the patient, finding his lower limbs burthensome, persuaded a surgeon to amputate them near the hip-joint. The operation was wholly without pain and the stumps healed readily.

The measures of TREATMENT indicated in cases of chronic myelitis are rest as long as the symptoms denote an inflammatory condition, and moderate counter-irritation over the spine. Remedies given with a view to promote the absorption of morbid products—namely, the iodide of potassium and mercury—are not indicated; and severe counter-irritation—by the moxa, issues, setons, &c.—is of no use. Electricity may be useful in retarding atrophy of the paralyzed muscles. The application of water to the spine by sponging and compresses is to be recommended, but cold affusions and hydropathic packing are hurtful. Experience has shown the hurtfulness of thermal baths. Attention to the bladder is important. Indications pertaining to the general condition of the patient are to be met. If the patient be confined to the bed, precautions are to be taken against the effects of pressure.

¹ *New York Medical Journal*, 1853.

Cerebro-spinal Sclerosis—Multiple or Insular Sclerosis.

Among the names for this affection may be mentioned multiple sclerosis, disseminated sclerosis, insular sclerosis of the brain and spinal cord, *sclérose en plaques disséminées*, cerebro-spinal sclerosis, and disseminated chronic interstitial encephalo-myelitis. The disease was recognized pathologically by Cruveilhier (1835) and by Türk (1855). From a clinical point of view it has been studied most thoroughly by Charcot and his pupils.¹ It is characterized anatomically by the development of many or of few nodules of sclerotic tissue in the central nervous system. These nodules are the result of a disseminated chronic interstitial inflammation. Charcot distinguishes, according to the situation of the nodules, three types of the disease—namely, the cerebro-spinal, the cerebral, and the spinal. The cerebro-spinal form is the most common type, its clinical history is best understood, and it is the one most readily diagnosticated. The spinal form, with our present knowledge as regards its symptomatology, is not readily distinguished from the ordinary forms of chronic myelitis.

In the majority of cases the spots of sclerosis can be recognized by the naked eye. In exceptional cases they may be visible only microscopically. They are distributed irregularly throughout the spinal cord, medulla oblongata, pons varolii, cerebrum, and cerebellum. The sclerotic islands in the pons and medulla are rarely absent, and they give rise to characteristic symptoms. Their number in the cerebrum and cerebellum is greater in the white than in the cortical substance. In the cord they occupy, unsymmetrically, both white and gray matter, more frequently the former. They may be concealed in the interior, or, reaching the surface, they may be visible from the exterior. It is rare for the sclerosis to extend throughout the entire thickness of the cord. The nodules may be scattered at wide intervals or several may coalesce. The size of individual nodules may vary between microscopic dimensions and several inches in length. The color of the sclerotic spots is reddish-gray, the consistence, especially in the brain, firmer than normal, the cut surface smooth and somewhat translucent, and the borders irregular and in many cases well defined. The affected parts may be shrunken or of normal or even increased size. The membranes, especially the pia mater, may be thickened and opaque or they may be unchanged.

The microscopical examination of the gray sclerotic nodules reveals, as the essential change, increase of the interstitial tissue, together with atrophy of the nerve-fibres and nerve-cells. The interstitial tissue appears as a finely-fibrillated but dense connective tissue, mingled with finely granular material. Large stellate cells, called Deiter's cells or spider-cells, are often present. The walls of the blood-vessels are notably thickened, and are often infiltrated with fat-molecules and lymphoid cells. Granular corpuscles and corpora amylacea are usually present, but not in large number. In the sclerosed patches most of the nerve-fibres have disappeared,² those remaining being, for the most part, naked axis-cylinders, sometimes much hypertrophied. At the borders of the sclerotic nodules the neuroglia-reticula are swollen and the cells are apparently in proliferation. The ganglion-cells, when the gray substance is involved, become filled with yellow pigment, lose their processes, and finally disappear by atrophy. It has been pointed out by Frommann that sometimes a considerable quantity of fat in the form of free globules

¹ Charcot, *Gaz. des Hôpitaux*, 1868; Bourneville et Guérard, *De la Sclérose en Plaques disséminées*, Paris, 1869.

² Later observations (Erb, Frommann) do not confirm the opinion of Charcot that insular sclerosis, in distinction from other forms of chronic myelitis, is characterized by the preservation of many of the nerve-fibres in the sclerotic islands.

and in cells occupies the sclerotic islands. This he refers to a fatty degeneration of the elements of the neuroglia. Similar gray translucent spots of sclerosis have been observed also in the cerebral nerves and in the roots of the spinal nerves. Sclerotic nodules have been recognized with especial frequency in the optic nerves.

The individuality of this affection has been recognized only within a few years. Prior to a knowledge of its clinical characteristics, as pointed out by Charcot and others, it was confounded with locomotor ataxia, general paralysis of the insane, senile trembling, and especially paralysis agitans. Typical cases at the present time are readily discriminated. This statement will not apply to the rare instances in which the lesions are limited to either the brain or the spinal cord. I have met with an instance, the diagnostic features being extremely well marked, in which there were no symptoms, other than tremor, pointing to a cerebral affection, the duration of the disease extending over many years.

The development of the disease is usually very gradual, and for a considerable period its peculiar characters may not be declared. Various indefinite symptoms referable to the brain or spinal cord may have existed for months, and even years, before a positive diagnosis is practicable. Among these symptoms are—cephalgia, vertigo, mental disturbance, apoplectic attacks, abnormal sensations in the limbs, muscular feebleness (paresis), lack of co-ordinating power (ataxia), etc. It is easy to understand that different cases offer a great diversity, as regards not only the initial symptoms, but those associated with the diagnostic characters of the disease, when it is considered how great are the differences as regards the number, size, and situations of the sclerotic patches. The interpretation of the diverse symptomatic phenomena is to be sought after in the pathological relations of the different parts of the brain, medulla oblongata, and spinal cord in which the lesions are liable to be seated. Charcot calls the disease polymorphous, in view of the great variety of the forms of disorder observed in different cases. Notwithstanding these variations, the diagnostic features, when these are present, render the differentiation from the several diseases just named not difficult.

Following incomplete paralysis of one or both of the lower limbs, and perhaps also of the upper limbs, accompanied often by rigidity of the muscles (spastic paralysis) and increased tendon reflexes, tremor occurs, and the most diagnostic feature relates to this symptom. The tremor is excited by volition, and is wanting as long as there is no exercise of the will (volitional tremor). The muscles are quiet or nearly so if the patient be entirely at rest, but whenever any action is excited by the will they take on automatic spasmodic movements more or less violent, and the patient's will is powerless for their arrest. These movements may extend from the limbs over the whole body. A hospital patient for a long time under my observation while sitting quietly was free from tremor, but as soon as he made any voluntary effort the motions of his limbs and body were so violent and grotesque that it was difficult to regard the spectacle as otherwise than ludicrous. The tremor which is thus characteristic of this disease is analogous to that of chorea in so far as it is automatic, but excited by the will. In chorea, however, automatic movements take place without as well as with the exercise of the will. The tremor differs from the inco-ordinate movements of ataxia in that the latter are not automatic. The tremor in cases of senile trembling and paralysis agitans differs in being independent of volition, taking place when the patient is entirely at rest. Moreover, in both these affections the movements are less violent, have less range, and are more rhythmical in character. The term *shaking tremor* expresses more correctly the movements in multiple sclerosis

than the word tremor alone. This symptom is referable to lesions seated in the medulla oblongata.

A peculiar disturbance of speech is diagnostic of this disease. The patient speaks in a slow, monotonous manner, with intervals between syllables, as in scanning. The peculiarity is known as the "scanning speech." The voice is sometimes reduced to a whisper. Aphonia and the feeble, monotonous voice are referable to paresis of the vocal cords. In some cases the lips, tongue, and muscles of the palate become paralyzed, as in cases of bulbar paralysis.

Impaired vision (amblyopia) and double vision (diplopia) occur not infrequently, and oscillation of the eyeballs (nystagmus) is so frequent in this disease and so rare in other diseases that it has much diagnostic significance. These symptoms represent sclerotic patches affecting the optic tracts or nerves and nerves going to the muscles of the eyeballs. Inequality of the pupils is a not infrequent symptom.

Sensory paralysis is rarely marked, and is not infrequently wanting. If, however, the sclerotic patches involve the posterior columns of the cord, ataxia and more or less impairment of sensibility are associated. There may be little wasting of the muscles, but in some instances it is otherwise, the inference in these instances being that the anterior horns of the gray matter of the cord are involved. Cystitis and bed-sores do not usually occur until late in the disease, and they are often absent.

Disturbances referable to the brain are rarely, but sometimes, wanting. The mental faculties generally fail. Patients often alternately weep and laugh irrationally, and progressive deterioration of the mind ends at length in imbecility. Apoplectic attacks are liable to occur, accompanied by hemiplegia. With these attacks there may be considerable fever, showing an intercurrent acute inflammatory condition. Patients usually recover from these attacks, but they sometimes prove fatal.

The DIAGNOSIS is to be based chiefly on the tremor, together with the peculiar disorder of speech, taken in connection with the varied motor, sensory, and mental disturbances. The diagnostic criteria probably proceed from sclerosis of the medulla oblongata and pons varolii. If these parts escape, which probably is rare, the clinical characteristics of the disease may be wanting. An important point in the diagnosis is the age of the patient. In the great majority of cases the beginning of the disease dates from a period between twenty and forty years of life.

Aside from the influence of age, nothing has as yet been definitely ascertained respecting the etiology.

The disease is usually progressive, but with a slow march, the duration sometimes extending over a period of from ten to twenty years. Long periods in which the disease appears to be stationary are not uncommon, and also periods in which the symptoms give delusive hopes of real improvement. Often the life of the patient is destroyed by some intercurrent affection. A fatal ending may be due to disturbances of respiration and deglutition incident to the occurrence of bulbar paralysis. Irrespective of these causes, death may be the result of exhaustion from cystitis, bed-sores, and the giving way of the processes involved in nutrition. Clinical experience thus far has furnished no ground for entertaining any hope of recovery from the disease.

The utmost to be hoped for in the way of TREATMENT is that the disease will remain stationary, or, if it be progressive, that the progress may be retarded. Various remedies have seemed to be of use in isolated cases. Among these are the nitrate of silver, arsenic, the chloride of barium, and the phosphide of zinc. The latter remedy, in a case under my observation,

repeatedly followed by distinct although limited improvement. Electricity and hydropathic treatment have appeared to be beneficial. More is to be expected from the removal as far as possible of all causes of disorder, from measures for the improvement of the general health, and from treatment governed by symptomatic indications, than from any remedies given with a view to a special influence upon the disease.

Locomotor Ataxia—Posterior Spinal Sclerosis.

This affection was described by Duchenne in 1858 and 1859 under the name of progressive locomotor ataxia, more fully than by any previous writer; hence Trousseau designated it Duchenne's disease. The principal symptoms of the disease, however, had been recognized previously by Romberg, who applied to it the old name *tabes dorsalis*. The distinctive character and the seat of the affection were clearly defined also by the late Dr. Todd prior to the researches of Duchenne. Other names of the disease are *gray degeneration of the posterior columns*, *sclerosis of the posterior columns*, and *posterior chronic leucomyelitis*.

The anatomical characters of locomotor ataxia consist of sclerosis of the posterior columns of the spinal cord, involving frequently a part of the lateral columns and of the gray substance. The posterior nerve-roots are atrophic and gray. The pia mater covering the posterior part of the cord is thickened, opaque, and is often adherent to the dura mater. In advanced cases the posterior columns appear shrunken, gray, and somewhat firmer than normal. The observations of Pierret (1872), under Charcot's direction, render it probable that the primary seat of the sclerosis is in two bands, each in the outer part of the posterior columns, and lying close to, and parallel with, the posterior horns of gray matter. These bands they call the *external* or *lateral bands*. This view of Pierret and Charcot is based, on the one hand, on the fact that sclerosis of the columns of Goll, although usually present in locomotor ataxia, does not cause ataxic symptoms, as shown in cases of ascending secondary degeneration and of primary sclerosis of these columns; and, on the other hand, on the observation of a case of locomotor ataxia in which the sclerosis was confined to the external bands, while the columns of Goll were normal. When, as is usual, the symptoms are most marked in the lower extremities, the changes in the posterior columns are most extensive and advanced in the lower dorsal and upper lumbar regions. Here the whole thickness of the posterior columns is involved. In very rare cases the symptoms are chiefly referable to the upper extremities, the sclerosis then being most developed in the cervical enlargement. As a rule, however, while the dorso-lumbar sclerosis occupies the greater part of the posterior columns, it is found that in the cervical region the sclerosis is confined either to the columns of Goll or to these together with the external bands. The almost constant involvement of the columns of Goll may be regarded as referable to an ascending secondary degeneration. The sclerosis may be traced continuously to the réstiform bodies of the medulla oblongata, where it ceases. There is a tendency in the disease during the later stages to extend to the posterior part of the lateral columns. The posterior horns of gray matter are generally involved. The nerve-fibres in Clarke's columns are atrophied in all typical cases. Extension to the anterior horns of gray matter is a rare complication, causing muscular atrophy. Gray degeneration of the optic nerves, and rarely of the oculo-motor, hypoglossal, and certain other cranial nerves, has been observed.

[Of late years, changes in the peripheral spinal nerves have been recognized and minutely described by Westphal, Déjerine, Pitres and Vaillard, and others.

It is to this peripheral neuritis that are to be ascribed the neuralgic pains, the anesthesias, muscular atrophies, and trophic disturbances (arthropathies?) so often observed in the course of locomotor ataxia. In fact, according to some authorities (for example, Hirt), the disease probably always begins with degenerative changes in the peripheral nerves.—H.]

Microscopical examination of the sclerosed parts reveals increase of the interstitial tissue, which appears as a dense but finely-fibrillated connective tissue, containing in the early stages many nuclei and granular corpuscles, and in the later stages abundant corpora amylacea. The walls of the blood-vessels are thickened, and the perivascular sheaths enclose a large number of fat-globules which have probably been derived from the products of fatty degeneration of the nerve-elements. The nerve-fibres lose their medullary sheaths, undergo atrophy, and for the most part disappear. The exact localization of the sclerosis as described above can only be determined by microscopical study. The morbid process is regarded by most writers as beginning in the nerve-fibres, either as a parenchymatous inflammation (Vulpian, Charcot, Erb) or as a degeneration (Leyden), the chronic interstitial inflammation being a secondary change.

Locomotor ataxia is not a form of paralysis, although it is generally associated with diminished sensibility, and not infrequently with more or less diminution of motor power. The distinctive characteristic of the affection is impairment or loss of the ability to combine and direct voluntary muscular movements. The patient may have as much muscular strength as in health, but there is either inability or difficulty in co-ordinating the action of the muscles by the will. A natural division is into the initial period or first stage, the ataxic period or second stage, and the paralytic or third stage.

Lancinating, shooting pains, usually at first in the lower, and later in the upper limbs, often constitute a prominent symptom. The patient often compares the pains to those caused by electric shocks. In consequence of their shooting, piercing characters and great intensity they have been called fulgurating or lightning pains. They are not positively characteristic, inasmuch as they occur in other forms of myelitis, and are not invariably present in cases of ataxia. The "girdle sensation," which is a symptom in other inflammatory affections of the cord, is often felt. Other events which may occur in the first stage are—incontinence of urine, frequent seminal emissions, anaphrodisia, or, on the other hand, a morbid excitability of the sexual organs, urethral and rectal neuralgic pains, a sense of fatigue in the muscles of the lower limbs after any exertion, attacks of vomiting accompanied by gastralgia (*crises gastriques* of Charcot), and paralysis of certain of the nerves of the eyeball (the oculo-motorius, the abducens, and rarely the trochlearis), giving rise to strabismus, diplopia, and ptosis. These paralytic symptoms may be transient, and they may disappear and return, sometimes remaining permanently. Impairment of vision in some cases occurs early, and it may end in amaurosis. The ophthalmoscope shows an opaque, pearly whiteness of the optic papilla, characteristic of atrophy of the optic nerve. Irregularity of the pupils is not infrequent. The pupil on one side may be contracted to the size of a pin's point, showing paralysis of the sympathetic; and with this symptom are sometimes associated dilatation of the vessels and increased heat on the corresponding side of the face. The pupil on one side may be contracted and on the other side dilated. Oftener both pupils are contracted. A symptom which possesses considerable diagnostic value is the absence of contraction of the pupil on exposure to light, while there is normal contraction in the acts of accommodation (Argyll-Robertson symptom). Difficulty of speech from paralysis of the hypoglossus, and paralysis affecting base of

of the trigeminus and facial nerve, are occasional symptoms. The acoustic nerve is rarely involved. Absence of patellar reflex is an early and almost constant symptom of locomotor ataxia. These events are liable to occur in the first stage—that is, they may precede the development of ataxia—or their occurrence may be delayed until the second stage. They may precede for a long period, months and even years, the ataxic characteristics. The latter mark the second stage of the disease.

The ataxia is generally first manifested in the lower extremities. It may, however, appear first in the upper extremities. This was true of a case which I have observed. One lower limb is sometimes affected before the other, and both limbs on the same side may be first affected. When one limb is first affected, whether it be a lower or an upper extremity, it is on the left oftener than on the right side. The defect of co-ordination is apparent when any combined movements are undertaken. In proportion as the affection is marked the patient's gait in walking is uncertain, irregular, and grotesque. The lower limbs are thrown forward by forcible jerks, without definite direction. The body is sometimes swayed from side to side in the attempt to maintain an equilibrium, and the arms are thrown out like those of a person balancing on the tight rope. In cases less marked the greatest difficulty is experienced in beginning to walk, and after getting under way the patient is unable to advance slowly, but walks with precipitation. The legs are thrown forward with a quick, jerking movement, and the feet are brought to the ground on the heels with force and are liable to strike against each other. Notwithstanding the violence of the exertions, the muscular strength being retained patients are sometimes able to walk for long distances. In an extreme degree of the affection walking, even with the aid of a cane or assistants, is impossible, and the patient is confined to the chair or bed.

The defect in co-ordinating power over the upper extremities is shown by an inability to execute acts which require the combined movements of the fingers. The patient is unable to button or unbutton clothes, and yet the grasp may have not less force than in health. A patient whom I exhibited at a clinic tried in vain to unbutton his vest, but his grip was too strong to be borne. In extreme cases the patient is unable to guide the hand to his mouth, and requires to be fed by others.

In a certain proportion of cases the affection progressively extends over the voluntary muscular system, and increases in degree more or less slowly. The defective co-ordinating power may be much more marked at some times than at others. A patient for some time under my observation, who had suffered from this affection for five years, habitually walked with a certain amount of uncertainty and irregularity, and enunciated with labor and slowly, but distinctly. This patient at times, for the space of an hour or so, walked with great difficulty, presenting in a marked degree the characteristic gait, and the embarrassment in speech was such that he was with difficulty understood. These paroxysms recurred on some days repeatedly, and he was sometimes exempt from them for several successive days. This patient had occasionally double vision and night-blindness.

A symptom, even when the affection is slight, is inability to stand with the eyes closed. This symptom is not pathognomonic of locomotor ataxia. The patient, with the feet in apposition and the eyes closed, soon reels, and would fall if not supported. This has been attributed to the coexistence of more or less anæsthesia of the soles of the feet. Patients, however, with notable loss of sensibility of the soles, but who have not ataxia, are sometimes able to stand without difficulty when the eyes are closed.¹ A moderate amount of ataxia occasions want of confidence in the powers of locomotion.

¹ Vide report of a case by Dr. Pepper, in *Am. Journ. of Med. Sciences*, July, 1871.

A patient under my care has the disease only in a sufficient degree to walk usually with what seems an eccentric gait; but were he to cross a street when it became necessary to hasten in order to get out of the way of carriages, he would scarcely be able to make any headway, and he carefully avoids such a contingency.

In most if not in all cases the cutaneous sensibility is more or less impaired. The amount of sensory paralysis varies in different cases. Generally both anæsthesia and analgesia are combined. There is also diminution of the sense of weight and of temperature. The so-called muscular sense is impaired. Retardation in the transmission of sensory impressions to the sensorium is usually marked. The difficulty in walking is increased by the impairment of sensibility. The patient's eyes are directed to the feet and ground in walking, and there may be inability to walk with the eyes closed.

As already stated, although distinct from motor paralysis, the latter may coexist with the ataxia, and may be either primary or secondary as regards the former. In cases of paralysis from different spinal affections, the difficulty in walking depends often measurably on defective power of co-ordination.

Impotence occurs, as a rule, sooner or later, either before or after the advancement of the disease to the ataxic stage.

Affections of the joints occur in a proportion of cases, small, but sufficient in number to show a pathological connection. These have been described, especially by Charcot, under the name of ataxic arthropathies. They may occur before as well as after the development of the ataxic condition. Generally, the larger, but sometimes the smaller, joints are affected. Those attacked by preference are the knee and the shoulder. The joints are attacked suddenly, without any traumatic cause; they are swollen from intra-articular effusion; pain and fever are wanting; and recovery often takes place after several weeks or months. On the other hand, permanent structural changes may be the result, leading sometimes to dislocation¹ and the lesions of deforming arthritis. The patellar reflex is wanting. Percussion over the ligamentum patellæ or over the tendo Achillis does not occasion spasmodic movements as in health. This is a point of diagnostic importance. Cutaneous reflexes are generally normal or nearly so. As a rule, for a long period the nutrition of the muscles is well maintained. The electrical reactions are normal in uncomplicated cases.

In the advanced or paralytic stage notable paralysis is added to the ataxia. The muscles waste, the patient falls into a cachectic state, cystitis and bed-sores occur, and death takes place by exhaustion. Happily, the disease progresses to this stage in but a small proportion of cases. It is generally reached, if reached at all, after a long period. When a certain amount of progress has taken place, sometimes the disease remains without further progress indefinitely or during life. If the disease be progressive, its progress may be extremely slow. Notable improvement takes place in some cases. I have known the ataxia to be so great as to compel patients to keep the bed for several months, and such a degree of improvement to follow that they were able to walk without much difficulty. Complete recovery is extremely rare, but if the disease be not far advanced it is possible. Hence the name progressive, applied by Duchenne, is by no means characteristic of the disease. In the great majority of cases death is owing to some intercurrent affection. The disease may not interfere with the continuance indefinitely of appetite, nutrition, and good general health.

The DIAGNOSIS involves a discrimination from paraplegia, and in some cases from general paralysis. The differential diagnosis may be easily made. The

¹ Charcot, *Leçons sur les Maladies du Système nerveux*, Paris, 1877.

ataxia is not a paralytic affection; and the difficulty in walking or in using any of the affected muscles depends not on deficiency of muscular power, but on the lack of ability to combine and direct the movements of the affected muscles. The difference in this respect is strikingly shown by causing two patients, one affected with paralysis and the other with locomotor ataxia, to walk side by side. The paralytic walks with a feeble, tottering, or shuffling gait, while the patient affected with ataxia throws out his limbs with force, but in an irregular, uncertain manner. The preservation of voluntary motor power in ataxia is shown by the resistance which the patient is able to make when the physician tries to bend the limbs, and also by the freedom and strength of movement when the patient is recumbent. If there be paralysis, more or less in degree, combined with ataxia, it is not a difficult problem to determine this fact and to estimate the relative prominence of either. The coexistence of mental aberration with general cerebral paralysis is a diagnostic feature of the latter. In that disease the voluntary muscles of the limbs, face, etc. are simultaneously affected. In locomotor ataxia different parts of the voluntary muscular system are successively affected, the affection being generally manifested first in the lower extremities. General paralysis of the insane and locomotor ataxia may occur together, either affection appearing first.

Affections of the cerebellum giving rise to vertigo may occasion an embarrassment in walking and standing suggestive of ataxia. The embarrassment is due to vertigo, and is analogous to that caused by drunkenness. With proper attention this cannot be confounded with the ataxic difficulty. Moreover, the vertigo is usually accompanied by other symptoms pointing to cerebellar disease.

Sclerosis of the lateral columns, or spasmodic spinal paralysis, presents diagnostic characters which, as will be seen, are sufficient for the discrimination of this affection. The muscles in locomotor ataxia are notably relaxed.

Before the appearance of ataxia the diagnosis may be considered established if lancinating pains, absence of patellar reflex, and the Argyll-Robertson pupil are all present as symptoms.

The ETIOLOGY of locomotor ataxia relates to age, sex, over-exertion of the muscles, together with exposure to cold and sexual excesses. The disease occurs very rarely prior to adult life. In the great majority of cases the ages are between thirty and fifty years. Men are oftener affected than women. The disease has been observed to follow various affections—namely, rheumatism, pellagra, epilepsy, hysteria, etc.—but the diversity of these antecedent affections renders it doubtful that the sequence denotes any etiological connections. The personal history in many cases gives nothing definite as regards the causation. Syphilis seems to be an undoubted factor in the causation of a certain proportion of cases of locomotor ataxia. [According to Erb, the proportion of cases in which a syphilitic history could be obtained was 60 per cent.; according to Fournier, about 90 per cent. Out of 247 cases studied by Hirt, syphilis had certainly existed in 218—*i. e.* in nearly 90 per cent.—H.] The analysis of the cases shows antecedent syphilis to have been generally mild, and that the ataxia occurs from five to ten years after the syphilitic infection.

TREATMENT.—The nitrate of silver, the iodide of potassium, arsenic, the chloride of barium, and phosphorus are remedies recommended in this disease. Each has been found useful by some, and not so by other observers. None are entitled to be considered as specially curative. Their degree of usefulness is limited in the cases in which they appear to be useful. The nitrate of silver may be given continuously in doses of from a third to a sixth of a grain for several weeks, and it should then be suspended for a

season. Phosphorus has seemed to me to be useful in several cases. It may be given in the form of phosphide of zinc or of the oleaginous solution [Considering the frequency of a syphilitic taint in ataxic patients, it might be supposed that the greatest benefit would be derived from an antisyphilitic treatment. Experience, however, has shown that, unless signs of syphilis are still present or the time since their subsidence is short, little can be accomplished by a course of mercurials or potassium iodide.—H.]

They who have had large experience in electro-therapeutics bear testimony to the usefulness of electricity. Both the faradic and galvanic forms are useful, the latter having the more testimony in its favor.

Thermal baths are generally regarded with disfavor by those who have observed their effects in a considerable number of cases. Sponging the body with cool or tepid water and the hydropathic packing, the latter employed with care and moderation, are recommended. The usefulness of these measures, as well as of electricity and the other remedies which have been named is to be explained by their general influence upon the functions of the body, this influence reaching thus indirectly the local disease.

There is general agreement as to the inutility of local depletion and counter-irritation.

The lancinating pains, the attacks of gastralgia with vomiting, seminal emissions, the affections of the joints, the retention or incontinence of urine, and other complications, claim of course appropriate measures of treatment. Stretching the sciatic or other nerves which are the seat of severe pain is a surgical operation which has afforded great relief in some cases, and has been without benefit in other cases. It is only a palliative measure.

Measures to improve and maintain nutrition, to invigorate the general health, to remove coexisting disorders, and to palliate symptoms, doubtless do much toward preventing or retarding the progress of the disease.

Inasmuch as measures of treatment appear in not a few cases to prevent or retard the progress of the disease, it is obvious that an early diagnosis is highly important. It is important to recognize the significance of the symptoms which precede the ataxic stage, with the hope that as a result of judicious management the disease may not advance to this stage. There seems to be no good reason, *a priori*, why the disease might not become stationary, to say the least, at this as well as at the second stage.

[A few years ago the "suspension method" of treating locomotor ataxia was universally prevalent, and the reports of its results were almost universally favorable. By this method patients were suspended for several minutes by an apparatus similar to that employed for fitting a plaster-of-Paris jacket in cases of Pott's disease. It seems highly probable that the beneficial effects of suspension were due entirely to auto-suggestion. Hirt has treated more than one hundred cases of locomotor ataxia by suspension, and in no instance was he able to note any marked or lasting improvement.—H.]

Hereditary Ataxia.

This rare affection was first described by Friedreich in 1863, and is sometimes called *Friedreich's disease*. Although several cases of typical locomotor ataxia sometimes occur in the same family, in Friedreich's disease there are certain peculiarities in the symptoms and the pathological lesion which distinguish the disease from typical locomotor ataxia.

A number of members of the same family are usually affected. In a observation of Carré there were 18 cases of ataxia in one family, occurring during three generations. Dr. W. E. Smith has reported 6 cases of here

lesion is the same as that already described—namely, an acute anterior poliomyelitis.

This affection in the adult is rare. After childhood the cerebral symptoms which in children accompany the initial fever are less marked. The clinical characteristics, however, which relate directly to the spinal affection are the same. The development of the paralysis is rapid. The distribution of the paralyzed muscles is irregular, and, as regards their number and situation, different cases present much diversity. In more or less of the affected muscles reflex and electrical excitability is soon greatly lessened or lost. There is no impairment of sensation. The bladder and rectum are unaffected. The sexual function is not involved. After the lapse of from one to two weeks improvement in certain, or it may be in all, the paralyzed muscles begins. If improvement begin in all and progress, the recovery may be complete after several weeks or months. The improvement and recovery, however, may be limited to a certain proportion of the paralyzed muscles, a greater or less number remaining permanently paralyzed. These rapidly atrophy, and as remote consequences distortions occur, but in a less degree than in childhood.

The main difficulty in diagnosis is to distinguish acute anterior poliomyelitis in the adult from primary degenerative neuritis involving several nerves. In both affections there is muscular paralysis with rapid atrophy and the reaction of degeneration, but in neuritis there are usually severe neuralgic pains, and often other sensory disturbances lacking in poliomyelitis.

The objects of treatment and the measures to be pursued are the same as in the disease occurring in childhood.

Subacute and Chronic Anterior Poliomyelitis—Subacute and Chronic Atrophic Spinal Paralysis.

Duchenne first described, under the name of subacute anterior general spinal paralysis, an affection characterized by the gradual or by the rapid development of paralysis—first, usually, of the lower and then of the upper extremities—without marked disturbances of sensation, combined with progressive atrophy of the paralyzed muscles, and by loss of reflex and of faradic excitability. The recorded post-mortem examinations do not suffice for positive statements as to the anatomical basis of the disease. It is believed that the disease is pathologically a subacute or a chronic myelitis of the anterior horns.

The clinical characteristics are analogous to those of the acute affection, exclusive of symptoms denoting acuteness. Fever is absent. The development of the paralysis, as a rule, is not rapid but gradual, extending over months or even years. Groups of muscles of the lower extremities are usually first affected, and the paralysis sooner or later may extend to groups in the upper extremities and in the trunk. The irregular distribution of the paralyzed muscles is a feature of this as of the acute affection. The paralyzed muscles present the reaction of degeneration, either complete or partial, and atrophy occurs, evidently from trophic disturbance. Reflex excitability of the paralyzed muscles is extinguished. Sensibility is but little or not at all impaired. The bladder and rectum are not involved.

Complete recovery takes place oftener than in the acute affection: but, in a certain proportion of cases, the recovery is limited to a greater or less number of the paralyzed muscles, the others remaining permanently paralyzed. Distortions follow the disturbance of the normal equilibrium of antagonizing muscles. Death is sometimes caused by an extension of the paralysis upward, so that deglutition and respiration become affected.

The susceptibility of the paralyzed muscles to reflex excitation of the skin and percussion of the tendons is quickly lost.

Owing to the degeneration of nerve and muscle the reaction of degeneration, as previously described (p. 674), rapidly makes its appearance. In seven or eight days the excitability of the nerve to the faradic current may be completely abolished. In consequence of the degeneration of the intramuscular nerve-filaments the response of the muscle to the direct application of the faradic current is also lost, but at a somewhat later period. The galvanic excitability of the nerve at the same time disappears. The galvanic excitability of the muscle, on the other hand, is increased, this increase lasting often for several months. The muscular contractions are sluggish and prolonged, and the anodal closure-contraction equals, and finally exceeds, the cathodal closure-contraction. After about three months the increased galvanic excitability is diminished in consequence of atrophy and destruction of the muscular fibres. The qualitative changes remain. There may be, finally, total disappearance of the galvanic muscular excitability.

If after two weeks the contractility of the muscle to the induced or faradic current be not destroyed, there is a good chance of restoration of the affected muscle. Restoration is also possible after the disappearance of faradic excitability during the period of increased galvanic excitability. Voluntary impulses can be transmitted through the nerves before the faradic excitability returns.

Speedy and notable wasting of the muscles which present the reaction of degeneration is a diagnostic feature. This occurs too early and goes on too rapidly to be referable simply to disuse; it denotes trophic disturbance, and is evidence of a connection of nutrition with the ganglion-cells in the anterior portion of the gray matter of the cord. The atrophy in some muscles may proceed to such a degree that all trace of the muscular tissue has disappeared. The temperature of the surface over the paralyzed parts is lowered, as determined by the thermometer as well as the touch, and the skin has a livid appearance.

Within a few weeks improvement begins either in all or in a certain number of the paralyzed muscles. In a small minority of cases the improvement in all the muscles goes on to complete recovery. In the large majority of cases the improvement is limited to muscles incompletely paralyzed and retaining more or less susceptibility to the faradic current. The muscles which, after the lapse of several weeks, are without any improvement, as a rule remain permanently paralyzed. As regards the number and the situation of the muscles so remaining different cases present great diversities. The permanent paralysis may be confined to one lower limb, to both lower limbs, to an upper limb, to an upper and lower limb, etc. It is rare for all the muscles of a limb to remain paralyzed in an equal degree. Often the paralysis is limited to a certain group of muscles, especially to the peroneal and anterior tibial, and sometimes even to a single muscle.

The permanent paralysis of a greater or less number of muscles involves no disturbance of the general health. The assimilatory and the nutritive processes (exclusive of those in paralyzed muscles) may go on as completely as possible. In all respects save the paralysis and its local consequences the health may be excellent and the duration of life is not shortened.

The local consequences of the paralysis are, however, by no means trivial. A great variety of deformities are results of this disease. The growth of the bones is arrested. Owing to a want of a proper antagonism of the muscles, distortions of the feet and hands are common. The joints become loose and often admit of ready dislocations. The painful spectacles so often met with of shortened, flaccid limbs, club-foot, etc., if not congenital, are generally more consequences of this disease.

The **DIAGNOSIS** of this disease, as regards other paralytic affections, after the development of paralysis is easy. The diagnostic points summarized are as follows: The paralysis following an initial fever and affecting muscles in rapid succession and in an irregular manner; the paralysis of a certain number of muscles rapidly becoming complete; the rapid appearance of the reaction of degeneration and the speedy disappearance of reflex and tendinous reaction; early and progressive atrophy of paralyzed muscles; absence of anæsthesia; coldness and blueness of the skin over the paralyzed limbs; tendency to gangrenous inflammation of parts exposed to pressure; beginning improvement within a few weeks in some, and sometimes in all, of the paralyzed muscles; permanent paralysis of certain of the affected muscles, the great majority of cases. The discrimination from the cerebral paralysis of children has been already considered.

We possess no actual knowledge of the **ETIOLOGY** of this disease beyond its being especially incident to childhood. Children, usually from one to four years of age, are attacked when apparently in perfect health and when nothing is apparent on which suspicion can rest as causing the attack. These facts render probable a special cause, the nature and source of which are unknown.

The disease involves very little danger to life. As regards **PROGNOSIS**, the danger relates to permanent paralysis with atrophy of a greater or less number of muscles and the deformities arising therefrom.

The object of **TREATMENT** in the early stage of the disease is the prevention of these; in other words, the prevention of the changes in the anterior gray columns of the cord, on which depend the permanent paralysis and atrophy of groups of muscles corresponding to the situation and the extent of the spinal lesions. For this object the treatment indicated in acute myelitis is recommended—namely, active purgation, local bloodletting by cups or leeches, the application of cold to the spine, dry cupping and vesication, mercurial inunctions, the internal administration of ergot, belladonna, and the iodide of potassium. The physician must use his discretion in the employment of these measures, having due regard to the age and the constitution of the patient. Could the diagnosis be made in the initial febrile stage, perhaps more would be accomplished by antipyretic treatment than by the measures just enumerated. Unfortunately, a positive diagnosis is rarely made in this stage.

The treatment after the occurrence of paralysis has for its object the restoration of motor power over the paralyzed muscles and the prevention of atrophy. For these objects the reliance is chiefly on electrical treatment. Neurologists are generally agreed upon the superiority of the galvanic current, but faradic electricity may be combined with advantage. The electrical treatment should be continued steadily for many months. Hydropathy employed with proper care, and massage, are useful. The system should be well nourished and invigorated by hygienic measures, together with tonic remedies whenever these are indicated by debility, want of appetite, feeble digestion, etc.

The treatment of the deformities which are likely to follow this disease falls within the province of surgery.

Acute Anterior Poliomyelitis in the Adult.

It was for a long time supposed that the form of acute atrophic spinal paralysis described in the preceding article was confined to children. It is now known that the same affection may occur in the adult. The pathologica

lesion is the same as that already described—namely, an acute anterior poliomyelitis.

This affection in the adult is rare. After childhood the cerebral symptoms which in children accompany the initial fever are less marked. The clinical characteristics, however, which relate directly to the spinal affection are the same. The development of the paralysis is rapid. The distribution of the paralyzed muscles is irregular, and, as regards their number and situation, different cases present much diversity. In more or less of the affected muscles reflex and electrical excitability is soon greatly lessened or lost. There is no impairment of sensation. The bladder and rectum are unaffected. The sexual function is not involved. After the lapse of from one to two weeks improvement is certain, or it may be in all, the paralyzed muscles begins. If improvement begin in all and progress, the recovery may be complete after several weeks or months. The improvement and recovery, however, may be limited to a certain proportion of the paralyzed muscles, a greater or less number remaining permanently paralyzed. These rapidly atrophy, and as remote consequences distortions occur, but in a less degree than in childhood.

The main difficulty in diagnosis is to distinguish acute anterior poliomyelitis in the adult from primary degenerative neuritis involving several nerves. In both affections there is muscular paralysis with rapid atrophy and the reaction of degeneration, but in neuritis there are usually severe neuralgic pains, and often other sensory disturbances lacking in poliomyelitis.

The objects of treatment and the measures to be pursued are the same as in the disease occurring in childhood.

Subacute and Chronic Anterior Poliomyelitis—Subacute and Chronic Atrophic Spinal Paralysis.

Duchenne first described, under the name of subacute anterior general spinal paralysis, an affection characterized by the gradual or by the rapid development of paralysis—first, usually, of the lower and then of the upper extremities—without marked disturbances of sensation, combined with progressive atrophy of the paralyzed muscles, and by loss of reflex and of faradic excitability. The recorded post-mortem examinations do not suffice for positive statements as to the anatomical basis of the disease. It is believed that the disease is pathologically a subacute or a chronic myelitis of the anterior horns.

The clinical characteristics are analogous to those of the acute affection, exclusive of symptoms denoting acuteness. Fever is absent. The development of the paralysis, as a rule, is not rapid but gradual, extending over months or even years. Groups of muscles of the lower extremities are usually first affected, and the paralysis sooner or later may extend to groups in the upper extremities and in the trunk. The irregular distribution of the paralyzed muscles is a feature of this as of the acute affection. The paralyzed muscles present the reaction of degeneration, either complete or partial, and atrophy occurs, evidently from trophic disturbance. Reflex excitability of the paralyzed muscles is extinguished. Sensibility is but little or not at all impaired. The bladder and rectum are not involved.

Complete recovery takes place oftener than in the acute affection: but, in a certain proportion of cases, the recovery is limited to a greater or less number of the paralyzed muscles, the others remaining permanently paralyzed. Distortions follow the disturbance of the normal equilibrium of antagonizing muscles. Death is sometimes caused by an extension of the paralysis upward, so that deglutition and respiration become affected.

females. There is no connection with social condition or particular occupations. Several members of the same family in repeated instances have been affected, but most cases of hereditary muscular atrophy do not belong to the Aran-Duchenne type. It has been supposed in some cases to proceed from undue muscular exertion. Like most affections, it is sometimes attributed to the action of cold.

The great object of **TREATMENT** is the arrest of the progress of the affection. The measures for this object have reference to the affected muscles and the general condition. Undue exertion of the affected muscles is to be avoided, but a certain amount of exercise is important. The circulation and nutrition within the affected muscles are to be promoted by friction and shampooing and the use of stimulating embrocations. As regards treatment addressed directly to the affection, however, the most potential measure is the employment of electricity. Each of the different forms of electricity is useful, and they may be employed in alternation. Measures having reference to the general condition are those which invigorate the powers of the system. Here, as in cases of progressive locomotor ataxia, judicious management, although it may fail to effect recovery, may do much toward retarding the progress of the affection and prolonging the life of the patient. The point in the progress of the affection at which the arrest is effected is of great importance to the patient; hence the desirableness of an early diagnosis.

In one of the cases at Bellevue Hospital which has been referred to, in which the muscles of the arm, thigh, and back are greatly atrophied, not only has there been no progress of the disease during nearly ten years, but the patient is greatly improved, and although the atrophied muscles remain the same, he has been able for several years to do active duty as a hospital nurse and in other kinds of labor.

Spastic Spinal Paralysis—Primary Lateral Sclerosis.

In 1875, Erb described a group of symptoms as a well-defined disease to which he gave the name *spastic spinal paralysis*. Charcot, who had previously recognized the main features of the disease, accepted Erb's description, but called the affection *spasmodic tabes dorsalis*. The leading symptoms are slowly-developing paralysis, rigidity of the affected muscles, contractures, and increased tendon reflexes. There is absence of sensory and of trophic disturbances in uncomplicated cases.

It is assumed by Erb and by Charcot that the anatomical characteristic of the disease is primary sclerosis of the lateral columns of the cord. This view is in harmony with the teaching of Charcot, that sclerosis of the lateral columns, whether primary or secondary, is attended by tension of the paralyzed muscles. The assumption, however, that Erb's spasmodic spinal paralysis depends upon primary lateral sclerosis has not as yet been confirmed by post mortem examinations. Charcot himself has published a case in which he had diagnosticated this disease during life, and the autopsy revealed multiple sclerosis. A variety of affections of the spinal cord and of the meninges may produce the combination of symptoms described by Erb, such as chronic hydrocephalus, transverse myelitis in the dorsal or cervical region, compression of the cord, multiple sclerosis, hydromyelus, and combined systemic diseases of the cord. In these cases the symptoms persist for a long time those of pure spastic paralysis, but eventually other symptoms, as a rule, are superadded. In the present state of the question it is improper to recognize as a distinct symptomatic affection the clinical picture drawn by Erb, but it is necessary to await future investigations before we attempt to localize the anatomical changes which form its basis.

article the ordinary form of progressive muscular atrophy will be described. This may be considered to be neuropathic in origin.

Progressive muscular atrophy may be *primary* or *secondary*. In the secondary form (deuteropathic of Charcot) the chronic anterior poliomyelitis is secondary to some other morbid process in the cord, such as primary lateral sclerosis(?), posterior spinal sclerosis, spinal meningitis, and insular sclerosis. Of the secondary form, that consecutive to lateral sclerosis is the most important, and is called amyotrophic lateral sclerosis. It will receive consideration in a separate article. The intimate connection between chronic bulbar paralysis and progressive muscular atrophy in symptomatology, development, and pathology has already been mentioned in treating of the former affection.

The ANATOMICAL APPEARANCES in the spinal cord in cases of progressive muscular atrophy are similar to those met with in the later stages of infantile spinal paralysis. The primary change is, however, best regarded as a degenerative atrophy of the ganglion-cells, and not as a myelitis. No changes may be visible to the naked eye, or a more or less distinct atrophy of the anterior horns may be discerned. The microscopical examination shows the various stages of pigmentary and sclerotic atrophy of the motor ganglion-cells in the anterior horns, the presence of a few granular corpuscles, and increase with induration of the interstitial tissue, especially well marked in the neighborhood of the atrophied cells or cell-groups. Gray degeneration of the anterior nerve-roots and of peripheral nerves supplying the affected muscles is also present. The changes in the muscles are not those of a simple fatty degeneration, as was at one time supposed. They consist in a simple atrophy of the muscular fibres, which become smaller and smaller, but preserve their striæ until much reduced in size. Many of the fibres possess a greatly increased number of sarcolemma nuclei, and some may present the characters of fatty degeneration. The interstitial tissue is at the same time increased in amount, and may contain some fat-cells. It is a noteworthy fact that the affected muscles do not undergo atrophy in their entire volume at once, as is the case in infantile spinal paralysis, but that individual fibres or bundles of fibres become atrophied, while adjoining fibres may remain of normal size. This peculiarity of atrophy of individual fibres or of single bundles in a muscular mass forms one of the distinguishing characters of progressive muscular atrophy.

Progressive muscular atrophy generally begins in one of the upper extremities, oftener in the right than in the left. The affection is at first usually limited to a certain number of muscles. In the larger proportion of cases some of the muscles of the hand are primarily affected. The muscles forming the ball of the thumb and the ball of the little finger and the interosseous muscles are first atrophied. Less frequently the muscles of the shoulder or of the arm or of the forearm are the first to become atrophied. Corresponding muscles of the other extremity are likely to become subsequently affected, the affection thus exemplifying the law of parallelism. More or less gradually the affection extends over the muscular system. Not only the muscles of the extremities, but those of the trunk, are likely to become atrophied, and in some cases the latter are first affected. The intercostal muscles and the diaphragm may be involved, and death may be produced by apnoea. The muscles of deglutition may become involved, and the affection may prove fatal by causing inanition. The affection is limited to the voluntary muscles.

A marked degree of atrophy of external muscles renders the appearance striking and characteristic. In a case which came under my observation the atrophy was limited to the muscles of the left shoulder, arm, and forearm. The right scapula was well covered by its muscles, but on the left

side this bone was conspicuous, its boundaries distinct, and the spinous ridge projecting. The whole of the upper limb was attenuated, presenting a remarkable contrast with its fellow. In a case reported by Reade, the patient, a young man, when stripped to the waist "exhibited the neck, chest, and arms to the elbow-joints reduced to the most abject degree of emaciation. The emaciation was perfectly symmetrical; the greater and lesser pectoral muscles were less dense than the strongest brown wrapping-paper; the muscles of the neck, anterior and posterior, proportionately attenuated; the muscles on the scapulæ, particularly the supra- and infraspinatus, were so much diminished as to show the spine of the bone with distinctness only less than the dry bone; all prominences from the deltoids were gone, and the muscles of the humeri were reduced to the cellular membrane, the mere elementary outline of the muscles, the biceps and triceps especially. From the elbows the muscles of the forearms and hands displayed the full development of a robust and vigorous man of his stature, with all the concomitant power, sensibility, and aptitude for use. All the muscles outside the pelvis and those of the inferior extremities were full, strong, and well formed."¹ A patient in Bellevue Hospital presents great attenuation of the arms and thighs, the forearms and legs retaining a large muscular development. In this case the muscles of the back are affected, so that in walking the spine is curved backward, and on raising the upper extremities the scapulæ are thrown outward in a remarkable manner, forming what has been called the "wing shoulder." In another case the atrophy is limited to the feet and about two-thirds of the muscles of the calves, the remaining third of the latter being unaffected. The feet have the appearances of bones covered only with integument. Cases have been reported in which the affection extended over the greater part of the voluntary muscular system. The tongue, the muscles of mastication, the facial muscles, and the muscles of the larynx may be included in the general atrophy. In a case cited by Thouvenel the power of moving the limbs and body was lost, and the patient was able only to move the head feebly. The tongue was involved in this case, and deglutition was difficult. Trousseau refers to a case treated by Bretonneau in which the power of speech and all voluntary movements, except of the head and of the forefinger of the right hand, were lost. This patient, a female, held communications with her family by indicating letters, in this way forming words and sentences. She dictated in this manner her last will and testament. When the atrophy is limited to a few muscles the loss of substance is rendered striking by the normal size of the adjacent muscles. Atrophy of one class of muscles—for example, the flexors or extensors of the limbs—causes distortion by the contraction of the muscles which are not affected, the contraction arising from the loss of antagonism. Distortions of the head, trunk, and extremities may be produced by the limitation of the atrophy to certain muscles, or by the progress of the atrophy being much greater in some muscles than in others. The characteristic appearances belonging to the affection give to it a physiognomy by which it is readily recognized in well-marked cases. Among the frequent deformities may be mentioned the claw-like hand, or *main en griffe*. The first phalanges are extended, the second and third are flexed. This deformity is due to paralysis of the interosseous and lumbrical muscles. In the early part of its progress the disease may escape recognition if a close examination be not made.

In general, the first evidence of trouble is weakness of the affected muscles, arising from the atrophy. Pain or soreness precedes and accompanies the affection in a certain proportion of cases. Generally the pain is not severe. It is referred to the affected muscles, and is of a neuralgic character.

¹ *Dublin Quarterly Journal*.

The affected parts are notably sensitive to cold, and their temperature is below that of other parts. Defective capillary circulation is sometimes shown by congestion of the surface. Quivering movements of the fibres of the affected muscles, called fibrillary contractions, are often observed, and sometimes subsultus of the tendons and slight twitchings of the parts to which the tendons are attached. These movements occur irrespective of the will, occasion no pain, and the patient may not be conscious of them. The sensibility of the surface is unaffected. The mental faculties remain intact, and there are no symptoms pointing to intracranial disease. The appetite, digestion, and nutrition may continue unaffected. There is no loss of power over the bladder or rectum, even when the affection is far advanced, nor does the heart become affected. Constipation may be produced by atrophy of the abdominal muscles. The affected muscles lose their electro-contraction only in proportion as they become atrophied and degenerated; and the fibres which are unaffected respond to the electrical current. For this reason it is difficult to make out the reaction of degeneration, which is confined to the atrophied fibres, but by careful examination it has been detected in muscles greatly atrophied. This apparent preservation of electrical contractility serves to distinguish the affection from the wasting of muscles incident to the acute and chronic forms of anterior poliomyelitis, which have been considered.

The progress of the affection is slow. More or less slowly increasing, it is thus, as a rule, progressive, as the name implies. This rule, however, is not without many exceptions. Often it remains stationary after having progressed to a certain extent. In a few cases recovery may be said to take place; that is, the affection ceases without leaving any permanent deformity or notable debility. It may continue, slowly progressing, a great number of years before tending to a fatal result. The prognosis is extremely unfavorable. The most to be hoped for is that it will cease to progress or that its progress will be very gradual. Retrogression is not to be expected after much change in the muscles has taken place. Life may be destroyed by apnoea if the respiratory muscles become affected, or by inanition from atrophy of the muscles concerned in deglutition. In other cases death takes place after a long and tedious confinement to the bed if the patient be not carried off by some intercurrent disease.

As regards DURATION, the following are the results of the analysis of 105 cases by Roberts: Mean duration of cases ending in recovery, one year and two months; of cases ending in permanent arrest, two years and three months; of cases ending fatally, five years and two months. Of the cases which recovered, the longest duration was two and a half years, and the shortest eight months. Of the cases proving fatal, the longest duration was twenty-three years, and the shortest twelve months. The longest case ending in arrest continued active for seven years, and the shortest for four months.

The DIAGNOSIS relates to the exclusion of other affections which are attended by muscular atrophy, such as diffuse myelitis, anterior poliomyelitis, primary neuritis, and primary muscular affections with atrophy. The chief points to be considered are the typical onset of the disease in the small muscles of the hand; the development of the atrophy first in individual muscles, and even in individual muscular fibres, and not in groups of muscles; the typical extension of the atrophy to the muscles of the shoulder and other parts; the development of bulbar paralysis in some cases; the apparent preservation for a long time of electric excitability; the absence of sensory disturbances; and the existence of paralysis only in proportion to the degree of atrophy.

The CAUSATION is obscure. The affection rarely occurs under adult age, and it is unusual after middle life. Males are much oftener affected than

females. There is no connection with social condition or particular occupations. Several members of the same family in repeated instances have been affected, but most cases of hereditary muscular atrophy do not belong to the Aran-Duchenne type. It has been supposed in some cases to proceed from undue muscular exertion. Like most affections, it is sometimes attributed the action of cold.

The great object of TREATMENT is the arrest of the progress of the affection. The measures for this object have reference to the affected muscles and the general condition. Undue exertion of the affected muscles is to be avoided, but a certain amount of exercise is important. The circulation and nutrition within the affected muscles are to be promoted by friction and shampooing and the use of stimulating embrocations. As regards treatment addressed directly to the affection, however, the most potential measure is the employment of electricity. Each of the different forms of electricity is useful, and they may be employed in alternation. Measures having reference to the general condition are those which invigorate the powers of the system. Here, as in cases of progressive locomotor ataxia, judicious management, although it may fail to effect recovery, may do much toward retarding the progress of the affection and prolonging the life of the patient. The point in the progress of the affection at which the arrest is effected is of great importance to the patient; hence the desirableness of an early diagnosis.

In one of the cases at Bellevue Hospital which has been referred to, in which the muscles of the arm, thigh, and back are greatly atrophied, not only has there been no progress of the disease during nearly ten years, but the patient is greatly improved, and although the atrophied muscles remain the same, he has been able for several years to do active duty as a hospital nurse and in other kinds of labor.

Spastic Spinal Paralysis—Primary Lateral Sclerosis.

In 1875, Erb described a group of symptoms as a well-defined disease to which he gave the name *spastic spinal paralysis*. Charcot, who had previously recognized the main features of the disease, accepted Erb's description, but called the affection *spasmodic tabes dorsalis*. The leading symptoms are slowly-developing paralysis, rigidity of the affected muscles, contractures, and increased tendon reflexes. There is absence of sensory and of trophic disturbances in uncomplicated cases.

It is assumed by Erb and by Charcot that the anatomical characteristic of the disease is primary sclerosis of the lateral columns of the cord. This view is in harmony with the teaching of Charcot, that sclerosis of the lateral columns, whether primary or secondary, is attended by tension of the paralyzed muscles. The assumption, however, that Erb's spasmodic spinal paralysis depends upon primary lateral sclerosis has not as yet been confirmed by post-mortem examinations. Charcot himself has published a case in which he had diagnosticated this disease during life, and the autopsy revealed multiple sclerosis. A variety of affections of the spinal cord and of the brain may produce the combination of symptoms described by Erb, such as chronic hydrocephalus, transverse myelitis in the dorsal or cervical region, tumors of the cord, compression of the cord, multiple sclerosis, hydromyelia, and combined systemic diseases of the cord. In these cases the symptoms may be for a long time those of pure spastic paralysis, but eventually other symptoms, as a rule, are superadded. In the present state of the question it seems proper to recognize as a distinct symptomatic affection the clinical picture drawn by Erb, but it is necessary to await future investigations before we attempt to localize the anatomical changes which form its basis.

The combination of locomotor ataxia with lateral sclerosis has been described especially by Westphal. In these cases there is an extension of the sclerotic process from the posterior to the lateral columns. Muscular rigidity is added to the characteristic ataxic symptoms. Secondary lateral sclerosis has been repeatedly mentioned already as forming the descending secondary degeneration of Türk.

The combination of lateral sclerosis with anterior poliomyelitis constitutes the disease called amyotrophic lateral sclerosis, which will be described in the next article.

From a clinical point of view the symptoms described by Seguin in 1873, and called by him "tetanoid pseudo-paraplegia," subsequently described by Erb and called spasmodic spinal paralysis, and by Charcot under the name of spasmodic dorsal tabes, represent a distinct and easily-recognized paralytic affection. Cases presenting its distinctive features, as delineated by these authors, have fallen under my observation.

A synopsis of the clinical history is as follows:

Incomplete paralysis (paresis) begins in either the lower or the upper extremities—according to Erb, much oftener in the former. The paralysis very slowly increases. After having reached a certain degree it is accompanied by twitchings of the muscles and muscular rigidity. The twitchings occur in connection with voluntary movements as well as irrespective of the will, and especially at night. The muscular tension or stiffness is at first excited by motor acts, and, lasting for a few moments only, after a time becomes persistent, and at length leads to a permanently rigid extension of the limbs.

Pressure on the toes excites tremor of the foot and sometimes of the leg. Tremor is excited by a rapid flexion of the foot or by pressure with the hand upon the toes. This symptom is called ankle-clonus (p. 673). It is not, however, peculiar to this affection. Tremor occurring with a certain degree of violence, and sometimes extending to the other limb, has been called by Brown-Séquard by the inappropriate name "spinal epilepsy." It may sometimes be excited by mere contact of the fingers with the skin.

The tremor, stiffness, and spasmodic twitchings added to the paralysis increase the difficulty in walking, and give rise to what is termed by Erb the "spastic gait," which he thus describes: "The feet seem to cleave to the ground; the tips of the feet find an obstacle in every irregularity of the ground; every step is accompanied by a peculiar hiping elevation of the whole body; . . . the patient immediately gets upon his toes, and steps forward on them, showing a tendency to fall forward. The legs are close together, held stiffly, the knees somewhat depressed forward, the upper part of the body slightly bent forward." This mode of walking is distinctive as contrasted with the purely paralytic and the ataxic gait.¹ The difficulty in walking is out of proportion to the impairment of muscular power, yet there is no resemblance to ataxia.

Reflex motions are abnormally excited by percussion of the tendons, the affection in this respect offering a contrast to ataxia. Sensibility remains intact. The bladder and rectum are unaffected. There is no tendency to bed-sores. The sexual functions may be retained. The muscles for a long period do not undergo atrophy. Cerebral symptoms are absent. The electrical excitability of the muscles is slightly diminished, but there is no reaction of degeneration.

The DURATION of the affection extends over many years. It may slowly progress in degree, and gradually be diffused over all the extremities, or, having reached a certain stage, it may remain stationary for an indefinite period.

¹ Vide *Ziemssen's Cyc. of Med.*, Am. ed., vol. xiii. p. 97.

Patients generally die from some intercurrent disease. If, however, it be otherwise, and the affection continue to be progressive, confinement to the bed is at length necessary. The affection may extend to the medulla oblongata and give rise to the symptoms of bulbar paralysis. Cystitis and bed-sores, not occur in typical cases.

The foregoing account applies to typical cases. The symptoms may be associated with those of ataxia in different degrees. The inference, then, is that the sclerosis also embraces the posterior columns. The affection may be unilateral, confined either to one limb or to the two limbs on one side. There may occur more or less speedily muscular atrophy. Under these circumstances the affection has been described by Charcot under the name amyotrophic lateral sclerosis. This form will be noticed under a separate heading.

The ETIOLOGY of this affection is not less obscure than that of the other sclerotic affections of the spinal cord. In the great majority of cases the age of patients is between thirty and fifty. Men are oftener affected than women, and the affection occurs in persons apparently in robust health. In a typical case which came under my observation the patient had suffered much from syphilis.

This form of paralysis admits of a favorable PROGNOSIS as regards a fatal termination. Erb states that recovery may be said to have taken place in two cases under his observation, and notable improvement in three cases. The chief source of danger relating to the disease is the liability to the occurrence of bulbar paralysis or muscular atrophy.

The principles of TREATMENT are essentially the same as in the other varieties of sclerotic disease. Electricity, especially the galvanic current, is to be employed, and hydropathic measures may be tried with proper care and precautions. Strychnia is contraindicated.

Amyotrophic Lateral Sclerosis.

Progressive muscular atrophy, as has already been mentioned, may be a primary affection or may be secondary to other diseases of the spinal cord. Of the secondary or deuteropathic forms of progressive muscular atrophy, that designated by Charcot in 1874 as amyotrophic lateral sclerosis has received especial attention. In this disease the symptoms of progressive muscular atrophy are preceded by paralysis and accompanied by rigidity. In other words, the symptoms of lateral sclerosis and of progressive muscular atrophy are combined. Post-mortem examinations have revealed the lesions of progressive muscular atrophy (degeneration and atrophy of the ganglion-cells of the anterior horns), together with sclerosis of the pyramidal tracts in the anterior and the lateral columns. The antero-lateral sclerosis occupies the same situations as in Türk's secondary descending degeneration; that is, a narrow, wedge-shaped tract on each side of the anterior median fissure, known as the columns of Türk, and a triangular column in the posterior part of each lateral column, known as the pyramidal tract of these columns. (See p. 670.) Bands of sclerotic tissue connecting the diseased parts of the anterior horns with the sclerosed lateral columns have been observed. The microscopical changes are those which have already been described as characterizing progressive muscular atrophy and gray degeneration of the pyramidal tracts. In some instances the degeneration of the pyramidal tracts has been traced throughout their whole extent from their origin in the cerebral cortex to their terminations in the spinal cord. The large pyramidal ganglion-cells in the motor cortical zone have been found atrophied in these cases. The disease is, in the majority of cases, accompanied by the symptoms and lesions of chronic

bulbar paralysis. The primary lesion is to be regarded as degeneration, and not inflammation.

The paralysis begins generally in the upper limbs, and extends to the lower, but in some instances the reverse is the case. The spastic symptoms are usually more marked in the lower extremities, and the atrophic symptoms in the upper extremities. The atrophy of muscles generally begins, as in progressive muscular atrophy, in the small muscles of the hand. In distinction from progressive muscular atrophy the tendon reflexes of the paralyzed muscles are increased. In an advanced stage of the disease contractures occur. Abnormal electrical reaction can be made out only in muscles which are markedly atrophied. In these the reaction of degeneration is apparent, but in most cases this is the so-called partial reaction of degeneration, the electric excitability of the nerves being normal or nearly so in consequence of the preservation of many nerve-fibres. (See p. 674.) Sensation is intact. There are no vesical disturbances. Finally, if life be sufficiently prolonged the symptoms of bulbar paralysis appear.

The affection, as compared with simple spasmodic paralysis, runs a rapid course. It arrives at an advanced stage within six months or a year, and death takes place in from two to three years.¹

In no instance has recovery been known to take place. The indications for TREATMENT are those which belong to progressive muscular atrophy and to bulbar paralysis. Irrespective of the muscular atrophy and bulbar paralysis, the treatment is the same as in cases of uncomplicated spasmodic spinal paralysis.

Compression of the Spinal Cord—Intraspinal Tumors.

Compression of the spinal cord may be produced suddenly or gradually. Fractures and dislocations of the vertebræ constitute the most frequent causes of sudden compression. Their consideration belongs to the domain of surgery. Meningeal hemorrhage and the rupture of aneurisms, abscesses, or cysts into the spinal canal may occasion rapid compression of the cord.

Of greater interest and importance is the study of the causes and results of slow compression of the spinal cord. The causes are many and diverse. Of the more important may be enumerated—*first*, tumors and inflammatory affections of the vertebræ, especially Pott's disease and cancer; *second*, extra-vertebral tumors, such as aneurism, cancer, or abscess, which make their way into the spinal canal either by erosion of the vertebræ or through the intervertebral foramina; *third*, tumors and inflammatory thickening of the meninges and of the perimeningeal tissue; and *last*, tumors of the spinal cord itself. Tumors of the cord itself are less frequent than those of the meninges. They include solitary tubercle, gumma, glioma, sarcoma, neuroma, and secondary carcinoma. Dilatation of the central canal is called *hydromyelus*, and is generally congenital. Cavities of variable size and length and more or less centrally located may be developed in the spinal cord in various ways. The name *syringomyelus* or *syringomyelia* is given to these pathological canals. (See p. 654.)

Of the tumors of the meninges and perimeningeal tissue, may be mentioned—lipoma, sarcoma, myxoma, fibroma, psammoma, gumma, enchondroma, secondary cancer, echinococcus, and cysticercus cysts. Calcific plates in the arachnoid, and especially in the arachnoid, are not uncommon in elderly persons, and, as a rule, produce no symptoms. In the list of tumefactions in this situation which act as causes of compression should be included hemorrhage and certain chronic inflammatory processes. Hemorrhage in the form of a

¹ Vide Charcot, *Leçons sur les Maladies du Système nerveux*, Paris, 1877, tome ii.

tumor (hæmatoma) may be the result of internal hemorrhagic spinal pachymeningitis. Of the inflammatory thickenings, that described by Charcot *cervical hypertrophic pachymeningitis* deserves especial mention. This affection has already been described (p. 647).

Of the causes of gradual compression of the cord, the most frequently best studied is *caries of the vertebræ*, or *Pott's disease*. It was formerly supposed that compression of the cord was due to the narrowing of the spinal canal in consequence of the angular curvature of the spine, or *kyphosis*, frequently produced in this disease. It is indeed certain that in rare instances the cord is compressed by the displaced vertebræ, but that this displacement is not necessarily or usually the cause is proven by the following facts: Extreme angular curvature may exist without symptoms of compression; these symptoms may be present in Pott's disease without curvature; and the symptoms may disappear while the kyphosis remains unchanged. We owe to Michaud,¹ a pupil of Charcot, the explanation of the mechanism of compression in these cases. By extension of the diseased process from the vertebræ to the perimeningeal tissue and the outer layer of the dura mater a peripachymeningitis and a pachymeningitis externa are set up, leading to the formation of new connective tissue and of pus, which undergo in part a caseous metamorphosis. The caseous purulent mass thus formed between the bone and dura mater and in the substance of the dura mater is really the agent of compression. There may be an extension of the inflammation to the inner layers of the dura and to the other membranes of the cord, but this is not necessarily the case.

Compression renders the cord anæmic and flattened, and if protracted leads to inflammatory changes which present the picture of a transverse myelitis followed by secondary ascending and descending degenerations. This is known as *pressure myelitis*. In a given case it is not always easy to determine how much of the disturbance is due to compression and how much to myelitis; but that compression often plays an important part is proven by the fact that the symptoms may rapidly disappear as soon as the cause of compression is removed.

It is obvious that the SYMPTOMATOLOGY in different cases of compression of the cord must vary very much according to the cause, the seat, the amount of pressure, the nature and extent of the induced changes in the cord, etc. Diseases of the vertebræ, as well as fractures and dislocations, are determinable causes. The existence of an intraspinal tumor can hardly be determined with certainty, and, assuming that a tumor exists, to determine its character from the symptoms is impracticable.

The prominent symptom in cases of compression from different causes is paralysis, greater or less in degree (paresis) or complete. The extent of the paralysis will of course depend on the seat of the affection. If seated in the cervical portion of the cord, it may give rise to general spinal paralysis. In very rare instances the paralysis may be paraplegia of the upper limbs, the lower limbs remaining unaffected. If the compression be limited to one-half of the cord, which is extremely rare, the result may be spinal hemiplegia with crossed anesthesia, as described by Brown-Séquard.

Much more frequently the paralysis has the form of paraplegia affecting the lower limbs. If the spinal affection be above the lumbar region, and if the latter be not involved, reflex action is not diminished, but is often increased. The increase is sometimes so great as to occasion severe contractures and rigidity. Reflex action is diminished or lost if the spinal affection involves the gray matter of the lumbar region. Motor paralysis is often neither

¹ *Sur la Méningite et la Myélite dans le Mal vertébral*, Paris, 1871.

accompanied by anæsthesia at the outset nor after a considerable period. The paralysis may or may not involve the bladder or rectum. Sooner or later, if lesions of the cord be progressive, these organs become involved, the paralysis of motion and sensation becomes complete, and death takes place, as when equally destructive lesions occur independently of tumors or the various causes of compression.

Pain in the spine, in parts of the trunk below the level of the spinal affection, and in the paralyzed limbs (*paraplegia dolorosa*) is especially marked in cases of cancer of the vertebræ extending to the cord. This symptom may be more or less marked, however, in other forms of disease. It is presumptive evidence of an intraspinal cancerous tumor that prior to the affection of the cord cancer existed in some other situation. That an affection of the cord is syphilitic is to be suspected whenever the patient has had syphilis; and with reference to treatment it is very important to seek for evidence of syphilis, although the existence of this disease be denied by the patient. It is to be considered that women may have been affected with syphilis without any suspicion on their part of the nature of the disease; and there are instances in which the physician must derive his knowledge on this point wholly from what he is able to observe without exciting by his questions any suspicion in the mind of the patient.

It is an important practical fact that the spinal cord may tolerate compression sufficient to cause paralysis for a long period without disorganizing changes. This is shown by the immediate disappearance of paralysis from displacement of vertebræ, in some cases after it had existed for years.

The PROGNOSIS, of course, varies in individual cases according to the nature of the tumor and the different causes of compression; but inasmuch as the nature of intraspinal tumors is rarely determinable with anything like precision, an opinion in cases of tumor concerning the probable course and termination must have another basis. In general, the prognosis is unfavorable in proportion as motor paralysis is progressive, as sensation is impaired, reflex excitability diminished, and as atrophy of the muscles takes place; in other words, in proportion as the symptoms denote destructive lesions of the cord.

In cases of pressure from displacement of vertebræ, recovery from paralysis or more or less improvement may be expected from measures to remove the cause of compression. In another work I have cited a case in which a patient who had been confined to the bed with paraplegia for three years, having suffered greatly during this period from pain and reflex muscular action, immediately recovered the use of his limbs under the treatment by Prof. Sayre according to his method of suspension and encasing the body in a plaster-of-Paris jacket.¹ This method secures extension of the spine and renders the spinal column immovable—objects of prime importance in cases of existing displacement and disease of the vertebræ leading thereto. As a means of securing rest it may be found to have a wider extent of useful application than has as yet been demonstrated.

The syphilitic alone, of the different tumors, offer encouragement in the way of medicinal treatment. Antisyphilitic medication sometimes accomplishes much, and it should be employed whenever there is ground for the suspicion that the spinal affection may be due to syphilis.

In other respects the treatment indicated is essentially the same as in cases of chronic primary spinal meningitis and myelitis.

¹ Vide *Clinical Medicine*, 1879, p. 560.

Pseudo-hypertrophic (or Myo-sclerotic) Paralysis.

The characteristics of this affection were first pointed out by Merton in 1858. It was, however, more fully described and its nosological individuality established subsequently by Duchenne. The affection is peculiar to infancy and childhood. It has been known, however, to occur at the age of twenty-six years. In a number of instances the disease has affected several members of the same family, the males oftener than the females.

The distinctive features are increase of the volume of certain muscles and diminished motor power. The muscles of the lower limbs are generally first affected, especially the gastrocnemii or the glutei. Subsequently the affection may extend to the muscles of the trunk and of the upper extremities. Corresponding muscles on the two sides may be affected, but there are many exceptions to this rule of symmetry. Not infrequently the affected muscles are irregularly distributed and the affection may be limited to portions of muscles. The increase of volume may be considerable, and the enlarged muscles are in striking contrast with those not affected.

The anatomical changes in the affected muscles are—hyperplasia of the areolar tissue, an accumulation of adipose tissue between the muscular fibres, and atrophy of the latter. As regards its pathological character the disease belongs in the category of sclerotic or cirrhotic affections. The enlargement of the muscles denotes "false hypertrophy."

The structural changes involve diminution of motor power proportionate to the compression and consequent atrophy of the muscular fibres. Seated in the muscles of the lower limbs, the affection causes a peculiar waddling gait, the limbs in walking being widely separated. If the extensor spinal muscles be affected, a lumbo-sacral anterior curvature takes place when the posture is upright. Frequently, the affection predominating in the flexor muscles of the foot, talipes equinus is a result of the greater action of the extensors, and with this is a claw-like deformity of the toes. After having reached a certain degree and extent, the affection may remain stationary for several years; but at successive epochs it is likely to increase and to become more and more diffused, until patients are reduced to a helpless condition. The progress of the affection is unattended by pain. There is neither hyperæsthesia nor anæsthesia. The functions of the bladder and rectum are unaffected. In an advanced stage the electro-contraction of the affected muscles is notably diminished or lost, but there is no reaction of degeneration. In a case reported by Dr. Balthazar Foster, after the lapse of five years the volume of the affected muscles became as much reduced as it had previously been increased.

It has been a pathological question whether this disease be a purely myopathic affection or whether it be primarily neuropathic. In a number of typical cases no lesion has been found in the spinal cord, so that the weight of evidence is in favor of the view that pseudo-hypertrophic muscular paralysis is due to a primary affection of the muscles of the nature described.

As regards the PROGNOSIS, a case reported by Benedikt is cited by Jaccoud in which a cure was effected by galvanism. Experience, however, thus far affords little encouragement to expect a cure from any measure of treatment. Electricity should be faithfully tried. By measures having reference to the general condition of the patient the affection may perhaps be prevented from progressing, and there may be more or less improvement. The disease rarely destroys life *per se*, death being due to some intercurrent affection. The duration in 13 cases in which the termination was ascertained, out of 85 cases analyzed by Dr. C. T. Poore, varied between two and thirty years.¹

CHAPTER V.

FUNCTIONAL DISEASES OF THE BRAIN AND SPINAL CORD.

Coma.—*Saturnine Encephalopathy.*—*Vertigo and Ménière's Disease.*—*Paralysis, Remarks on.*—*Treatment of Functional Paralysis.*—*General Paralysis.*—*Hemiplegia.*—*Paraplegia.*—*Acute Ascending Paralysis.*—*Nervous Asthenia, or Neurasthenia.*—*Spinal Irritation.*

FOLLOWING the inflammatory and structural diseases of the brain and spinal cord, certain functional affections referable to these central parts of the nervous system may be more advantageously considered as forming a separate group than as included among the neuroses, which will occupy the concluding chapter of this section. The group will embrace the following affections: coma, saturnine encephalopathy, vertigo, general paralysis, hemiplegia, paraplegia, acute ascending paralysis, nervous exhaustion or neurasthenia, and spinal irritation.

It is to be understood, here and elsewhere, that the term functional is used provisionally, in a conventional sense, to distinguish diseases without any established anatomical characters. In a literal sense a purely functional disease probably has no existence. In other words, disturbance of function always involves some anatomical change; but in the diseases which, for the sake of convenience, are distinguished as functional either anatomical changes have not been ascertained or their pathological connection with these diseases is doubtful.

Mental disorders are properly embraced among the functional affections of the brain. They do not usually enter into the course of instruction in the Principles and Practice of Medicine. They are, however, to be included within the range of the studies of the physician. Lectures and treatises are devoted specially to these disorders, and their management constitutes one of the specialties of medical practice; but all practitioners are called upon to treat affections of the mind falling short of well-marked insanity. Melancholia and hypochondriasis in their lighter grades—that is, not amounting to insanity—come constantly under the notice of the physician in general practice. Want of energy, lack of buoyancy, mental apathy, and inertia often exist without any obvious disease. The physician should consider these as generally denoting corporeal ailment; and this should be impressed upon the minds of patients, since they are thereby led to reformations and measures of management which will be likely to afford relief, and are better enabled to strive against the depressing influence of mental disorder. A vast amount of unhappiness is due to causes which under intelligent medical direction may be removed, or to functional morbid conditions which judicious treatment may relieve. It is a grave error to attribute disorders of the mind exclusively to mental causes. These few remarks open up a subject of great importance. Insanity is to be prevented by the general practitioner. They who devote themselves to the treatment of the insane have not the opportunity of preventing the development of insanity.

The study of mental disorders is important to the physician as involving questions of medical jurisprudence. The existence or otherwise of insanity sufficient to require or warrant confinement in institutions for the insane, the exemption of responsibility for criminal acts, incompetency to perform legal obligations, to take care or dispose of property, etc., are practical questions concerning which physicians are called upon to give testimony; but for

information bearing on these questions the student and practitioner are referred to works treating of disorders of the mind and of medical jurisprudence.

Coma.

The term coma expresses a state of unconsciousness from which the patient either cannot be aroused or is aroused with more or less difficulty. It is customary to apply this term to extreme degrees of unconsciousness, more correctly expressed by the terms lethargia and carus. The latter term denotes a degree in which the patient cannot by any efforts be aroused. This degree is generally called profound coma. Sopor expresses an abnormal degree of somnolence, or moderate coma. A patient in this state is often said to be semi-comatose. Coma differs from normal sleep qualitatively as well as quantitatively. Sleep is a physiological event of essential importance to the welfare of the economy. Coma is a pathological condition from which the system derives no benefit. It follows that coma is never a substitute for sleep.

Coma is a symptom occurring in most of those diseases of the brain which have been considered—namely, hyperæmia and anæmia of the brain, thrombosis and embolism, cerebral and meningeal hemorrhage, meningitis, encephalitis, and tumors. In all these affections, except perhaps active hyperæmia, the rationale of the coma is a diminution of the supply of oxygenated blood to the brain-substance. Coma may be an effect of cerebral anæmia (ischæmia) due to impoverishment of the blood and enfeebled circulation, as in the hydropcephaloid affection first described by Marshall Hall. (Vide p. 590.) Coma is a pathological element in certain of the neuroses which remain to be considered—namely, epilepsy, hysteria, and catalepsy. It is an incidental event in various diseases exclusive of those of the nervous system; examples of which are acute and chronic affections of the kidneys, acute yellow atrophy of the liver, pernicious intermittent fever, scarlet fever, smallpox, typhus and typhoid fever, diabetes mellitus, etc. It may be produced by such toxic agents as opium and other narcotics, alcohol, ethers, chloroform, etc. The sudden loss of consciousness at the instant of the attack in epilepsy is attributed to cerebral anæmia caused by spasm of the arteries within the brain. Of the other instances, the causation of the coma involves a toxic agency certainly in some, and probably in most if not in all cases. The nature of these agents in the general diseases just named and their *modus operandi* are not understood.

There are cases of coma not connected with any of the foregoing diseases, and not clearly referable to any known morbid condition of the brain. The coma is then to be considered and treated as an individual affection. It is, of course, in these as in other cases merely a symptom, but the pathology, and perhaps the etiology, are unknown or conjectural. The coma may be greater or less in degree, sometimes not exceeding stupor, and sometimes so profound as to constitute carus. It may occur suddenly, constituting a veritable apoplectic attack, or it may be developed more or less slowly. It may last for a few hours or it may continue for several days. It may end, sooner or later, either in death or recovery.

In fatal cases morbid conditions may be found after death which were not determinable during life; examples are—thrombosis of the basilar artery or of the longitudinal sinus and meningeal hemorrhage. The two former of these conditions not many years since would have escaped recognition as causes of the coma; and so further developments in pathological anatomy may furnish an explanation, post-mortem, of cases in which adequate morbid

appearances are not now discoverable. In the progress of etiology, too, toxic agents causing coma may be discovered, of which now nothing is known. It is not an unreasonable expectation, in view of the fact that urea and Mesturin have only within a few years been recognized as coma-producing principles.

Coma in some instances seems attributable to cerebral exhaustion; that is, follows prolonged or excessive mental activity in conjunction with impaired nutrition and general debility. It must be confessed that the term cerebral exhaustion does not embody any clear idea of the pathological condition which the coma represents, but it has a practical significance in relation to the causation and treatment. Of course, in deciding that coma is to be regarded as a functional affection the various diseases and determinable morbid conditions with which it is known to have pathological connections are to be excluded. Recognizable internal toxic agents, *e. g.* urea, and those which are external, *e. g.* opium, alcohol, etc., are also to be excluded. The diagnosis involves a careful investigation of the causation in these different directions.

Assuming a case in which the pathology and etiology are not determinable, the prognosis and treatment must be based upon circumstances pertaining to the coma. Other things being equal, the prognosis is unfavorable in proportion to the degree and duration of the coma. If the patient cannot be aroused sufficiently to open the eyes or protrude the tongue, the danger is great, and it increases with the continuance of the comatose state. When the ability to swallow is lost a fatal ending is to be expected. *Per contra*, if the coma be moderate in degree the prognosis is favorable. Absence of paralysis, the temperature of the body not increased, mobility of the iris, the pupils neither contracted nor dilated and equal in size, the ophthalmoscopic appearances normal, the respirations quiet and of regular rhythm,—these are points of importance in the exclusion of grave cerebral diseases and in their bearing upon a favorable prognosis.

The TREATMENT is to be governed by the symptomatic indications in individual cases. These rarely, if ever, point to depletion by bloodletting or other depressing measures. The opposite treatment is usually indicated by feebleness of the circulation and general debility. Supporting treatment is especially indicated in feeble subjects and when cerebral exhaustion is an etiological factor. It might prove a serious error, under these circumstances, to pursue therapeutical measures on the supposition of the existence of cerebral meningitis or hyperæmia.

The propriety of counter-irritation is doubtful. Rest, alimentation, nerve-tonics, and the judicious employment of wine or other alcoholics are the measures which generally meet the indications present.

Saturnine Encephalopathy.

A rare form of poisoning by lead is characterized by cerebral disturbances of a grave character—namely, coma, convulsions, and delirium. These three events are combined in a considerable proportion of cases. An attack may occur either abruptly or after certain premonitory symptoms. These are—headache, vertigo, ringing in the ears, and in some instances amaurosis. Other manifestations of lead-poisoning—paralysis, arthralgia, colic—may or may not precede the encephalopathic attack. The coma is more or less profound. In favorable cases it disappears after having continued for one or two days. In unfavorable cases it increases in degree and continues until death. The convulsions are epileptiform in character (eclampsia vel epilepsia saturnina). Paroxysms lasting from five to twenty minutes occur after variable intervals. The delirium is in some cases active and violent, and in

other cases hilarious. It is sometimes characterized by hallucinations of sight and hearing. Either of the three events may be predominant. Coma and convulsions in some instances occur without delirium, and coma between the paroxysms of convulsions is sometimes wanting. Amaurosis, if it does precede, is likely to accompany, the attack. The amaurosis is not caused by retinal changes, and the ophthalmoscope shows the normal appearances.

A satisfactory pathological explanation of these effects of lead-poisoning cannot be given. They have been attributed to anæmia of the brain from changes in the minute cerebral arteries, to œdema of the brain from increased arterial pressure, and to the direct irritation caused by the presence of lead. Uræmia is probably a pathological element in some cases. The urine is diminished in quantity, and has been found to contain albumen. The effects, however, are not in all instances referable to uræmia, inasmuch as the evidence of diminished elimination of urea is not always present. Heubel has produced similar effects in dogs by poisoning them with lead, and this is one of the recognized causes of the so-called gouty or small, granular kidney.

The PROGNOSIS is grave in proportion to the frequency and violence of the convulsions, together with the degree and continuance of the coma. The rate of mortality has not been definitely ascertained, but the proportion of fatal cases is large.

There is little to be said with reference to the TREATMENT. Depletory or debilitating measures are contraindicated. It should be ascertained, by examinations of the urine, how far uræmia may be a factor in causing the coma and convulsions. Hydragogues and sudorific measures are indicated if there be ground for supposing that there are symptoms of the accumulation of urea in the blood. The inhalation of chloroform or the administration of the chloral hydrate may be resorted to in order to control the convulsions. The iodide of potassium should be given to the extreme of toleration.

Vertigo—Ménière's Disease.

Vertigo is a symptom occurring in various cerebral diseases, and also when it is to be regarded as an individual functional affection. In this article it is considered as a functional affection and as a symptom of Ménière's disease. It occurs as a paroxysmal affection. A person seemingly, perhaps, in good health suddenly becomes giddy, surrounding objects appear to be revolving, or the person seems to himself to be performing movements of gyration, which, according to Charcot, always appear to be from the left to the right. The sensation is like that caused by long-continued rotatory movements of the body. If the vertigo be moderate or slight, it simply renders the person unable to walk steadily. He reels like a drunken man. In a greater degree walking is impossible, and there may be inability to stand without support. In some instances the patient falls, but without loss of consciousness and without muscular spasm of either the facial or other muscles. The attack is accompanied by a sense of prostration, which, however, is due in no small degree to apprehension. Nausea is a frequent symptom, and vomiting sometimes occurs. The paroxysm varies much in duration in different cases. It may last for a few moments or the vertigo may continue for hours and days.

Successive attacks recur after variable intervals. Days, weeks, or months may intervene. In some cases vertigo for a certain period may be produced by slight exciting causes, such as any intellectual effort, sudden muscular exertion, looking upon a bright light, etc. A patient may be exempt while in the recumbent posture, but he may experience vertigo whenever the attempt

is made to sit up or stand. For this reason patients sometimes keep the bed for a long period.

Attacks of vertigo generally give rise to great apprehension. The patient fears that apoplexy, paralysis, or a fit of some kind is impending. If the apprehension be not removed by positive assurances from the physician of the absence of danger, it may lead to a distressing state of despondency. The patient is afraid to walk or to be left alone, and all public assemblages are avoided, lest something may happen to him to excite disturbance. In a case which has been under my observation the patient, a gentleman in middle life, notwithstanding assurances of the absence of danger, has for many years been constantly attended by either a relative or a servant, although a long period has elapsed since an attack occurred and his health is excellent. This state of anxiety has repeatedly, in cases under my observation, continued for months and years. The physician is fully warranted in giving positive assurances that these attacks of vertigo are devoid of danger. Of a large number of cases which I have observed, in no instance has apoplexy, paralysis, epilepsy, or any serious affection followed. It is an unfortunate error to state, as is done by some writers, that vertigo is premonitory of the cerebral affections just named. The needless apprehension of patients is sometimes encouraged by the fact that it is shared by the physician. I have met with cases in which danger of apoplexy and paralysis has been represented to the patient. Charcot relates a case in which the attacks were confounded with epilepsy, the patient having for a long time been under treatment for that disease. Assurances of the absence of danger may do much good, not only by removing needless apprehension, but in the way of effecting a cure; for the mental anxiety occasioned by the attacks increases the liability to their recurrence.

Of the PATHOLOGY of vertigo more cannot be said than that it represents a functional cerebral condition. Its etiological relations are better understood. A French writer, Ménière, in 1861 pointed out the supposed connection of a disease characterized by deafness and vertigo with an affection of the semi-circular canals of the internal ear. Subsequent clinical observations have established this causation in a certain proportion of cases. The vertigo is not infrequently preceded and accompanied by tinnitus aurium, sometimes referred to one ear and sometimes to both ears. Sudden deafness in one ear or in both ears has been observed to be coincident with the attacks of vertigo. The attacks have been found to cease on the cure of suppurative otitis, and even on the removal of an accumulation of wax or a foreign body from the meatus.¹ The most rational explanation is that a reflex influence exerted upon the brain emanates from the aural organs. The affection in these cases is now known as *Ménière's disease*.

All cases of functional vertigo are not cases of *vertigo ab aure læsa*. In perhaps the larger proportion there is no evidence of aural disturbance. Dyspeptic ailments appear to be causative in some cases, but not constantly as contended by Trousseau, who called the affection stomachal vertigo (*vertigo a stomacho læso*). It is sometimes fairly attributable to prolonged over-tasking of the mental faculties and anxiety of mind. Excessive venery, the immoderate use of tobacco, and intemperate indulgence in coffee or tea have a causative influence. It may be incident to the debility which remains after convalescence from a severe disease; for example, typhoid fever. DaCosta attributes it in some cases to lithæmia (uricæmia).²

The TREATMENT involves, as the first and most important measure, removal

¹ Vide "A Clinical Analysis of the Inflammatory Affections of the Inner Ear," by H. Knapp, in *Archives of Ophthalmology*, 1871, vol. ii. No. 1.

² Vide *Am. Journ. of Med. Sciences*, Oct., 1881.

of the supposed cause or causes. The ears should be carefully examined with reference to removable morbid conditions. Measures addressed to cerebral congestion—namely, bloodletting, counter-irritation, purgation, or reduced diet—are hurtful. On the contrary, tonic remedies, a nutritious diet, and hygienic means of invigorating the general health are generally indicated. The practitioner should bear in mind the importance of assuring the patient positively of the absence of all danger. This will sometimes do much toward the cure. A cure is often soon effected, but in some cases the disorder persists for a long time. Charcot extols the efficacy, in cases of vertigo, of quinia given in full doses (20 grains) for several weeks. [In the same form of vertigo Hirt strongly recommends the hypodermic injection of 9 or 10 drops of a two per cent. solution of pilocarpine. The injections are administered every second day, and should be continued for several weeks. This method of treatment is somewhat debilitating, and should only be employed in comparatively robust individuals.—H.]

Paralysis—General Remarks.

Paralysis is an important symptomatic event in the clinical history of different cerebral and spinal diseases which have been already considered. It is not always referable to either an inflammatory or a structural disease, and it is then to be distinguished as functional.

By the term paralysis is understood either the loss or an abnormal diminution of voluntary power over muscles. The term is also applied to the loss or a diminution of sensibility. The latter is sensory and the former motor paralysis. Sensory paralysis, however, is expressed by the terms *anæsthesia* and *analgesia*; the first relating to the sensibility to touch, and the second to the sensibility to pain. Analgesia may exist without anæsthesia. A patient, for example, partly under the influence of chloroform or ether, may feel the cutting of the knife in a surgical operation, but without any sensation of pain. On the other hand, the loss of sensibility to touch (anæsthesia) carries with it the loss of sensibility to pain (analgesia). Cutaneous analgesia is ascertained, clinically, by pinching or pricking the skin. Anæsthesia is ascertained by measuring the distance from each other at which two points in contact with the skin are recognized. An instrument devised for this purpose, called the *æsthesiometer*, may be used, but the common compasses used by the draughtsman will answer as well, and, if these be not at hand, two pins will suffice. The farther the two points of contact must be removed from each other in order that each may be separately felt, the less the sensibility to touch. The sensibility is undiminished if the patient be able to feel two points of contact approximated as closely as they are when appreciable in health. The sensibility to touch differs in different parts of the body considerably in health. It is most acute on the prolabia, the tip of the tongue, and the ends of the fingers. These normal differences are to be taken into account in judging of anæsthesia, and also variations within normal limits in different healthy persons and in corresponding situations on the two sides of the body. Moderate deviations from the average degree of sensibility, as thus tested, or from an exact uniformity of the two sides, are not to be considered as abnormal without corroborative evidence of sensory paralysis.

Motor paralysis is expressed by the term *akinesia* or *akinesis*. The term paralysis, however, is generally used instead of this term, and if not designated as either sensory or motor the latter is understood. Paralysis may affect either the voluntary or the involuntary muscles. The heart, œsophagus, stomach, intestines, bladder, and arteries may be the seat of akinesia.

This pathological condition enters into the consideration of these organs in other sections of this work.

Under the name *erythromelalgia* Dr. S. Weir Mitchell¹ first called attention to an affection characterized by vaso-motor paralysis of the vessels of the extremities. Males more than thirty-five years of age are most frequently affected. The symptoms are burning pain in the feet, rarely in the hands, accompanied by flushing and congestion of the part, which may be somewhat swollen. The temperature of the part is increased. The sensation is normal or it may be sometimes increased. There are no trophic troubles. Erythromelalgia is an interesting counterpart to the disease known as local asphyxia or symmetrical gangrene, which is caused by vaso-motor spasm.

Paralysis is complete when there is total loss of voluntary power over the paralyzed muscles. It is incomplete when this power is not entirely lost, but is more or less diminished. The term *paresis* is often used in a sense equivalent to that of incomplete paralysis. Incomplete paralysis or paresis differs, in different cases, between the slightest appreciable impairment of the normal motor power and a degree approaching as closely as possible completeness. Paralysis is general when it embraces the muscles of the four extremities, either with or without the muscles of the face. It is partial when a portion of the muscular system is involved, as in hemiplegia and paraplegia. It is local when a very few muscles, or perhaps a single muscle only, are paralyzed.

Paralysis may be *neuropathic* or *myopathic*. A myopathic paralysis depends on a primary morbid condition of the muscles paralyzed. A neuropathic paralysis depends on some cause which either prevents the action of volition upon the cerebral fibres which are continued into the nerves going to the paralyzed muscles, or obstructs the transmission of volition at some point between the muscles and the part of the brain in which the voluntary act originates. For the performance of voluntary motion there are three requisites—namely, the communication of the voluntary influence to certain parts of the brain, the conduction of this influence from the brain through motor nerves, and the ability of muscles to contract in obedience to the will. Paralysis may depend on causes involving primarily either of these three requirements.

An important division of neuropathic paralyses is into central and peripheral. Central paralyses depend on morbid conditions seated in either the brain or spinal cord, and they may be further divided into cerebral and spinal. Peripheral paralyses depend on morbid conditions affecting nerves at any point between their terminations and their central connections with either the brain or the spinal cord. Paralyses are peripheral when they depend on affections of cranial or spinal nerves within the skull or spinal cord.

There are certain points of difference in the effects of cerebral, spinal, and peripheral paralysis, respectively, which are of practical importance as regards localization of causative conditions and differential diagnosis. In cerebral paralyses the reflex excitability of the affected muscles is retained and may be increased. The electrical excitability is also the same as in health, or it may be increased. The muscles do not speedily become atrophied. The cutaneous sensibility is often undiminished, or it is not diminished in proportion to the motor paralysis, and is regained in a short time, although the loss or impairment of the voluntary power over the muscles remains. In spinal paralysis the paralyzed muscles may or may not retain their reflex and electrical excitability, the differences in these respects being dependent on the situation of the affection of the cord, together with the degree and the extent of lesions. The reflex excitability is sometimes notably increased. Sensibility may be either

¹ *Am. Journ. Med. Sciences*, July, 1878.

retained, diminished, or lost. There may or may not be trophic disturbance. These points have entered into the clinical history of the different special affections which have been considered.

The characteristics of peripheral paralysis will be considered in the next chapter. The reaction of degeneration, which is of much value in the diagnosis of the different kinds of paralysis, has already been described (p. 673).

The foregoing remarks relate to paralysis dependent on different pathological conditions. Paralysis which are dependent on molecular changes not appreciable, or on histological lesions not yet ascertained, and which are therefore to be considered at present as functional, generally end in recovery. Their duration is variable. It may be but a few hours, and even minutes, or, on the other hand, days, weeks, and months. The paralysis is in some cases intermittent. The recovery is sometimes abrupt, and sometimes it takes place after a more or less gradual improvement. The paralyzed muscles do not waste, except as an effect purely of disuse. There may be anæsthesia or the cutaneous sensibility may remain unaffected. In functional paralysis the electrical excitability is retained, and the phenomena of the "reaction of degeneration" are wanting. Reflex excitability is sometimes retained and sometimes diminished or lost. The circumstances under which the paralysis occurs, and their pathological relations, are of importance in the discrimination. The paralysis which often follow diphtheria, and sometimes other acute febrile diseases, are generally to be considered as functional, although these diseases may be followed by organic paralysis, usually of spinal or of peripheral origin. The so-called hysterical paralysis are examples of typical functional paralysis. The association of paralysis with these affections is often of significance with regard to diagnosis. Causative circumstances are to be taken into account. Functional paralysis may be referable to exhaustion from prolonged muscular exertions and to the action of cold. There is no pathological propriety in calling the paralysis attributed to the latter cause rheumatic; and clinical experience affords no proof of any relationship between paralysis *a frigore* and rheumatism.¹ The so-called reflex paralysis will be presently noticed in connection with paraplegia. Finally, the functional character of paralysis may be inferred from the probable causation by certain vegetable poisons, such as ergot, tobacco, lathyrus sativus, absinth, camphor, etc. Saturnine paralysis may be regarded as peripheral, and these will be considered in the next chapter. Other differential points relate to the particular varieties of functional, cerebral, and spinal paralysis—namely, general paralysis, hemiplegia, and paraplegia—and will be noticed in connection with these disorders.

Treatment of Functional Paralysis.

In the treatment of functional paralysis a primary object is the removal of supposed direct or indirect causative agencies. Exhaustion from over-exertion of body or mind is an indication for rest. Toxic agents, tobacco, etc. should not continue in operation. Anæmia claims appropriate therapeutic and hygienic measures. Cystitis, phimosis, or other local diseases which may

¹ The usage of German writers in designating as rheumatic all affections supposed to be produced by exposure to cold has been adopted by some English writers, but it is not to be recommended. Under the name "paralysis from commotion" German writers embrace cases in which the affection is due to injury, but without appreciable lesions. (Vide Eichhorst, *Handb. d. Spec. Path. u. Therap.*) Cases in which paralysis occurs after a variable period dating from railway accidents have been described, especially by Erichsen. These cases have been considered as important in a medico-legal point of view.

be suspected of standing in the relation of causes by means of a reflex influence or in other ways should receive proper attention.

Of remedies having direct reference to the paralysis, electricity holds the first rank. Experience shows the usefulness of both the faradic and the galvanic current, individual cases differing as regards the superiority of the one over the other. There need not be that delay in resorting to electricity which is an important precaution in cases of paralysis dependent on diseases involving inflammation. Care, however, is to be taken not to employ too strong currents, or to prolong or repeat unduly their applications. For practical details the reader is referred to works which treat specially of electricity as a curative agent. Its curative efficacy must consist in its effects upon the functional activity of the nerves and muscles involved in the paralysis, on the circulation in these parts, and on their nutrition. Its action is that of an excitant, and it is evident that if carried too far it may do harm rather than good. The success of electrical treatment in all paralytic affections will depend on the exercise of judgment in determining the indications in particular cases, and on skill in its employment. The advantage of experience in its practical application, together with the time and appliances which it requires, renders it desirable that some physicians should give to it special attention. Hitherto, the employment of electro-therapeutics in this country has been too much in the hands of uneducated practitioners who know but little of the agent which they employ, and still less of the human organism.

Friction and massage, or kneading with deep pressure, are important measures of treatment. Stimulating liniments facilitate the rubbing, and are to a certain extent in themselves useful. These measures are serviceable by promoting the circulation and maintaining nutrition. They should be systematically carried out and persisted in. If the paralysis be complete, passive movements are important. They should be resorted to daily, and continued as long as they are tolerated without fatigue. If the paralysis be incomplete, daily exercise of the paralyzed muscles by means of the will is of more importance than any remedial measure. As much exercise of the paralyzed muscles as can be taken without fatigue is desirable. The physician should impress the importance of this measure, the more because patients are slow to appreciate it.

Douches of alternately cold and warm water are useful. They should not be continued long enough to be followed by uncomfortable sensations; on the contrary, it is desirable that they should give rise to agreeable effects. Benefit is also often derived from the use of the sponge-bath followed by brisk friction.

Of drugs, strychnia or nux vomica and phosphorus are to be recommended. Whether or not they have any specially curative effect, clinical experience affords evidence of their utility.

General Paralysis.

The disease known as general cerebral paralysis, general paresis, or the paralysis of the insane (*dementia paralytica*) is fully considered in works devoted to the subject of insanity. Exclusive of this disease, general paralysis referable to intracranial morbid conditions is rare. It may be a result of two attacks of hemiplegia, the first attack affecting one, and the second the other, side. Hemorrhage in the central portions of the pons varolii or in the medulla oblongata may give rise to double hemiplegia, or, in other words, general paralysis. Instances of general paralysis involving muscles supplied by cranial nerves are among the curiosities of clinical experience. In a case

under the observation of the late Prof. Coventry power was lost over all the voluntary muscles except the orbicularis palpebrarum and the respiratory muscles. Paralysis following diphtheria has been known to involve not only the extremities, together with the neck and trunk, but the muscles of the face, throat, and mouth. The intellect in these cases may be intact; excito-motory or reflex movements perhaps remaining unaffected, respiration, deglutition, digestion, and all the functions necessary to existence going on, but, as regards voluntary manifestations, the patient being in a state of living death. General paralysis involving cranial nerves has also been known to occur in connection with hysteria. In a case for many months under observation complete paralysis of the four extremities coexisted with incomplete bilateral paralysis of the face. The paralysis in this case was attributed to lead.

In the great majority of cases general paralysis is spinal. The seat in the spinal cord is to be inferred whenever cranial nerves are not involved and there are no symptoms denoting cerebral disease. General spinal paralysis, as has been seen (*vide* Chapters II. and IV.), is incident to inflammatory and structural affections of the spinal cord and its meninges. These are to be excluded in arriving at the conclusion that the paralysis is functional. The paralysis may be complete, or there may be a greater or less degree of paresis, and it may or may not be associated with anæsthesia. It follows diphtheria in rare instances, and is sometimes connected with hysteria. It was produced by woorara in a case of rabies, to which reference will be made in treating of that disease. It may be caused by exhaustion and exposure to cold. This causation was exemplified in the case of a man forty-five years of age, who during a severe snowstorm rode eight miles in a horse-car, standing on the rear platform, his back exposed to the storm. After reaching home he became unconscious for a short time, and on recovering his consciousness there was complete loss of motion and sensation below the head. He was disposed to somnolency, but was easily aroused, and his mental faculties were intact. I saw him on the fifth day after the date of the attack. Under a treatment consisting of stimulants, frictions, and nutritious food he had, in a measure, recovered from the paralysis. This treatment was continued, and in a short time the recovery was complete.

In functional spinal paralysis the paralytic condition may be developed rapidly or more or less gradually. The muscles of all the limbs may be simultaneously affected, or the paralysis may begin in one limb, the other limbs becoming successively affected. The bladder and rectum are rarely involved. The respiratory movements, as a rule, are not affected. Exceptionally there is much suffering from dyspnœa. I have known paralysis of the diaphragm to occur, as shown by the purely costal breathing and by inability to sneeze, although an intense desire and grimaces were produced by the introduction of snuff into the nostrils.

Recovery may take place after a few days or it may be delayed for many months.

Strümpell has reported a remarkable case of complete anæsthesia of the whole surface of the body, and in a nearly equal degree of the accessible mucous membranes. All kinds of sensation were lost. There was no sense of smell or of taste. There was complete amaurosis of the left eye and partial deafness of the right ear. The muscular sense was gone. The patient was not conscious of muscular contractions or of fatigue. Some reflex action was preserved. There was motor paralysis of the right arm and leg, but none on the left side. The movements of the non-paralyzed limbs were normal when controlled by the eye. If the eye in which the sight was preserved were closed, the movements were uncertain, although not ataxic. The

patient at once fell asleep when the eye and the ear in which the perceptions were preserved were closed.

Hemiplegia.

Except when due to cerebral affections which have already been considered—namely, hemorrhage, softening from thrombosis or embolism, encephalitis, and tumors—hemiplegic paralysis is of infrequent occurrence. Examples of functional hemiplegia are as follows: Cases have been reported in which it took place suddenly during strong mental excitement, as in a fit of violent anger, recovery being sometimes speedy and sometimes slow. Todd designated the affection, in these cases, *emotional hemiplegia*. It sometimes follows epilepsy. In a case under my observation in which epileptic paroxysms recurred at short intervals for several days, hemiplegia occurred before the series of paroxysms had ceased, the face as well as the limbs on one side being paralyzed. The paralysis disappeared completely after a few days. Hysterical paralysis is sometimes hemiplegic. The face and tongue are not involved, and as a rule the left side is paralyzed. Hemiplegia may follow chorea, the limbs paralyzed being those of the side more affected with the choreic movements. The paralysis in these cases does not extend to the face or tongue. The paralysis which follows diphtheria is sometimes hemiplegic. I have known transient hemiplegia to follow insolation.

The following cases, stated as concisely as possible, will serve to illustrate hemiplegia from either embolism or thrombosis not giving rise to softening and hysterical hemiplegia:

A merchant, aged seventy-five, of active habits, attending daily to business, left his home in the morning in his usual health. He was observed to act strangely. He walked with difficulty and had trouble in moving his left hand. He was prevailed upon to return home in a carriage, although he insisted that nothing was the matter with him. In an hour after his return I saw him. He was somnolent, but easily aroused. There was paresis of the left upper and lower limbs and of the left side of the face. The tongue was deviated to the left side. On the following day there was marked improvement. The improvement continued, and on the sixth day recovery was complete, and he insisted on attending to his business as usual. There were no signs of cardiac disease. A little laurel-water and aconite were the drugs prescribed. He was allowed at once a nutritious diet. Six years afterward there had been no return of the paralysis and the patient was in good health. Thrombosis was the probable causative condition in this case.

A man, aged about seventy, after a long walk in the afternoon retired at night feeling well, and slept soundly until morning. On awakening there was paresis of the upper and the lower limb on the right side. The face and tongue were not involved, but there was aphasia, the patient being able to speak but a few words. Aside from these symptoms he had no ailment. His appetite was unaffected. The paralysis and aphasia disappeared in the course of a few days, no treatment being employed. Three years afterward he had had no return of paralysis and was in good health. The diagnosis in this case lies between thrombosis and embolism.

A case at my hospital clinic exemplified the occurrence, first of embolism, and afterward of thrombosis. The first attack was sudden, without loss of consciousness, and the paralysis was on the right side. The paralysis was complete, but after an hour it had entirely disappeared. Several months afterward hemiplegia again occurred. In this attack the paralysis was developed gradually, becoming nearly complete in the course of a week. In a few weeks there remained only a slight diminution of motor power.

Intermittent hemiplegia of very brief duration was exemplified in the case of a clerk, aged forty years, who at breakfast, while apparently in perfect health, had a sudden attack of complete hemiplegia of the right side, without loss of consciousness or any confusion of ideas. The paralysis disappeared completely in the course of an hour. During the following two weeks he had ten or twelve recurrences of the hemiplegia, the paralysis lasting for a few moments only, his health otherwise being perfectly good. The attacks then ceased to recur, and I learned several months afterward that he was well. This patient had had rheumatism, but there were no signs of cardiac disease.

A dressmaker, aged eighteen, a patient in Bellevue Hospital, exemplified hysterical hemiplegia. Three weeks before her admission, having retired perfectly well the previous night, in the morning she was unable to move the left lower limb. Sensibility was also lost. Toward evening she suddenly lost sensibility and the power of motion in the left upper limb. After a week she recovered power over the upper limb. The paralysis of the lower limb persisted. In walking with the aid of a crutch she dragged the paralyzed limb. There was no facial paralysis and the tongue was not deflected from a right line. There were no symptoms of cerebral disease. She had retention of urine, requiring the catheter, but after a time she succeeded in urinating, the physician in charge refusing to continue the use of the catheter. She was notably hysterical, and the *globus hystericus* was well marked. A month after her admission she was much frightened by a thunderstorm, and had hysterical convulsions. The cold douche promptly arrested the convulsions, and on recovering full consciousness she at once regained, almost completely, power over the paralyzed limb. The next day she walked without difficulty, and the following day went out of the hospital on a permit. Suddenly, after the lapse of a week, she again became hemiplegic on the same side as before. She recovered in a short time under the use of the shower-bath. She subsequently had paraplegia, with analgesia and anæsthesia. She recovered, and was discharged from the hospital well. This case illustrates the occurrence of *hemianæsthesia*, which in this instance and in the larger number of cases is of hysterical origin. *Hemianæsthesia* may be produced also by cerebral lesions. (See p. 615.) The loss of sensation may affect all forms of sensation, including the special senses.

Spinal hemiplegia, with motor paralysis on one side and anæsthesia on the opposite side, probably always implies a lesion limited to the half of the cervical portion of the cord on the side of the akinesia.

Instances have been observed of paralysis affecting the upper limb of one side and the lower limb of the other side. This form of paralysis has been called *hemiplegia cruciata* (not to be confounded with alternating paralysis, p. 615), and may be produced by lesions situated at the crossing of the pyramids in the medulla oblongata.

Malingers sometimes feign hemiplegia. They are likely to pretend that there is loss of sensation as well as of motion; and this should excite suspicion. Hughlings-Jackson has pointed out a method of discovering this deception. The malingerer keeps the arm close to the body when asked to stoop forward. In doing this he exerts a voluntary power over the limb. In hemiplegia when the patient stoops the palsied arm falls forward.

Paraplegia.

Paraplegia is to be considered as functional when the absence of any anatomical change is to be inferred from the symptoms and course of the affection. As a functional affection it is much more frequent in its occurrence

than general paralysis or hemiplegia. It is the most frequent form of hysterical paralysis. I have met with a case in which repeated attacks had occurred between the ages of seven and ten years, the patient being subject to other hysterical manifestations. It is a not infrequent sequel of diphtheria. It may be referable to exhaustion and exposure to cold. The following case is probably an example of sexual excess as a causative agent: A young woman admitted into Bellevue Hospital stated that she found both lower limbs completely paralyzed on awakening in the morning. She was subject to nocturnal attacks of epilepsy, and a paroxysm occurred during the night when the paralysis took place. She was a prostitute, and had had sexual intercourse with several persons on that night. There was complete loss of sensibility. Slight reflex movement could be excited. On the ninth day after her admission recovery of motion and sensation was complete, and she was well enough to be discharged on the thirteenth day, having had no treatment directed specially to the paralysis.

The subject of *reflex paralysis* has relation chiefly to paraplegia. Many clinical observers within late years have reported cases of paraplegia associated with various affections of different organs—the kidneys, bladder, uterus, ovaries, intestines, etc.; and a causative connection has been inferred from the fact that patients recover from the paralysis after recovery from their local affections. The latter, it is supposed, induce paralysis by a morbid influence transmitted through the reflex system of nerves; and hence the significance of the name *reflex paraplegia*. In order to establish a causative connection between different local diseases and paralysis it is necessary to show that the former precede the occurrence of the latter in a number of cases too large to be explained by mere coincidence. That facts sufficient to show this have been accumulated may fairly be doubted; and when, on the other hand, it is considered that the various local diseases supposed to have a causative connection are not associated with paralysis in the vast majority of cases, such a connection, when the association exists, is conjectural.

The pathological explanations of reflex paralysis are far from satisfactory. The theory of Brown-Séquard is that a reflex influence causes spasm of the arteries of the spinal cord, and that the paralysis is due to anæmia and defective nutrition thus induced. Assuming spasm of the vessels limited to a segment of the cord to be caused by a reflex influence, that this condition is persistent enough to produce the pathological effects attributed to it is highly improbable. Another explanation is that the supposed reflex influence has a paralyzing effect exerted through the vaso-motor nerves upon the arteries, and causes paraplegia by inducing congestion of the cord; but paraplegia does not take place in connection with diseases which must induce spinal congestion, such as the cold stages of intermittent fever, dilatation of the right side of the heart, etc.; and it is, to say the least, conjectural to include congestion of the cord among the causative conditions giving rise to paraplegia.

In some reported cases of supposed reflex paraplegia lesions of the spinal cord have been found after death. Leyden, Duménil, Weir Mitchell, and others think that the extension of neuritis centripetally sometimes to the spinal cord will explain the occurrence of paralysis in the cases in which it is supposed to be due to a reflex influence.

In view of these considerations the theory of reflex paralysis lacks a solid foundation.

Paraplegia may be an imagined disease. I have met with an instance in which this self-deception was diagnosticated, the case being analogous to one reported by J. Russell Reynolds, and called by him paralysis "dependent on idea." These cases are to be distinguished from cases of simulated paraplegia. I have met with the latter in connection with hysteria. Kunze

relates the case of a woman who, having kept the bed for a considerable time under the conviction that she had paraplegia, on the occasion of the house taking fire resumed instantly the use of her limbs, and on reaching the house of a relative at once became again a paraplegic. It is not easy to discriminate imagined paraplegia, inasmuch as hysterical paralysis may instantly be removed by a mental impression. This is seen in cases of aphonia from laryngeal paralysis. I have given the synopsis of a case in which paraplegia disappeared under the influence of fright during a thunderstorm. Caution is to be observed in the diagnosis; and if made the physician is to use discretion either in asserting that the supposed paralysis is imagined, or in employing electricity or some other method of treatment with reference to a physical influence, conjoined with a confident assurance that the treatment will be successful.

Acute Ascending Paralysis.

Under this name Landry in 1859 described a disease characterized by rapidly-developed paralysis, beginning in the lower extremities and extending to the upper extremities, and often to muscles supplied by nerves originating in the medulla oblongata. Sensation and the functions of the bladder and rectum generally remain normal. No anatomical lesions explaining the paralysis have been discovered. The disease is sometimes called *Landry's paralysis*.

After prodromic symptoms of an indefinite character, with slight fever, lasting for a few days and sometimes for several weeks, paresis of the lower extremities occurs. The paresis begins in the feet, and in the course of a few days extends over the limbs, the paralysis increasing in degree and becoming complete. The paralysis extends to the trunk, and thence to the upper extremities. The respiratory muscles are affected, and dyspnoea becomes a prominent symptom. Subsequently the muscles concerned in speech, mastication, and deglutition are involved. Death takes place by apnoea and by exhaustion from innutrition. The duration varies between a few days and several weeks, the average being from eight to twelve days.

The intellect remains intact, and those cranial nerves only are implicated which arise from the medulla oblongata. Sensibility of the skin and muscles is but little, if at all, affected. There is sometimes hyperaesthesia. The paralyzed muscles do not become atrophied; their electrical excitability is generally unaffected; and reflex excitability is not diminished until the latter part of the disease. The rectum and the bladder are not affected. There is usually fever, but not of a high grade.

In a small proportion of cases the disease ceases its progress before grave symptoms are manifested, and recovery shortly takes place.

The disease affects men oftener than women, and the majority of cases are in persons between twenty and forty years of age. Beyond these facts nothing is known of the etiology. The most plausible supposition concerning the nature of Landry's paralysis is that the disease is of an acute infectious character, with localization in the motor tracts of the spinal cord, perhaps in some cases in peripheral nerves. This view is supported by the occurrence of prodromic constitutional symptoms, by the existence of fever, the development of more or less enlargement of the spleen, and the frequent presence of albuminuria.

Clinical experience has thus far afforded no evidence of the success of any particular method of treatment. The iodide of potassium, nux vomica, the wet pack, and the galvanic current are recommended. Alcoholics, ammo-

nia, and stimulating tonics, together with sustaining nourishment, are indicated with a view to obviate the tendency to death.

Nervous Asthenia—Neurasthenia.

The term nervous asthenia or nervous exhaustion may be used to denote a morbid condition common in this country, especially in the larger cities. As the name signifies, debility, prostration, or exhaustion, affecting especially the nervous system, constitutes the affection. It occurs without anæmia or any notable disorder of the vital functions. It proceeds from undue functional activity of the nervous system connected with the exercise of the intellectual and emotional faculties. This morbid condition was considered as a distinct functional affection in the first edition of this work (1866). So far as I know, it had not been so considered prior to that date. Under the name neurasthenia, introduced by Beard, writers in this and in other countries have accorded to it a place among the functional disorders of the nervous system. Popularly, and to some extent among physicians, it is known by the name "nervous prostration."

Physicians are often consulted by patients who, although far from being well, have no well-defined malady. They complain of languor, lassitude, want of buoyancy, aching of the limbs, and mental depression. They are wakeful during the night and enter upon their daily pursuits with a sense of fatigue. Under the pressure of mental excitement they may be able to exert themselves with their usual energy, but when the excitement subsides they are jaded and worn out. They become apprehensive that their powers are giving way, and they often fancy the existence of some serious malady. An investigation of the different organs of the body reveals no evidence of disease. The lungs, heart, kidneys, etc. are sound. None of the affections embraced in the nosological catalogue may be discovered, yet the morbid condition is real. This brief sketch represents a class of cases with which every physician is familiar.

An inquiry into the habits and circumstances connected with the daily life in the cases now referred to will show that the mind has been for a long period unduly taxed by the cares and responsibilities of business, over-exertion in the pursuit of wealth or other objects of ambition, long-continued anxiety or inquietude; in short, the patient is suffering from wear and tear of the nervous system. The action of mental conditions is increased by other causes which tend to diminish the vigor of the body, such as irregular habits with respect to diet, the hours devoted to sleep and rest, etc. The causes which act directly through the mind are especially operative in this country, owing to the early age at which persons engage in the active pursuits of life, the great inducements to excessive exertions, and the emulation excited by the activity of others. It is not uncommon to meet with persons who have overtaken the nervous system without any rest or recreation for many consecutive years.

The condition of nervous asthenia is in itself not a small evil, causing much discomfort and unhappiness to the patient, and rendering him uncomfortable to others by inducing depression, irritability, or moroseness. That this condition favors the development of diseases to which there may be a predisposition, or co-operates with the various causes of disease, is probable. It often engenders a desire for stimulants, and thus leads to intemperance. It may eventuate in confirmed melancholia, hypochondriasis, or other forms of mental derangement.

An essential part of the TREATMENT relates to the causation. Frequently it is desirable to endeavor to procure, temporarily, complete relief from exer-

tion and care. It is, however, extremely injudicious to advise permanent relinquishment of active occupations. After rest and recreation for a season sufficient for recuperation of the nervous system a return to accustomed pursuits is advisable, with injunctions to observe proper moderation and to comply with the laws of health as regards a fair apportionment of time to recreation and a proportionate exercise of all the faculties of the mind. It is of course desirable that causes of mental uneasiness and anxiety should be removed, but this part of the treatment often is not within the range of medical control. Habits tending to impair bodily vigor are to be corrected, such as dietetic imprudences, late hours, sexual errors or vices, the immoderate use of tobacco, etc. Hygienic measures to invigorate the body are important, such as nutritious alimentation, out-of-door life, sea-bathing, or the sponge-bath, etc. Tonic remedies, varied from time to time and long continued, are serviceable both morally and medicinally.

At the present time there is perhaps a tendency to exaggerate the pathological relations of the neurasthenic morbid condition. No anatomical system in the body tolerates functional activity better than the nervous system, provided the organism be sound and the requirements of health in other respects be observed. Patients are sometimes disposed to attribute to over-exertion of the mental faculties what is really due to other violations of the laws of health. The opinion that the symptoms denote excessive brain-work is often received with satisfaction. In some cases, considering the small amount of intellectual work accomplished and the limited capabilities of the brain, this opinion seems almost ludicrous.

Spinal Irritation.

The name spinal irritation dates from the publication of a paper by Brown of Scotland in 1828. Shortly afterward the work of Teale on neuralgia and that of Tate on hysteria appeared, these authors referring the phenomena of these diseases to irritation of the spinal cord. In 1834 the published observations of W. and D. Griffin claimed, in behalf of the supposed morbid condition thus named, a larger scope of application, and this condition soon came to be generally recognized as an individual functional affection. In an article contained in the *American Journal of the Medical Sciences* for April, 1844, I gave the results of an analysis of 58 cases which I had observed and recorded. For several years I was accustomed, in medical lectures, to include spinal irritation among the functional diseases of the nervous system. I was at length satisfied that the phenomena grouped under this name had other pathological connections, and that the claim of spinal irritation to a place in the nosology was not well grounded. Others held this opinion, and the name had nearly passed out of use; but within the past few years it has again come into vogue, and it is now recognized by many as denoting a neuropathic affection.

In so-called spinal irritation more or less pain is referred to the spine, and pressure over certain parts of the column, these parts differing in different cases in number and extent, shows greater or less tenderness. This tenderness is also shown by the application of ice, a hot sponge, and electricity. With the spinal tenderness are associated, in different cases, a variety of symptomatic phenomena, and these, in their situations, are in correspondence with the relations of the latter to the spinal cord. Thus, intercostal and cervico-occipital pains, nausea, vomiting, singultus, palpitations, and nervous cough are associated with tenderness over the cervical and dorsal vertebræ, whereas pain in the lower parts of the body, tympanites, colic, and dysuria are associated with lumbar tenderness. Patients generally are mentally depressed, the power of physical or mental endurance is diminished, sleeplessness is common,

general hyperæsthesia of the surface of the body is sometimes marked, the extremities are cold, and different cases offer a great variety of subjective symptoms. The great majority of patients are women.

That there are cases which exemplify the clinical history of spinal irritation, as described formerly and at the present time, cannot be denied; but that the phenomena are caused by irritation of the spinal cord, or that they are attributable to a morbid condition (either to hyperæmia or to ischæmia) in this part of the nervous system, is by no means certain. In a large proportion of cases the phenomena are effects of general anæmia. In some instances they may be due to toxical blood-conditions, and they may be caused by reflex influences originating in local disorders of different organs.

Clinical observations show that when there is tenderness over the spine in connection with disorders of various kinds, soothing applications or mild counter-irritants over the tender portion or portions are often serviceable as palliative measures of treatment. Curative measures must be employed in other directions.

It is important not to consider the pains and tenderness referred to the spine in cases of so-called spinal irritation as symptoms of inflammation of the cord or of its meninges. The absence of fever, the sex of the patient, the existence of anæmia and often of hysteria, point to a purely functional disorder and render the exclusion of spinal meningitis and myelitis easy.

The name spinal irritation was introduced at a time when local pain and tenderness were regarded as evidence of inflammation, and, as the name denotes a functional condition, its introduction had a favorable influence on the treatment, inasmuch as at that time antiphlogistic measures—namely, bleeding, cathartics, mercury, and severe counter-irritation—were considered indispensable in treating inflammatory affections.

CHAPTER VI.

DISEASES OF THE NERVES.

Neuritis.—Multiple Neuritis.—Peripheral Paralysis.—Beri-beri—Kak-ke.—Paralysis of the Third Cranial Nerve.—Paralysis of the Fourth Cranial Nerve.—Paralysis of the Fifth Cranial Nerve.—Paralysis of the Sixth Cranial Nerve.—Paralysis of the Motor Portion of the Seventh Cranial Nerve.—Paralysis of the Eighth Cranial Nerves.—Paralysis of the Ninth Cranial Nerve.—Local Paralysis of other than Cranial Nerves.—Paralysis of the Cervical Sympathetic Nerve.—Paralysis from Lead.—Paralysis from Arsenic, Copper, Mercury, and Phosphorus.—Neuralgia.—Trifacial Neuralgia.—Cervico-occipital Neuralgia.—Cervico-brachial Neuralgia.—Dorso-intercostal Neuralgia.—Lumbo-abdominal Neuralgia.—Crural Neuralgia.—Sciatic Neuralgia.—Coccygodynia.—Dermalgia.—Myalgia.—Cephalalgia.

THE diseases to be considered in this chapter are those affecting either nervous trunks, their branches, or their terminal distributions; in other words, diseases of the peripheral nervous system. In this division are embraced neuritis, paralytic affections, and neuralgia referable to nervous trunks or branches. Paralysis from lead will be included among the peripheral paralyses.

neuritis is a much more frequent disease than is supposed. The disease has many peculiarities to merit a special consideration. The nerves are reddened, and more swollen than normal. It shows hyperemia, and an increase in the number of red corpuscles, frequently containing pigment. The nerve-fibers are swollen, and the nerve-trunk is enlarged. The nerve-fibers may be broken up and the nerve may terminate either in atrophy or in chronic neuritis. Sometimes special infection, such as syphilis, causes the disease of the interstitial tissue and the nerve is firmer than normal and of a more homogeneous color, or diminished in size. The changes are found in the nerves. These changes are found in a nerve-trunk, and they are not confined to the propriety, as parenchymatous neuritis.

well as affections of the intervertebral ganglia, has been repeatedly described in cases of herpes zoster intercostalis.

THE DIFFERENTIAL DIAGNOSIS of neuritis from neuralgia is not always easy. In fact, some cases of neuralgia are probably the result of a neuritis. The main points in the diagnosis are the paroxysmal character of the pain in neuralgia, as well as the existence of isolated points of tenderness (Valleir's points), and the absence of paralysis.

THE TREATMENT has reference especially to causative circumstances. Beyond the indications relating to causation, revulsive and soothing local applications are indicated. Subcutaneous injections may be required to relieve the intensity of the pain. The employment of electricity is useful in the form of the weak galvanic current, although some recommend strong currents. In chronic neuritis cauterization has been employed with benefit in some cases.

Multiple Neuritis.

THE ANATOMICAL LESIONS in multiple neuritis are in many cases degenerative, resembling those in divided nerves; but in some, particularly in acute cases they are inflammatory. In the first class of cases the medullary sheaths of the nerve-fibres are broken up into fragments; the cells in the sheath of Schwann are enlarged and increased in number; fatty granular corpuscles accumulate in the situation of the medullary sheath as well as between the nerve-fibres; and the axis-cylinder, which may remain for a long time intact, finally disintegrates. In inflammatory cases an inflammatory exudate, consisting of serum, pus-cells, and red blood-corpuscles, also accumulates in the interstitial tissue of the nerve-trunk. Microscopical examination is requisite to determine the changes, as often no distinct alteration is visible to the naked eye. If the case terminate in recovery, the nerve-fibres are regenerated in the same manner as after section of nerve-trunks. In chronic cases a new growth of connective tissue appears in the nerve-trunks.

The affection involves many, sometimes most, of the spinal nerves. The cranial nerves may also be affected, but less commonly than are the spinal nerves. The lesions are not distributed uniformly over the nerves, but are more intense in some places than in others. Usually, a nerve-trunk is more or less affected throughout its entire length. If the spinal nerve-roots be also involved, there are, usually, slight atrophic or degenerative changes in the ganglion-cells of the anterior horns of the spinal cord. From the symptoms it may be inferred that the motor nerve-fibres are by preference the seat of the disease.

THE CAUSATION of primary multiple neuritis is not known, but the symptoms support the usually-accepted view that the disease is due to some special infection. Certain cases of paralysis after acute infectious diseases, particularly after diphtheria, are referable to a multiple neuritis.¹ [Chronic alcoholism is a generally recognized cause of the affection.—H.] The affection is most common in early adult life.

SYMPTOMS.—Multiple neuritis may pursue an acute or a chronic course. The acute cases begin generally with fever and constitutional symptoms, often of considerable severity. Swelling of the spleen and albuminuria are sometimes present. These symptoms indicate the infectious nature of the disease. At the onset there is pain, usually severe, and felt generally in the loins and in the extremities. Moderate swelling of the joints has also been observed. Paralysis soon makes its appearance, as a rule first in the form of paresis of

¹ According to Scheube, the disease which is known as beriberi or kak-ke, and which prevails in Japan and India, is a multiple neuritis.

the lower extremities. The paralysis increases in intensity and in extent, involving the upper extremities, and, it may be, the muscles of the trunk, especially the muscles of respiration. Reflexes, particularly the tendon reflexes, are diminished. As may be inferred from what has been said on p. 675, the paralyzed muscles rapidly atrophy, and the nerves and muscles soon present the reaction of degeneration. In the mean time the pain has usually lessened, although some remains, especially upon pressure over the affected nerves and muscles. Abnormal sensations, called *paræsthesiæ*, such as numbness and formication, are often experienced. There usually is some loss of sensation, but marked *anæsthesia* is not generally produced. On the other hand, in acute cases there often is pronounced *hyperæsthesia*. The functions of the bladder and of the rectum remain intact. Herpetic eruptions, *œdema*, and less frequently other trophic disturbances may occur. There is often observed great frequency of the pulse, probably due to involvement of the vagus.

Acute multiple neuritis may terminate within a few days or two weeks in death. The most frequent cause of death is paralysis of the respiratory muscles. In some cases recovery takes place, which is usually gradual, as considerable time is required for the regeneration of the nerve-fibres. In other cases the acute symptoms subside and more or less paralysis remains permanently, or the disease may pursue a chronic course.

Multiple neuritis may begin insidiously, and without acute symptoms lead to atrophic paralysis. In these chronic cases recovery is also possible, or the disease may come to a standstill with more or less permanent paralysis.

The main difficulty in *DIAGNOSIS* is to distinguish multiple neuritis from anterior poliomyelitis, with which it has doubtless often been confounded. The main points in this diagnosis relate to the presence of pain and other sensory disturbances in neuritis which are absent in uncomplicated anterior poliomyelitis. The distinction between acute ascending paralysis and multiple neuritis may also occasion some difficulty, but careful attention to the symptoms which have been described will generally lead to a correct diagnosis. [Locomotor ataxia is excluded by the absence of the Argyll-Robertson pupil as well as of bladder disturbances, and by the presence of tenderness over the course of the nerve-trunks.—H.]

The *PROGNOSIS*, as is evident from what has been said, is grave, but not extremely so. In distinction from the spinal cord, the peripheral nerves are capable of extensive regeneration, so that recovery may take place after the paralysis has become complete and has lasted for a number of weeks or even months.

In view of the probably infectious nature of the disease, it is recommended at the onset of acute cases to administer large doses of salicylic acid. The intensity of the pain will usually require the use of opium in some form. Counter-irritation in the form of stimulating liniments may be applied over the affected parts. The systematic and long-continued use of electricity, beginning with not too strong galvanic currents, is important. Cutaneous faradization is sometimes employed as a means of counter-irritation. In chronic cases especially massage may be beneficially employed.

[Beri-beri—Kak-ke.]

Beri-beri is an infectious disease which prevails endemically in Northern Brazil, Japan, India, China, the Straits settlements, the Malay Archipelago, and other tropical and sub-tropical countries. Clinically, it manifests itself chiefly through the signs and symptoms of multiple neuritis. Up to a quite recent period there has been great diversity of opinion concerning the cause

of the disease, some attributing it to a diet composed largely of fish, some to the habitual consumption of rice, while others have confounded its symptoms with those produced by the intestinal parasite the anchylostoma duodenale. As a rule, those who have had the greatest opportunities of observing the disease clinically have been at a disadvantage as concerns the modern methods of bacteriological investigation. Two notable exceptions must, however, be made to this statement: Drs. Musso and Morelli have studied beri-beri from a bacteriological standpoint in the pathological institute of Montevideo,¹ and have succeeded in isolating four micro-organisms: (1) A staphylococcus, classified as staphylococcus pyogenes albus; (2) a micrococcus in chains; (3) a small colorless micrococcus; (4) a micrococcus which, when inoculated in animals (guinea-pigs and dogs), produced a universal degenerative neuritis. The latter is therefore considered by these observers as the specific organism of beri-beri. Pekelharing and Winkler² have also succeeded in obtaining from the blood of beri-beri patients micrococci which, inoculated in animals, produced polyneuritis.

Cold and dampness are undoubted predisposing causes, the disease, according to Bentley,³ being most prevalent during the decline of one monsoon and the setting in of another. The affection is said by W. Duncan Scott⁴ to be more prevalent among Chinese miners than in any other body of men. These miners work in "deep open pits with sloping sides of sand, often glaring white, and the heat at the bottom of the pit is often very great. Water often, if not always, lies there, in which they may stand ankle-deep or deeper. This itself may be an auxiliary influence in causing œdema and nervous disturbance in the lower extremities."

F. C. Shattuck and J. J. Putnam of Boston have described cases of multiple neuritis occurring among the fishermen of the Grand Banks, the symptoms of which were remarkably similar to those of beri-beri.⁵ As a matter of course, all affections in which multiple neuritis is a conspicuous symptom will present strong points of resemblance, but, in view of the observations of Pekelharing and others above referred to, the question of identity can probably only be settled by a bacteriological investigation.

Those who have had most experience of beri-beri believe it to be non-contagious. The virus of the disease becomes concentrated in buildings, such as barracks, prisons, and the holds of vessels, in which people are crowded together under unfavorable hygienic circumstances.

ANATOMICAL CHARACTERS.—The chief anatomical alterations thus far observed consist of œdematous infiltration of the connective tissues, especially of the lower extremities, effusion into the serous cavities, dilatation and flabbiness of the heart, œdema of lungs, and congestion of spleen, liver, brain, and spinal cord. The kidneys are said by Bentley to be pale and enlarged. Accounts of minute examinations of the organs above mentioned have been absent from the reports examined by the writer. According to Leopold, the signs of multiple neuritis are constant, consisting of disappearance of the axis-cylinders of the nerves of the affected region, segmentation of the myelin, and small-celled infiltration of the sheath of Schwann. The spinal cord is, as a rule, intact, but in the severest cases signs of anterior poliomyelitis may be detected.

³ *Beri-beri*, by Arthur J. M. Bentley, 1893.

⁴ *Practitioner*, May, 1892.

⁵ *Journal of Nervous and Mental Disease*, August, 1890.

SYMPTOMS.—Two principal forms of beri-beri are encountered—the *oedematous* and the *paralytic*, or, as they are sometimes styled, the *dry* and the *wet*. The latter, which is the acute form of the disease, begins with fever, usually of slight intensity and either intermittent or irregular. This fever is sharply defined from the malarial by the absence of rigors. With the subsidence of the fever—sometimes during its course—*oedema* of the lower extremities with paresis and numbness sets in. The *oedema*, at first most marked over the dorsum of the foot, may extend upward and involve the loose tissues of the scrotum and penis. Effusion into the serous cavities may occur. According to Leopold, the *oedema* is due to venous stasis, which, in its turn, is caused by a gradual dilatation of the right ventricle. He bases this opinion upon the alleged fact that coincidently with the *oedema* there develops a systolic cardiac murmur, loudest at the apex, and an increase in the transverse diameter of the heart. The pulse is full, strong, and increased in frequency. The respiration is embarrassed and there is a sense of thoracic oppression. The tongue is clean, the bowels usually constipated, the urine diminished, though free from albumin and of high specific gravity. Enlargement of spleen and liver is constant. The gait is awkward and stiff and the knee-jerk diminished or absent.

Dry beri-beri may either begin as such or it may be a development of the acute or wet variety. In this form the nervous symptoms are more prominent, consisting of *anæsthesia* and *paræsthesia* (formication, pricking and tingling sensations) of the lower extremities, paresis, and muscular atrophy. The gait is peculiar, the patients stepping high on account of the paralytic dropping of the foot. The knee-jerk is generally absent, though sometimes, according to Duncan Scott, exaggerated, and the muscles of the calf are usually tender on pressure. In a certain number of the cases the muscles undergo marked atrophy—so much so that Bentley describes an *atrophic* form of the disease. The same observer classifies as “acute pernicious” the cases in which there is a rapid progress from bad to worse. In cases of this class the “dyspnoea becomes extreme, sleep becomes uneasy, there is difficulty in lying down, vomiting is often present, and muscular spasms of different parts of the body occur. The pulse is increased in frequency and feebleness, there is fluttering about the heart, the lips and countenance become livid, there is a scared aspect, the extremities become cold, and the patient soon dies nearly suffocated. In the more sudden cases these symptoms follow one another with the utmost rapidity, and a few hours suffice to close the scene.”

Anæmia is not a prominent symptom of the disease. According to Bentley, *anæmia* was “entirely absent” in the great majority of his cases, but this statement is not supported by accounts of examinations of the blood.

DIAGNOSIS AND PROGNOSIS.—The diagnosis of beri-beri is readily made in the countries in which it is endemic, and is based upon the occurrence in groups of cases presenting the signs and symptoms of *oedema* and multiple neuritis. The exact status of such cases as those described by Shattuck and Putnam has yet to be determined. It is highly probable that beri-beri is caused by a specific organism, and that in future, as is the case with diphtheria, the diagnosis in doubtful cases will have to be determined in the bacteriological laboratory.

In making a prognosis the marked tendency of the disease to relapse should be borne in mind, as well as the fact that with each relapse the tendency to a fatal termination increases.

The mortality varies in different countries and in different epidemics in the same country, the lowest estimate (the epidemic occurring in the jail at Singapore in 1880) being 8.02 per cent., the highest (epidemic in Mauritius) 60 per cent.

TREATMENT.—In the œdematous form of the disease vapor-baths administered daily and diaphoretics have seemed to be of decided benefit. Acetate of potassium, jaborandi, the compound spirit of juniper, and the compound tincture of ether are the diaphoretics most commonly employed. In case constipation is present, purgatives such as calomel, the compound jalap powder, or the compound rhubarb pill may be administered. Frictions of the œdematous extremities with stimulating liniments are of undoubted service. When dyspnoea becomes urgent, a blister should be applied to the præcordial region. Under these circumstances also a hypodermic injection of 15 drops of ether may be employed.

Scott, believing the blood in beri-beri to be hyperacid, prescribes alkalies such as potassium bicarbonate and the sesquicarbonate of ammonium, and aims to have derived marked benefit from the tincture of belladonna. In the paralytic variety the drugs most commonly employed are ergot, nuxvomica, and nitrate of silver. A cure in this form of the disease may be hastened by the judicious employment of electricity.—H.]

Peripheral Paralysis.

In preceding articles various causes of peripheral paralysis have already been mentioned. These causes will here be enumerated. Peripheral paralysis may be caused by inflammation, degeneration, compression, and injury to a nerve. It may be caused by toxic substances, of which the most important is lead, and less common causes are copper, arsenic, certain vegetable alkaloids, and some other substances. Peripheral paralysis is common after phthisis, and is less frequent after other acute infectious diseases, such as smallpox, typhoid fever, measles, etc. It may be the result of syphilis, but rarely of other chronic infectious diseases. An important cause of peripheral paralysis, particularly of facial paralysis, is exposure to cold. No satisfactory explanation of reflex peripheral paralysis has been given. Finally, peripheral paralysis may occur without known cause.

Peripheral paralysis may be the result of some demonstrable change in the nerve, such as inflammation, degeneration, or tumor, or it may be purely functional. As our knowledge extends, the instances of purely functional paralysis become fewer.

The following are the main points to be considered in the diagnosis of peripheral paralysis: The paralysis affects a muscle or a group of muscles supplied by a nerve-trunk or a nerve-branch. In certain forms of spinal paralysis (anterior poliomyelitis) the paralysis may be confined to a group of muscles, but this is a group of muscles functionally associated, and not necessarily supplied by a single nerve-trunk. In severe peripheral paralysis the affected muscles undergo rapid atrophy, and the nerves and muscles take on the reaction of degeneration according to the principles already laid down (p. 675). The reflexes are generally diminished in peripheral paralysis. These vary as to the existence of sensory disturbances, but a certain degree of these is not uncommon, and marked anæsthesia may accompany the motor paralysis.

The **TREATMENT** in cases of peripheral paralysis has relation to local causes whenever these can be ascertained and reached. Their continued operation should, if possible, be prevented. Lacerations and divisions of nerves are

to receive proper surgical treatment with reference to the restoration and reunion of separated or injured parts. Tumors pressing upon nerves are to be removed if practicable, abscesses opened, and inflammation treated according to the indications. It is obvious that the probability of improvement and recovery must depend on the nature of the causes and the extent to which they can be successfully treated. Cases in which the paralysis is due to cold or to transient external pressure, and those in which there is no discoverable causation or appreciable lesion, generally tend to a favorable termination; and this may be hastened by therapeutic measures.

The chief therapeutic agent is electricity. The employment of this agent is to be governed by rules the consideration of which is not embraced within the scope of this work. Local frictions, the use of stimulating liniments, the cold and warm douche, the topical application of strychnia, and voluntary exercise of the paralyzed muscles whenever the conduction of volition is not wholly obstructed, are measures of utility in peripheral as in central paralysis. In cases of peripheral as in cases of central paralysis the probability or the possibility of a syphilitic connection is to be considered with reference to the treatment. Antisyphilitic medication should be employed whenever there is ground for a suspicion of this connection.

Paralysis of the nerves of special sense—namely, the olfactory, the optic, or the auditory nerve—is frequently dependent on abnormal conditions relating to the accessory organs of smell, sight, and hearing. This remark applies more especially to the eye and ear. Affections of the eye and ear involving loss or impairment of sight and hearing belong in the province of surgery, and treatises are devoted specially to them. It is important, however, for the physician to take cognizance of paralysis affecting these senses, as denoting intracranial disease. In most cases paralysis of the nerves of special sense, if due to intracranial disease, is associated with paralysis of other parts. Paralysis of the other cranial nerves severally claim brief consideration. It is more correct to say paralysis of the parts to which the branches of a nerve are distributed than to apply the term to the nerve, but the latter is a convenient mode of expression and is sanctioned by usage.

Paralysis of the Third Cranial Nerve.

Paralysis of this nerve, the motor oculi communis, gives rise to dropping of the upper eyelid or ptosis, diverging strabismus, protrusion of the eyeball, and dilatation of the pupil. These effects correspond with the distribution of the several branches of the third pair of nerves. The internus rectus muscle being paralyzed, the eyeball is turned outward by the externus rectus and the superior oblique muscle; and dilatation of the pupil is caused by paralysis of the circular fibres of the iris. The effects are so obvious and characteristic as at once to be referable to paralysis of this nerve. Paralysis of this nerve may be produced by an injury in the neighborhood of the eye, by the action of cold, and by over-exertion in occupations which require especially the use of the eyes. If produced by cold or over-use, the paralysis is functional and will not be permanent. Double vision and imperfect accommodation accompany paralysis of this nerve. The paralysis is rarely limited to this nerve if it proceed from intracranial lesions, but it is associated with paralysis affecting other nerves or with other marked effects of cerebral disease. It is rare in cases of hemiplegia. Occasionally it is the first event pointing to grave cerebral lesions. It may be a forerunner of hemiplegia, convulsions, or coma. In a case under my observation paralysis affecting this nerve on

the right side occurred without other central symptoms three weeks before an attack of apoplexy and left hemiplegia, the latter proving fatal two hours after the attack. If ptosis exist without strabismus and dilatation of the pupil, it may be inferred that the paralysis is not central but peripheral. The paralysis is then limited to the upper branch of the nerve. So also, if the inferior branch be alone affected, causing external strabismus and dilatation of the pupil without ptosis, the paralysis is probably peripheral.

Paralysis of the Fourth Cranial Nerve.

Paralysis of this nerve, the patheticus, produces effects less marked than those of paralysis of the third nerve. Movement of the eye at the same time downward and inward is impaired. Double vision exists of objects occupying the lower part of the field of vision, and is therefore manifested especially in looking downward, as in going down stairs. Paralysis of this nerve is an isolated affection in some cases of syphilis.

Paralysis of the Fifth Cranial Nerve.

The effects of complete paralysis of this nerve are shown by its division within the skull in inferior animals. Loss of sensibility (anæsthesia and analgesia) on one side of the face, of the mucous membrane within the mouth, the conjunctival membrane on that side, and the anterior portion of the tongue, and paralysis of the masticatory muscles on the same side, immediately follow. The intracranial division of this nerve is followed within a short time by ulceration of the cornea, and sometimes by suppurative inflammation of the whole eye. Complete paralysis of the trigeminus from disease is rare. The motor portion may be affected either separately or in conjunction with the sensory divisions. Impairment or loss of the power of mastication denotes paralysis of the motor or third division. Bilateral paralysis of the motor portion occurs rarely in cases of bulbar paralysis. The different sensory divisions may be affected separately—namely, the ophthalmic, the superior and the inferior maxillary. The loss or impairment of sensibility is then confined to the portions of skin and mucous membrane supplied by the branches of the paralyzed division.

Ulceration of the cornea, absence of reflex conduction, redness and swelling of the face and of the gums, constitute evidence that the paralysis is peripheral, the local cause being perhaps intracranial, but extracerebral. When the paralysis is central, it is accompanied by symptoms denoting cerebral disease, and other cranial nerves are generally involved.

Pain is sometimes referred to parts supplied by the branches of the nerve, notwithstanding anæsthesia and analgesia in these parts are complete (anæsthesia dolorosa). The cause of the pain is situated in the portion of the nerve posterior to the seat of the affection which causes the paralysis. The explanation is the same as when, after an amputation, pain is felt to be in the amputated limb ("eccentric projection of perception").

Bilateral paralysis of this nerve is sometimes observed. In a case reported by Althaus the common sensibility of the face and scalp was lost, together with the sense of temperature and of tact; the mucous membrane of the eyes, nose, and mouth was completely anæsthetic; the sense of taste was preserved, although the exercise of it seemed less prompt than in health; and the muscles of mastication were completely paralyzed. The tongue presented a frightful spectacle, having been bitten and lacerated in every direction during the act of taking food. The patient experienced no pain when a tooth was drawn. The lips were covered with froth. The sense of smell and of

sight were not affected, except that the latter was obstructed by thick *leucoma* of both corneæ. The patient suffered much from photophobia. There was an abundant secretion of mucus from the Schneiderian membrane. Hearing was intact, but the patient was greatly annoyed by tinnitus aurium. The paralysis was produced by long exposure of the face to a keen wind, the morbid condition being supposed to be inflammation of the neurilemma at the point where the nerve emerges from between the transverse fibres of the *pons varolii* at the base of the brain. The brain was unaffected, and the paralysis was limited strictly to the distributions of the fifth pair. At the end of three months, under treatment consisting of the systematic application of the continuous galvanic current to the several branches of the affected nerve, the recovery was nearly complete.¹ An important indication for treatment is to protect the anæsthetic parts, particularly the cornea, from external injury.

Paralysis of the Sixth Cranial Nerve.

Paralysis of this nerve, the motor externus or abducens, leads to converging strabismus, the eyeball being turned inward by the action of the internal rectus or adductor muscle, from the loss of the antagonism of the external rectus or abductor muscle. The patient is unable to turn the eyeball outward, whereas in ordinary cases of strabismus this can be done if the other eye be closed. Paralysis of this nerve sometimes occurs in cases of cerebral meningitis and in connection with lesions giving rise to hemiplegia. This nerve, however, escapes in the majority of the cases in which paralysis of other parts occurs from intracranial affections. When the nerve is paralyzed, paralysis of the third cranial nerve is frequently associated. The effect of paralysis of both these nerves is immobility of the eyeball as regards lateral movements, which can be turned neither inward nor outward. Double vision is likely to exist when the paralysis is limited to the sixth nerve. Functional paralysis of this nerve is not uncommon. It may be caused by neuritis, and it is sometimes attributable to syphilis.

Paralysis of the Motor Portion of the Seventh Cranial Nerve—Bell's Paralysis—Mimetic Paralysis.

Paralysis of this nerve, the *portio dura*, or the motor facial nerve *par excellence*, is much less infrequent than paralysis of the sensitive portion of the fifth nerve. Complete paralysis of this nerve produces characteristic appearances, by means of which the affection is at once recognized. The expression of the physiognomy peculiar to the person is abolished on the affected side. The naso-labial fold is flattened on this side. In speaking or smiling the mouth and sometimes the extremity of the nose are drawn to the opposite side. This appearance is so striking and distinctive that the existence of the paralysis is immediately apparent. The power over the orbicularis palpebrarum being lost, the patient is unable to wink or to close the eye. When the attempt to close the eye is made, the eyeball is turned upward, so that the cornea is concealed by the upper lid. The upper lid is abnormally elevated and the lower lid is depressed, so that the eye appears to project more than in health. Owing to the loss of power over the orbicular muscle, the tears are not diffused over the conjunctiva as in health, and hence results epiphora. From the constant exposure of the conjunctiva in sleep as well as in waking hours it becomes inflamed, and opacity of the cornea may be a result of the conjunctivitis. The eyebrow is lowered, and the patient is unable to frown or to wrinkle the forehead on the affected side, from loss of

¹ *Transactions of the Royal Medical and Chirurgical Society of London*, 1869, vol. lii.

power over the corrugator supercilii and the anterior portion of the occipitofrontalis muscle. The ala nasi ceases to dilate, but may contract in inspiration; and dilatation, if it occur, is in expiration. Loss of power over the orbicularis oris on the affected side renders the patient unable to whistle; expiration is imperfect, the saliva dribbles from the angle of the mouth; and the pronunciation of certain letters—namely, *a*, *b*, *p*—is difficult. Loss of power over the buccinator renders the cheek flaccid; it is liable to be wounded in mastication, and the patient is annoyed by the accumulation, between the cheek and gums, of food which he is obliged to remove with the finger. The cheek and lips of the affected side are sometimes puffed outward by the expired breath, as in the act of expelling tobacco-smoke from the mouth. These obvious appearances are readily understood by reference to the anatomical distribution of the branches of this nerve. They are, of course, less marked in proportion as the paralysis is incomplete. The velum pendulum palati on the paralyzed side is sometimes abnormally flaccid, and the uvula is deflected to the opposite side. The auditory sense on the paralyzed side is more acute than in health. After long continuance of the paralysis contracture of the paralyzed muscles may develop, causing deviation of the features to the affected side.

Paralysis of this nerve is not very infrequently an isolated affection, existing independently of cerebral disease. The seat of the affection may be intracranial, but extracerebral; that is, the seat, although within the skull, is between the central connection of the nerve and its entrance into the meatus auditorius. It may be due to the pressure of a tumor on the nerve after it emerges from the stylo-mastoid foramen. The nerve may be affected within the petrous portion of the temporal bone from fracture, or in connection with caries of this bone resulting from median or internal otitis. Facial paralysis occurs not infrequently from the action of cold upon the face. I have met with instances of its occurrence in connection with anæmia. It is sometimes produced in new-born children by the employment of the forceps in labor. Facial paralysis may proceed from the various intracranial affections which have been considered. In these cases it is frequently associated with paralysis affecting other nerves. It is sometimes a forerunner of a grave cerebral affection.

If central, the paralysis is generally preceded or accompanied by symptoms denoting a cerebral affection. If the nerve be affected in a situation involving the chorda tympani, the sense of taste on the lateral half of the anterior portion of the tongue corresponding to the paralyzed side is diminished, as may be shown by comparing the sensations produced by placing successively on the two sides of the anterior extremity of the tongue some bitter substance in powder, such as aloes. The salivary secretion is diminished. These effects are due to the involvement of the chorda tympani in the paralysis. The taste and the salivary secretion are not affected if the cause producing the paralysis act upon the nerve anterior to the situation at which the chorda tympani is given off.¹ Flaccidity of the palatine arch on the affected side and deflection of the uvula to the sound side denote that the cause of the paralysis acts upon the nerve either within the aqueductus Fallopii or before it enters this canal, the branches supplying the levator palati and the azygos uvulae muscles being here given off. If the paralysis be central, the electromuscular contractility is preserved; and if it be peripheral, the reaction is rapidly lost. The paralysis is peripheral when the nerve is affected at any point beyond its origin. Paralysis of the sixth nerve accompanying paralysis of the facial nerve denotes a central lesion, these nerves arising near each other

¹The fibres of the chorda tympani nerve are probably derived ultimately from the glossopharyngeal nerve, although some assign them to the trigeminus.

in the floor of the fourth ventricle. The absence of reflex movements is evidence that the paralysis is peripheral. If winking be not produced by touching the eyeball, the sensibility of the latter being preserved, the nerve is affected after leaving its central connection; and on the other hand, if the eye be closed involuntarily, following an impression made on the conjunctiva when the voluntary power is lost, the paralysis is central. Abnormal acuteness of hearing is evidence that the nerve is affected behind the point at which the twig going to the stapedius muscle is given off. The paralysis is much oftener complete when it is peripheral than when it is central. Accompanying hemiplegia, the paralysis is generally incomplete and the orbicular muscle of the eye is but little affected. It is rarely wholly unaffected, as stated by Todd. Evident diseases of the ear or of the parotid gland often account for the paralysis as well as its peripheral character, and they point to the seat of the affection.

In cases of facial paralysis dependent on neuritis caused by cold, or when it is functional, recovery may be expected after the lapse of several weeks. If the paralysis continue without improvement for two or three months, it is probably not functional, but if not dependent on central lesions it proceeds from either disease of the nerve or something pressing upon it and occasioning obstruction. Under these circumstances it will be likely to remain a permanent affection. The prognosis is also grave in proportion as the electromuscular contractility is diminished.

Bilateral paralysis (*diplegia facialis*) has been repeatedly observed, but examples are extremely rare.¹ It may result from injury or disease of the two nerves or from intracranial lesions. The expression is then abolished on both sides of the face. The face remains immovable, the only changes which are observed relating to the circulation. It is as if the face were covered by a mask. Relaxation of the soft palate may coexist, rendering the voice unnatural. Moreover, articulation is difficult from the immobility of the lips. Mastication is difficult from the same cause. The saliva dribbles from the mouth. The eyes are constantly open and staring (*lagophthalmus*). Aside from the great inconvenience which bilateral facial paralysis occasions, the prognosis is serious or otherwise according to the situation and nature of the morbid conditions on which the paralysis is dependent. In a case which came under my observation with the double facial paralysis was associated incomplete general paralysis, and the patient died by apnoea from inability to expel, by coughing, matter in the air-passages. Paralysis affecting the *ala nasi* may lead to an amount of depression with inspiration sufficient to occasion notable obstruction. The cartilaginous portions of the nostrils on both sides are sucked in with the inspired breath to such an extent as to constitute a serious obstacle to respiration.

Paralysis of the Eighth Cranial Nerves.

The paralysis affecting the pharynx, which occurs as a sequel of diphtheria in certain cases, and which is sometimes limited to this situation, is to be considered as a paralysis of that division of the eighth pair called the glosso-pharyngeal. This local paralysis will be referred to in treating of diphtheria.

Paralysis of this nerve, together with paralysis of the *par vagum*, occurs in various cerebral affections which produce deep coma, giving rise to impairment and loss of power of deglutition and diminished frequency of the respirations. This paralysis precedes a fatal termination. It may occur from a small extravasation of blood into or near the medulla oblongata. I have met with

¹ For a report of 28 cases of double facial paralysis, see article by Dr. Pierreson in *Archives générales de Médecine*, Août et Septembre, 1867.

an example, the apoplectic attack being characterized by notable disturbance of respiration and inability to swallow, without complete loss of consciousness. Paralysis of these nerves occurs also in bulbar paralysis. The vagus is an inhibitory nerve of the heart. Its irritation causes slowing of the heart-beats, and if it be intense their cessation in diastole. Its paralysis causes increased rapidity of the cardiac pulsations.

Paralysis of the spinal accessory nerve, giving rise to aphonia, has been already referred to in treating of the affections of the larynx. Incomplete aphonia may be a result of paralysis of this nerve from the pressure of an aneurismal or other tumor on the recurrent laryngeal nerve, and it is sometimes produced by the surgeon in operations on the neck.

Paralysis of the Ninth Cranial Nerve.

Paralysis of this nerve, the hypoglossus, on one side, involves loss of power over the genio-hyo-glossus and other muscles of the tongue on that side. The effect is a deviation of the tongue from a right line when protruded, the apex pointing to the side of the paralysis. The direction in which the apex points is readily understood when the action of the muscles which protrude the tongue is considered. These muscles extend from the chin to the base of the tongue; and when from paralysis the protrusion is effected by the muscle on one side, the base is drawn toward that side, and as a result of the base moving in one direction the apex turns in the opposite direction, the latter being toward the paralyzed side. Paralysis of this nerve rarely exists as an isolated affection, and it is generally symptomatic of intracranial disease. It exists frequently in cases of hemiplegia.

In determining the existence of this paralysis it is to be borne in mind that the tongue may deviate from a right line in consequence of absence of teeth on the side to which the apex is turned or of irregular inward projection of teeth on the other side. Dropping of the upper lip on one side produces an appearance as if the tongue deviated to the opposite side; and to obviate liability to error on this score the upper lip should be raised with the finger while the tongue is protruded.

Paralysis of the hypoglossal nerve on both sides is extremely rare, but cases are sometimes observed. In complete paralysis of this nerve on both sides there is inability to protrude the tongue, and the power of speech is lost from inability to articulate. Incomplete paralysis renders protrusion of the tongue and articulation more or less imperfect. Paralysis of this nerve on both sides enters into the paralytic affection which has been considered under the head of Bulbar Paralysis.

Local Paralysis of Other than Cranial Nerves.

Paralysis may be produced by injuries or diseases affecting nervous trunks in any part of the body. The loss or impairment of motion or sensation, or both, extends over the parts supplied with the nervous filaments given off by the nerve below the situation of the injury or disease. Traumatic local paralysis follows division or wounding of nerves and contusions. If a contusion give rise to paralysis by simple shock or stunning the nerve, recovery may be expected; but paralysis due to palpable injury of the structure of a nerve is likely to be permanent, although reunion, with a restoration of function, may take place after the division of a nerve of considerable size. Diseases which give rise to local paralysis by affecting nerves are tumors or morbid growths situated within and without the neurilemma, and inflammation of the neurilemma or of the nerve-substance. The latter generally occurs either by exten-

sion of inflammation seated primarily in the structures adjacent to the nerve affected or by primary inflammation of the nerve. Paralysis due to the pressure of a tumor may be recovered from if the pressure be removed before extensive disorganization or atrophy has resulted.

Pressure on a nervous trunk, continued steadily for several hours, may lead to temporary or even permanent paralysis. Paralysis of an upper extremity has repeatedly occurred from remaining in profound sleep or in a state of intoxication with the arm hanging over the back of a chair, the paralysis being due to pressure on the brachial plexus. I have met with many examples of paralysis of the forearm attributable to lying, while intoxicated, with the weight of the body upon the arm. Paralysis of a single muscle or a small group of muscles, when not traumatic, is significant of syphilis as the cause.¹ Among the more common examples of peripheral paralyses of spinal nerves from pressure or injury may be mentioned paralysis of the serratus magnus, of the deltoid, of the muscles supplied by the musculo-spinal nerve, by the ulnar nerve, or by the median nerve, paralysis of the diaphragm, and paralysis of muscles supplied by the anterior crural or by the sciatic nerve.

The following interesting case of local sensory paralysis from injury has fallen under my observation. The injury was received by falling from a considerable height upon the deck of a vessel, and striking upon the nates in a sitting posture. Permanent paralysis of the sensibility of the rectum and anus followed the contusion. Excrescences which at one time existed around the anus were removed without any sensation of pain. The patient has no consciousness of the accumulation of feces in the rectum, and never experiences the desire for defecation. Hence the bowels are habitually constipated. The contraction of the sphincter, due to reflex influence, is intact. Involuntary evacuations occur only when diarrhoea exists and when voluntary power over the muscles is requisite to prevent their occurrence. There is no paraplegia, no difficulty in evacuating the bladder, and no sexual deficiency. The accident occurred more than forty years ago, and in the mean time the person has had good health.

Paralysis of the Cervical Sympathetic Nerve.

The experiment of dividing the sympathetic in the neck, repeated by Bernard in 1851, and its effects studied more fully than by previous observers, is now made familiar to medical students by those teachers in physiology who employ vivisections. The reader is therefore presumed to know that the immediate results of this experiment are congestion of the head on the side corresponding to the section, rise of temperature due to increased rapidity of circulation, and contraction of the pupil on the same side. These effects on the circulation are attributable to paralysis of vaso-motor nervous filaments. Paralysis of this nerve occurs from pressure by a tumor, and it has followed surgical operations and other wounds. Contraction of the pupil is one of the symptoms of aortic aneurism when the tumor is so situated as to press upon this nerve. Dr. S. Weir Mitchell has reported a case in which paralysis of the right sympathetic was caused by a wound from a musket-ball. The right pupil was contracted, and the eye on that side was myopic. On exercise the right side of the face became flushed, while the left side was pale.² Dr. William Ogle has reported a case in which, from the local appearance and the phenomena, it was inferred that the right sympathetic had been destroyed by an abscess in the neck. In this case the right pupil was contracted and the eyeball was somewhat retracted. The right side of the head

¹ Vide article by Dr. Keyes in the *New York Medical Journal*, Nov., 1870.

² Vide *Injuries of Nerves*, by S. Weir Mitchell, M. D., Philadelphia, 1872.

was redder and warmer than the left, especially after exercise. A singular feature in this case was that the patient sweated on the left side of the face only. This was observed repeatedly after active exercise and during exposure to great heat in a Turkish bath. Although this condition had existed for two years, no inflammatory process had followed.¹ Functional paralysis of the sympathetic system in different situations has been supposed to be involved in certain cases of paralysis affecting the upper and the lower limbs, and to enter largely into the pathology of nervous affections accompanied by disturbances of circulation, secretion, and nutrition. These views are founded chiefly on the relations of the sympathetic system to the vaso-motor nerves, as shown by experimental observations on inferior animals.

Paralysis from Lead.

The accumulation of lead within the system may give rise to partial and even to general paralysis, but as a rule the paralysis due to this cause is local. In the great majority of cases the paralysis is limited to the extensor muscles of the upper extremities. The muscles supplied by the musculo-spiral nerve are those chiefly affected. The triceps and the supinators escape. The usual form of lead paralysis is that commonly known as *wrist-drop*. This name expresses the peculiar appearance of the upper extremities. The patient is unable to raise the hand to a line with the forearm. Frequently the first series of the phalangeal bones of the hand cannot be brought on a line with the back of the hand, but the second and third series can generally be extended, as they are acted upon by the interossei muscles. The dropping of the hands is characteristic of this affection. Whenever the peculiar appearance referred to is presented, the physician is justified in assuming that the paralysis is from lead. In lead paralysis of the lower extremities the peroneal muscles are usually first affected, and then the extensors on the leg, the anterior tibial muscle remaining intact. The paralysis is shown by inability to raise the feet with the heels resting on the floor or to raise the toes. The feet drop when the patient walks, and he therefore steps high to avoid tripping. Paralysis of the muscles of the lower limbs is not common. In a case under my observation the extensors of both the feet and hands are paralyzed, and the patient is affected with dropping at the ankle as well as at the wrist.

The appearance is diagnostic, but other evidence of lead-poisoning may almost always be obtained. As a rule, paralysis succeeds other characteristic effects of lead, especially the affection known as lead colic. (Vide p. 460.) The blue line on the gums referred to in treating of lead colic is always to be sought for. Generally, the occupation of the patient suggests the source of the paralysis, but in some cases the mode in which the lead has been introduced into the system is ascertained only after careful investigation. An examination of the urine for the presence of lead should not be omitted.

Lead paralysis belongs among the symmetrical or bilateral affections. It is very rarely limited to one side, and corresponding muscles on the two sides are usually affected, but in general differently as regards the degree of paralysis. The paralysis may be complete or incomplete, and cases differ much in respect to its degree. The power over the flexor muscles is frequently more or less impaired, but in some cases with almost complete loss of power over the extensors the flexors are but little if at all affected. This fact was illustrated in a striking manner in a case under my observation at Bellevue Hospital. Wishing to group several cases of paralysis for a clinical lecture in the hospital amphitheatre, which is situated at the top of the

¹ Vide *Trans. Royal Med. and Chirurg. Society of London*, 1869, vol. lii.

building, I desired to have a patient affected with complete paraplegia carried up from a ward on the ground-floor. Four flights of stairs were to be mounted. One of the patients, who was to make part of the group, was affected with lead paralysis, the extensors of the hand being nearly powerless. He was a man of great strength, and he volunteered to carry his fellow-patient to the amphitheatre on his back. It was necessary to assist him in obtaining a firm grasp of the patient, but when this was obtained he performed the feat with ease, and after the lecture brought the patient down to the ward.

Lead paralysis belongs to the group of atrophic paralyses. The peripheral nerves and muscles rapidly assume the reaction of degeneration, but complete loss of electrical reaction is not common. These facts make it probable that lead paralysis is due either to an affection of the peripheral nerves or to an affection of the ganglion-cells of the anterior horns of the spinal cord (polio-myelitis anterior). The weight of evidence seems to favor the view that the paralysis is of peripheral origin, but in some instances changes have been found in the ganglion-cells of the anterior horn. Further investigations upon this point are requisite. It is an interesting fact that alterations in the electrical reactions have been found before paralysis appeared, and also in nerves and muscles which did not become paralyzed. Voluntary power over the muscles is restored before normal response to the faradic current appears.

It is to be borne in mind that muscles other than those involved in the common form of lead paralysis, or the wrist-drop, may be paralyzed by this cause. The evidence of lead-poisoning is therefore to be sought after in cases of paralysis in which other adequate causes are not evident. Anæsthesia and analgesia of the surface have also been observed, affecting limited portions of the integument of the body and extremities. The muscles of the larynx concerned in phonation have been known to become affected, leading to aphonia, as well as those of the lips and tongue, rendering articulation difficult.

The DURATION of lead paralysis is very variable. It is sometimes of short duration, but much oftener continues for a considerable period, and improvement, if it take place, is very gradual. If under proper treatment no improvement take place for several weeks, the prognosis is unfavorable as regards recovery, and the paralysis is likely to be permanent. If the paralysis continue long enough to lead to notable atrophy of the affected muscles, and if they do not react to either the faradic or the galvanic current, the condition as regards recovery or improvement is hopeless. The proportion of cases in which this result takes place is not small.

The TREATMENT of paralysis from lead involves, in addition to the measures applicable in general to paralysis, remedies having reference to the elimination of lead from the system. The iodide of potassium is supposed to form with the lead a soluble compound, and in this way to promote its elimination. It must be admitted that the clinical proof of this effect of this remedy is not very conclusive. Warm baths and the hot-air bath are useful. It is doubtful whether sulphur baths, which have been much recommended, possess any advantage derived from the action of sulphur on the body. As regards the treatment addressed to the paralysis, the clinical evidence of the benefit of strychnia, given internally and applied endermically, is conclusive. A most important measure of treatment is the employment of electricity, first in the form of the galvanic current, and then of the faradic current when this begins to produce response. Prophylactic measures are important for those whose occupation involves contact with lead.

Paralysis from Arsenic, Copper, Mercury, and Phosphorus.

Paralysis is an occasional effect of either acute or chronic arsenical poisoning, more frequent of the former than of the latter. The paralysis affects most frequently the muscles of the lower extremities (paraplegia). General paralysis is sometimes produced by this metal. There are usually, in addition, sensory disturbances. Recovery takes place as a rule, with some exceptions.

Paralysis from copper is preceded by the symptoms of gastro-duodenitis. Cases of paralysis from this cause are extremely rare.

Mercury sometimes causes paralysis which is always preceded by mercurial poisoning. The effects of mercury upon the mouth, conjoined with the occurrence of tremor, point to the cause of the paralysis. The iodide of potassium is proposed to promote the elimination of mercury, as well as of lead, from the system, and is therefore indicated in cases of mercurial poisoning.

Paralysis has been observed after acute and chronic poisoning with phosphorus.

THE TREATMENT having direct reference to the nerves and muscles involved in the paralytic affections caused by these metals is the same as in cases of paralysis from other causes.

Neuralgia.

The term neuralgia is used to distinguish functional affections of which the characteristic is pain. In a purely neuralgic disease there is neither anatomical lesion nor any appreciable lesion in the painful part. There is a condition of morbid sensibility, and this is all that can be said of its essential pathological character. Visceral neuralgias, as they are called—that is, neuralgias seated in organs belonging to the respiratory, circulatory, digestive, and excretory systems—are considered in the several sections devoted to the diseases of these organs. The neuralgic affections to be here considered relate to the nervous trunks or their branches not connected with the organs composing the foregoing physiological systems.

As regards symptomatology, diagnosis, causation, prognosis, and the general principles of treatment, whatever is true of any one of these affections is only true of all of them. In order to avoid repetitions, therefore, I shall consider these neuralgic affections collectively, or neuralgia in general, under the several aspects just named, and shall afterward notice briefly the important features of the affections individually.

Neuralgia may occur abruptly, but in the great majority of cases there are premonitions. The premonitions are—a feeling of weight, a sense of heat, or an uncomfortable sensation in the seat of the affection. The neuralgic pain is either chiefly or exclusively in paroxysms, or there may be more or less continued pain, with exacerbations in which the pain is much increased. Continued pain may be dull or contusive, but during the paroxysms or exacerbations the pain is described as darting, tearing, or lancinating, and it is excruciating. The paroxysms or exacerbations are of variable duration, lasting in some cases for a few seconds only, and in other cases for several hours or even days. The intermissions or remissions are not less variable in different cases; and their duration may be only a few seconds or moments, or they may extend to days. The lancinating pain shoots in the direction of the nervous trunk and its branches; and patients sometimes delineate the tract of distribution of the nerve affected in defining the directions in which the pain extends. In the great majority of cases neuralgia is unilateral.

Tenderness on pressure, limited to circumscribed points, is an important diagnostic feature of neuralgia. Valleix was the first to show that, as regards

their relations to the nerves, the tender points are situated as follows: 1st, where nervous trunks or branches emerge from the skull or spinal canal; 2d, over branches which penetrate muscles on their way to the integument; 3d, at the termination of branches which are lost on the surface; and 4th, in places over trunks near the surface. The situation of the tender points in intercostal neuralgia has been stated in treating of that affection. (Vide p. 97.) The diagnostic evidence to be derived from this source in other neuralgic affections will be stated when these are severally noticed. Pain may not be produced by pressure made with the open palm; and, indeed, firm pressure thus made often relieves the pain. The tenderness is shown by pressure made with the ends of the fingers or by percussion. The pain thus produced is often acute, causing the patient to cry out or to try to escape from the exploration. If, however, the pressure be continued, the tenderness is often found to diminish or temporarily to disappear. The tender points are frequently quite limited, the end of the finger being often sufficient to cover them. As a rule, the pain produced by pressure is acute in proportion to the acuteness of the spontaneous pain. The tenderness is most marked during paroxysms or exacerbations of pain. In the intervals between paroxysms, the patient being entirely free from pain, the tenderness on pressure may disappear. Exclusive of the tender points, there may be either hyperæsthesia or anæsthesia of the surface, and the latter may follow the former in the same case.

Paroxysms or exacerbations of pain are excited or increased by sudden or violent movements of parts in which the affected nerves are situated. A concussion of the whole body, as in coughing or sneezing, excites or increases the pain. Cold or hot applications to the surface over the seat of pain in some cases are insupportable.

Fever or any notable constitutional disturbance does not belong to the clinical history of neuralgia. The functions of parts to which the affected nerves are distributed may not be notably disturbed. A neuralgic attack, however, often induces hyperæmia in the site of the pain, as shown by temporary redness of the conjunctiva in cases of neuralgia affecting the ophthalmic division of the fifth pair. Involuntary contractions of muscles and cramps sometimes occur. An increased secretion of tears, saliva, and mucus may accompany paroxysms of neuralgia affecting the several divisions of the fifth pair; and glandular organs within the body are probably in like manner excited in the visceral neuralgias.

Neuralgic affections have no fixed duration. They may end, either spontaneously or under the influence of treatment, in a few hours or days, and they may continue for years or during life, in spite of all methods of treatment. The prognosis is always favorable as regards a fatal termination. Persons who suffer attacks at variable intervals for a lifetime are at length carried off by other maladies not developed in consequence of the continuance of the neuralgia.

Neuralgic pain may proceed from a palpable lesion, such as a tumor either involving or pressing on the affected nerve, the presence of a foreign body, the traction of a cicatrix, from neuritis, etc. In such cases the neuralgia is not, strictly speaking, functional. As a functional malady its causation differs in different cases. It proceeds in certain cases from malaria. This is always to be suspected in cases occurring in so-called malarious districts. When due to this cause the paroxysms sometimes recur with the same regularity as the paroxysms of intermittent fever, but it may proceed from malaria when the paroxysms do not exemplify a law of periodicity. It is one of the effects of lead-poisoning. Next to lead colic (and this is, in fact, a neuralgic affection), neuralgia is the most frequent form in which the poison-

ous effects of lead are manifested. Anæmia, by whatever cause induced, favors the occurrence of neuralgia. A large proportion of those who suffer from neuralgic affections are anæmic.¹ Persons are most likely to suffer from neuralgia between the age of twenty and of fifty. Prior to ten years of age it is extremely rare. Women are more subject to it than men, and of the different species of neuralgic affections, some occur more frequently in the male and some in the female sex. Females, for example, are more subject to intercostal neuralgia, and males to sciatic neuralgia. A neuralgic attack is sometimes referable to exposure to cold, particularly to a current of cold moist air continued upon the part which becomes affected. Cases occur more frequently in the cold than in the warm seasons of the year.

The situation of the pain is not evidence of the seat of the morbid condition giving rise to neuralgia. The mind may refer the pain to the terminal branches or the parts to which they are distributed when the morbid condition is seated at any point in the course of a nervous trunk or at the point of connection of a nerve with the spinal cord. This is illustrated by the fact that after an amputation the condition of the extremities of the divided nerves gives rise to pain which the patient refers to the amputated limb. Anstie held that, as a rule, in the neuralgic affections denominated functional there is some morbid change at the central connection of the nerve or nerves to which the pain is referred. He was also led to think that in a large proportion of cases an hereditary tendency is involved in the causation, and, further, that the development of these affections is favored by exhaustion and debility, aside from anæmia.² There is ground for the belief that local diseases may cause neuralgia of nerves at a distance by a reflected morbid influence (reflex or irradiated neuralgias). Weir Mitchell has observed cases in which injury of a nerve was followed by neuralgia in other and remotely-situated nerves.

The DIAGNOSIS of neuralgia is to be based on the character of the pain, its situation in the course of a nervous trunk or its branches, and tenderness in certain circumscribed spaces on the surface. Other diagnostic points are the recurrence of pain in paroxysms or marked exacerbations, shifting of the situation of the pain and tenderness, and the difference, as regards pain, between pressure with the ends of the fingers and with the open palm. In the shifting of pain from one nerve to another, which is a highly diagnostic feature, the nervous trunks successively affected do not always have a common origin; and thus the neuralgia may be transferred from a cranial to a spinal nerve. These are the positive diagnostic points. Negative points are those by which inflammation and structural lesions are excluded, such as the absence of fever, etc. In determining the affection to be functional, neuritis is to be excluded, and it is to be ascertained, if practicable, that the pain is not dependent on a local mechanical cause, such as a tumor pressing on the nerve at some point in its course. Syphilitic periostitis is also to be excluded.

The TREATMENT of neuralgia is rational and empirical. The rational treatment consists, in the first place, in fulfilling indications which relate to morbid conditions suspected to stand in a causative relation to the neuralgia. The physician in individual cases is to seek for evidence of malaria or lead-poisoning, conditions having diagnostic criteria irrespective of the neuralgic affection. Appropriate measures of treatment are to be addressed to these or any other associated morbid conditions under the supposition that they may have more or less to do with the existence of the neuralgia. Diathetic conditions, especially the rheumatic and gouty, are to be considered as probably contrib-

¹ With regard to the dependence of neuralgia on anæmia, Romberg says: "It seems as if pain were the prayer of the nerve for healthy blood."

² *Neuralgia, and the Diseases that Resemble it*, 1872.

uting to the neuralgic affection, and with reference to the cure of the latter these conditions claim appropriate measures of treatment. Attention is always to be directed to the coexistence of anæmia. Symptomatic phenomena, together with the venous hum in the neck, may denote the anæmic condition when it is not manifested by pallor of the face and the prolabia. If anæmia coexist, preparations of iron should be continued for a long period. An eligible plan is to give in succession different ferruginous preparations for weeks or months, enjoining upon the patient not to expect restoration to health until after a long continuance of the remedies. This treatment addressed to the anæmia is indicated, provided the anæmic condition continue, notwithstanding the neuralgia may cease. The disappearance of the venous hum is evidence that the anæmic condition is removed.

The relief of pain enters into the rational treatment. In severe paroxysms or exacerbations opiates are called for. Large doses are sometimes indicated by the intensity of pain. The most prompt and effective method of affording relief is the hypodermic injection of a solution of morphia. In the use of opiates for the relief of neuralgic pain the risk of the formation of the habit of taking opium is always to be borne in mind, yet in severe cases which resist therapeutical measures this risk must sometimes be incurred. If the pain be not intense, relief may be obtained by belladonna, hyoscyamus, stramonium, conium, the preparation known as chlorodyne, and the tincture of aconite. Local applications will often do much toward the relief of pain. Of these the most efficient are liniments of the tincture of aconite, chloroform, and opium. Belladonna, stramonium, veratria, and aconitia, applied in the form of ointment, are sometimes efficacious.

An arrest of the paroxysms of pain by opiates is sometimes curative; that is, the paroxysms or exacerbations do not recur. If the development of the affection have been recent, it is not easy to decide whether a cure be effected by the remedy or whether the affection have no intrinsic tendency to continue; but the paroxysms sometimes cease to recur, after having been once or repeatedly arrested, when the affection has existed for a greater or less period, and in these cases it is fair to attribute a curative efficacy to the arrest. In order to arrest a paroxysm a full opiate should be given as soon as the paroxysm begins, or, if practicable, the occurrence of the paroxysm may be anticipated by a full opiate. Before abandoning this plan of treatment it should be employed in several recurring paroxysms. The continued employment of some form of opiate or of some one of the narcotic extracts, especially belladonna, during the intermissions or remissions, in some cases effects a cure. Gelsemium and the hydrate of chloral or the croton-chloral are to be included among the palliative remedies.

The empirical treatment of neuralgia consists in the use of remedies which experience has shown to be sometimes curative, which are to be tried without following any particular rational indications. These remedies are in some cases efficacious and in other cases devoid of any curative effect; and often there are no means of determining beforehand which one of the remedies will be most likely to prove successful. In rebellious cases the different remedies are to be tried in succession. Methodic counter-irritation is undoubtedly efficacious in a large proportion of cases. Of the different modes of counter-irritation, Valleix preferred the actual cautery, the hot iron being passed along the course of the affected nerve, taking care that cauterization shall be superficial, so as not to lead to deep eschars and suppuration. To avoid the pain occasioned by the cautery he advised etherization. He stated that he had resorted to the actual cautery in more than 150 cases, and always with success if the neuralgia were functional. This method may be resorted to in cases which resist milder means of counter-irritation, together with

her empirical remedies. Milder means should first be tried. Of the latter, succession of small blisters applied over the painful and tender points will frequently prove successful. Prof. Alfred Stillé advises blisters of only half an inch in diameter, the period of application to be from one to two hours only, the vesicated surfaces to be healed as rapidly as possible, and the blisters to be repeated in a few days if the neuralgia continue. He states, as a result of the employment of this method of treatment in almost every case which has come under his observation in public and private practice for many years, that "in no single instance has it failed to mitigate the symptoms, and in very many it alone has achieved a cure."¹ During the process of vesication the neuralgic pain is frequently increased. When quickness of vesication is desirable, it may be effected in a few moments by the strong aqua ammoniæ, and still more quickly by means of a hammer heated by hot water. By the latter means, or by an instrument devised for the operation known as *firing*, a rubefacient effect may be quickly and conveniently produced, and in mild cases this may suffice without vesication. Sinapisms are proverbially useful, and in certain cases will suffice, in conjunction with internal remedies.

Electricity is a therapeutical agent of great power in many cases of neuralgia. Both the faradic and the galvanic forms are useful, but the latter is in most cases to be preferred. Applied in conjunction with acupuncture, it has been successfully resorted to in some rebellious cases. Duchenne recommended the method called cutaneous faradization. The palliative effect of electricity is probably due to a temporary blunting of the excitability of the nerve or nerves to which the pain is referred; their capacity either to originate or to conduct painful sensations being diminished or annulled by passing through them the electrical current. This measure, however, in many cases has not only a palliative but a curative efficacy. The testimony of those who have had great experience in its employment is stronger than that which can be cited in behalf of any other remedy. Strong pressure upon an affected nervous trunk sometimes has a palliative effect. The pressure at first may occasion great pain, but continued or repeated at short intervals it is borne without suffering and diminishes for a time the excitability of the nerve.

Of the internal remedies which experience has shown to be efficacious, the more important are quinia, arsenic, the precipitated carbonate of iron, the preparations of zinc, strychnia, the essential oil of turpentine, the iodide of potassium, and phosphorus.

Quinia, as already stated, is especially indicated when the neuralgia is attributable to malaria, and it will be most likely to prove successful when paroxysms occur periodically; but it is efficacious also in cases in which there is no ground for suspecting a malarious causation and in which there is no observance of the law of periodicity. To be fairly tried, this remedy should be given in full doses—from fifteen to thirty grains daily to an adult—and continued for at least ten days. Of the foregoing list of remedies, this is entitled to the first rank. Arsenic may be tried in cases in which there is an intolerance of quinia or when the latter fails to effect a cure. It is a remedy of great value in neuralgic affections. To be fairly tried, it should be carried to the extent of producing some of its characteristic toxical effects.

The precipitated carbonate of iron, advocated some years ago by Hutchinson, is sometimes efficacious. It is to be given in large doses—namely, from one to two drachms twice or thrice daily. Ferruginous remedies are rationally indicated by coexisting anæmia, and this condition is present in a very large proportion of the cases of neuralgia. The efficacy of the preparation named is doubtless, in a measure at least, attributable to the coexistence of anæmia. The hydrochlorate, nitrate, and valerianate of ammonium have been found in

¹ *Therapeutics and Materia Medica.*

some cases notably efficacious. Bartholow extols as the most successful of the different methods of treatment the injection of from five to ten minims of pure chloroform in the neighborhood of the affected nerve. This treatment is especially useful in neuralgia affecting nerves superficially situated.¹

Of the preparations of zinc, the valerianate is best suited to cases of neuralgia. Strychnia may be given internally or applied locally upon a blistered surface. In the latter mode of administration the benefit may in some cases be measurably, and perhaps chiefly, due to the counter-irritation. The oil of turpentine is but little used in neuralgic affections, but I have known it to prove promptly successful in doses of a drachm, combined with castor oil given on alternate days, after a variety of remedies had been employed without success. The iodide of potassium has been advocated by Graves, Watson, and especially by Neucort.² The writer last named advised its use in large doses. The coexistence of the rheumatic diathesis is regarded as specially indicating this remedy. The bromide of potassium has been found efficacious in certain cases. According to Anstie, this remedy is especially useful in young persons who may be supposed to suffer from the nervous consequences of unsatisfied sexual desire. He thinks its efficacy is rarely secured under a less quantity per diem than ninety grains. In some cases of neuralgia large doses of phosphorus have been found to be of great benefit. [Among the latest and most approved remedies for neuralgia in general are antipyrin, acetanilid, phenacetin, salol, and exalgine.—H.]

Division of a nerve (neurotomy) and the removal of a section (neurectomy) are surgical procedures resorted to chiefly in cases of neuralgia affecting the fifth or trifacial nerve. They will be noticed in connection with facial neuralgia. Stretching of an affected nerve is another method of treatment, the consideration of which belongs to surgery.

In conclusion, a permanent cure in cases of neuralgia will often depend on the correct appreciation and judicious management of associated morbid conditions, together with hygienic measures to invigorate the general health. Good alimentation is always indicated, and it is desirable that fatty articles of food should enter largely into the diet. Cod-liver oil, if well tolerated, is useful.

Trifacial Neuralgia—Prosopalgia—Tic Douloureux.

In this neuralgic affection the pain is seated in the sensory fibres of the fifth or trifacial nerve. Pain and tenderness on pressure are either limited to, or most marked in, circumscribed spaces situated as follows: The point of exit of the frontal branch above the orbit, the upper eyelid, the upper and lateral portion of the nose, the point of exit of the infraorbital branch, the lower margin of the malar bone, over the temporal bone, the point of exit of the inferior maxillary branch, and over the parietal bone. It is rare that pain and tenderness are situated in all these spaces, but generally in at least one of the spaces within the range of the three branches of this nerve, whence it receives its name—trifacial. In different cases the pain is either limited to, or especially marked in, different branches of the nerve—namely, the supra-orbital, infraorbital, and inframaxillary. It is rare for this affection to be limited to a single branch, with the exception of that portion of the inferior maxillary which is contained within the inferior maxillary bone.

When the first of the three branches of the nerve is the seat of the neuralgia, during the paroxysms of pain there is intolerance of light, with retraction of the eye on the affected side, and more or less abundant secretion of tears.

¹ Vide *Practice of Medicine*, p. 630.

² "De la Névralgie lombaire, etc.," *Archives générales de Médecine*, 1858.

In this situation the neuralgic affection has sometimes been called migraine, hemicrania, and browache, but true migraine differs from neuralgia. Increased heat of the nostril and an abundant secretion of mucus are effects of the neuralgic affection when seated in the second of the three divisions, and salivation sometimes attends an affection of the third division. The branches which accompany the facial nerve (portio dura) may be the seat of pain; a fact which formerly led to the supposition that the latter nerve was affected. Spasmodic contraction of the muscles of the face on the affected side is an occasional effect; hence the affection was formerly called *tic douloureux*, or painful spasm. The affection in the vast majority of cases is limited to the nerve on one side; that is, it is unilateral. The right and the left side are affected in about an equal proportion of cases.

Trifacial neuralgia in point of frequency ranks with intercostal and sciatic neuralgia. An occasional cause is caries of the teeth. It is by no means frequently referable to this cause, but that it is so occasionally cannot be doubted. Teeth, however, are often needlessly sacrificed from a supposed causative connection. It is not sufficient to show such a connection that there is tenderness on striking one or more of the teeth. If the neuralgia proceed from this cause, touching the offending tooth or teeth will excite a paroxysm of pain extending into more or less of the branches of the nerve.

Trifacial neuralgia is to be discriminated from inflammation of the membrane lining the supraorbital and the maxillary antrum and from syphilitic periostitis. The two former of these affections are distinguished by the different character of the pain, its fixed situation, and the occurrence of a discharge into the anterior nares. The latter affection is recognized by the fixed tenderness on pressure, the existence of swellings or nodes, the aggravation of pain in the night-time, and other evidence of syphilitic disease. Neuralgia in this situation is often dependent on malaria, and the paroxysms of pain sometimes exemplify the same laws of periodicity which govern the recurrence of the paroxysms of intermittent fever. Trifacial neuralgia rarely occurs in infancy. In the majority of cases the age is between thirty and fifty years, and it occurs oftener in women than in men.

This neuralgic affection is curable in the majority of cases. Exceptionally, it resists all the therapeutical measures which have been considered as applicable to neuralgic affections in general. The branches which are generally affected in these rebellious cases are the frontal and the inferior maxillary. As a last alternative, division or excision of a portion of the affected branch is sometimes resorted to. The long-continued and extreme suffering from frequently recurring paroxysms in some cases warrants this procedure after other measures have been faithfully tried. Mere division of a nervous branch usually affords only temporary relief. The affection returns after the divided extremities have united. A portion of the nervous branch must be removed to prevent or delay reunion. The removal of a portion of the inferior maxillary nerve within the inferior maxillary bone has sometimes proved successful after the failure of all other measures; but in a considerable proportion of cases the affection returns sooner or later. In a case under my observation, in which the patient has suffered from paroxysms of intense pain recurring at intervals of a few moments for the greater part of ten years, the removal of a portion of the nerve by trephining the inferior maxilla, the operation being performed by Prof. Hamilton, procured relief for several months, but the pain subsequently returned.

Facial neuralgia, persisting indefinitely, resisting medication, and characterized by spasmodic movements of the muscles of the face during the paroxysms of pain, is distinguished by Trousseau as *epileptiform neuralgia*.

There are few forms of disease more distressing than this or more hopeless as regards the prospect of effecting a cure. A case which came under my observation exemplified the persistency of this form of neuralgia, and also exemption from suffering for an unusually long period procured by simple division of the nerve. The patient, a man aged about sixty, had suffered intensely from neuralgia affecting the supraorbital branch of the fifth pair on the left side for more than two years. The paroxysms of pain recurred at intervals of a few minutes, and were often excruciating beyond description. After trying a great variety of remedies and different systems of practice, the nerve was divided by Valentine Mott, and the patient was comparatively free from suffering for three years. At the end of this period, while under treatment for enlargement of the heart and general dropsy, the neuralgia suddenly returned with the same violence as before the operation. Paroxysms were produced by mastication, by movements of the lips in pronouncing words containing labial letters, by touching the face, and they occurred without any exciting cause. The nerve was divided a second time by Prof. J. R. Wood, with immediate and almost complete relief, which continued until the patient's death, several weeks after the operation.

Carnochan was the first to perform neurectomy beyond the spheno-palatine ganglion for the relief of persistent neuralgia of the superior maxillary branch. He reported three cases of successful performance of this operation in 1857.¹ This operation, since that date, has been performed by James R. Wood and others with success.²

Facial neuralgia, after having persisted for a long period, sometimes occasions disturbance of nutrition on the affected side of the face, denoted by tumefaction, an increase of adipose tissue, thickness and firmness of the beard, and it sometimes appears to give rise to pustular or erythematous inflammation. An analysis of 128 cases by Notta showed, as occasional complications, in addition to those already mentioned, paralysis, either complete or incomplete, of the retina, iritis, glaucoma, inflammation and ulceration of the cornea, tumefaction of the tongue on one side, paralysis of the motor oculi, deafness, and anæsthesia of the face on the affected side.³ Certain of these complications are attributable to paralysis of the vaso-motor nerves. Anstie, who verified the correctness of Notta's observations, observed, in addition, grayness of the hair on the affected side and discoloration of the skin from the presence of dark pigment.⁴

Cervico-occipital Neuralgia.

The pain in this neuralgic affection is seated in the posterior branches of the first four of the cervical nerves, especially in that branch of the second cervical nerve called, from its size and distribution, the occipitalis major. The nerves on both sides may be affected.

Painful and tender points are situated as follows: Between the mastoid process and the cervical vertebræ, over the posterior cervical plexus, on the parietal portion of the head, on the mastoid process, and in the concha auris. Shooting pains start from the cervical vertebræ just below the occiput, and extend over the posterior and superior portion of the cranium. Darting pains

⁴ For a report of cases observed and collected by Prof. Henry D. Noyes, witness particularly to the effect upon the eye of paralysis of this nerve, vide *New England Journal of Medicine*, vol. xiv. p. 163.

is sometimes referred to the external auditory meatus. In cases of neuralgia affecting primarily the cervico-occipital nerves, the pain is likely to extend to the branches of the trifacial distributed to the frontal portion of the head, and in like manner in cases of neuralgia affecting primarily the superior division of the trifacial the pain often extends to the branches of the cervico-occipital nerves.

Cervico-occipital neuralgia is to be discriminated from myalgia affecting the muscles of the neck, or *torticollis*. In the latter affection the pain is limited to the affected muscles, the tenderness on pressure is more diffuse, and it is not confined to circumscribed points. The pain is excited exclusively by movements of the affected muscles, and so long as the head remains motionless there are no painful paroxysms.

Cervico-brachial Neuralgia.

In cervico-brachial neuralgia sensory fibres of the four lower cervical nerves and of the first dorsal nerve are affected. The pain is frequently referred to the shoulder, and it may extend to the neck. It shoots downward along the arm to the forearm and hand, following the course of one or more of the nervous trunks of the upper extremity. The pain may be limited to the ulnar, radial, median, or musculo-cutaneous nerve, giving rise to different varieties of the affection. Of these varieties the most frequent is neuralgia affecting the ulnar nerve. Painful and tender points are situated as follows: Near the last cervical vertebra, near the acromial end of the clavicle, over the upper part of the deltoid muscle, in the axilla, at the inner condyle of the humerus, and near the lower end of the ulna and radius.

Pain referable to the cervico-brachial nerves is sometimes an effect of injury of the upper extremity by a wound, a burn, or a contusion. Functional neuralgia is to be discriminated from the pain incident to neuroma or other morbid growths affecting the periphery of these nerves by the failure to discover a tumor in the course of the nerves. Pain referred to these nerves may be symptomatic of vertebral lesions, and also of cervical arthritis. In cases of the latter, movements of the head, especially those of rotation, even in the intervals between the paroxysms, are painful. Another feature is, that the patient when lying down is obliged to raise the head with a hand on the occiput to avoid pain. Myalgia affecting the muscles of the upper extremity is to be discriminated by the larger extent of surface which is tender on pressure, by the absence of paroxysms of pain except when provoked by movements of the affected muscles, and by the limitation of the pain to the affected muscles.

Herpetic vesicles in patches, constituting herpes zoster, sometimes occur in the course of the nerves involved in this affection.

Dorso-intercostal Neuralgia.

This affection has been considered in the section devoted to diseases affecting the Respiratory System, to which the reader is referred (p. 97).

Lumbo-abdominal Neuralgia.

Neuralgia having its seat in the branches of the five lumbar nerves is of infrequent occurrence. It occurs much oftener in females than in males. It is often referred to the hypogastrium, and it may resemble that of colic. The pain and ovarian pain are incident to this affection. In males the affection is sometimes characterized by pain extending along the spermatic cord into the scrotum, accompanied by notable tenderness of the testicle.

Painful and tender points are situated near the upper lumbar vertebra, a little above the middle of the crest of the ilium, in the neighborhood of the inguinal ring, in the scrotum, and in the female on the labia majora. Pains are excited by muscular efforts, the acts of coughing or sneezing, straining at stool, and sometimes by micturition.

Myalgia affecting the lumbar muscles, or lumbago, is to be discriminated by the existence of pain and tenderness on both sides, whereas in neuralgia they are generally confined to one side; by the tenderness being diffused over the affected muscles, and not limited to certain points; and by the absence of paroxysmal pain except when produced by movements of the affected muscles.

In the case in which pain extends to the uterus, inflammation of the organ, or metritis, and carcinoma are to be excluded. In uterine neuralgia the os uteri is tender on pressure, and the tenderness is either limited to or most marked on one side. The pains in these varieties of neuralgia may simulate those caused by the passage of a calculus along the ureter, or renal colic. The pains in the latter are more intense and persisting; and they are developed suddenly, whereas the development of a neuralgic affection is generally gradual. The absence of symptoms which distinguish renal colic warrants its exclusion.

Crural Neuralgia.

This neuralgic affection is rare. It is characterized by shooting pains in the direction of the trunk of the anterior crural nerve and its branches, and by painful and tender points in the groin, the inner aspect of the thigh, knee, and ankle.

Sciatic Neuralgia.

Sciatic neuralgia, or sciatica, in frequency ranks with intercostal and facial neuralgia. It occurs in men oftener than in women, the relative proportion of cases being as three to two. It very rarely occurs before the age of twenty and rarely after sixty. It is sometimes symptomatic of pregnancy, of enlargement of the retro-peritoneal lymphatic glands, of accumulation of feces or foreign substances in the sigmoid flexure of the colon, and of intrapelvic tumors; but in the great majority of cases it is a functional affection.

As in the foregoing neuralgic affections, shooting pains, in paroxysms or exacerbations, extend along the trunk and branches of the affected nerve. In indicating the course of the pain the patient often delineates with accuracy the anatomical distribution of the sciatic nerve. The character of the pain is sometimes described as burning and sometimes as a sensation of coldness. The patient feels as if a current of hot or cold liquid were flowing in the course of the affected nerve. A continued contusive pain, more or less intense, exists in the larger proportion of cases. This pain, as in the other varieties of neuralgia, is referred to the circumscribed spaces which are tender on pressure.

Painful and tender points in this neuralgic affection are found in certain of the following situations: On the sacrum, over the sacro-iliac junction, about the middle of the crest of the ilium, at the sciatic notch, between the trochanter major and the tuber ischii, on the thigh along the track of the nerve, in the popliteal space, on the external border of the patella, over the articulation of the fibula with the tibia where the nerve passes around the fibula, over the lower and posterior part of the external malleolus, and on the dorsum and the outer portion of the soles of the feet. The points situated at the sacro-iliac junction, behind the trochanter major, at the head of the fibula and the external malleolus, are those most frequently painful and tender. Pressure with the finger upon some of the foregoing points may not occasion

more or less painful, but excite a paroxysm or exacerbation of pain extending to other parts in the course of the affected nerve.

The intensity of the pain, as in the other kinds of neuralgia, varies much in different cases. The movements of the affected limb in some cases occasion such an amount of suffering that the patient remains in bed, keeping the limb as nearly motionless as possible. In other cases the patient is able to walk, but with more or less difficulty. Pain is felt especially when the weight of the body falls upon the affected limb, and relief is found in the use of a cane. Sometimes difficulty in walking is felt only in beginning to walk, and after a short time the patient walks with ease. The suffering is occasionally relieved by exercise. In severe cases muscular twitchings and cramps accompany the paroxysms or exacerbations of pain.

Sciatic neuralgia rarely, as compared especially with facial neuralgia, exemplifies in the recurrence of paroxysms the law of periodicity. Like other neuralgic affections, its duration is very variable. As a rule, in favorable cases it persists for several weeks, disappearing, as it is usually developed, gradually. In the vast majority of cases sooner or later it ends in recovery, but in some cases it continues indefinitely in spite of all remedial measures. If it continue for a considerable period so severely as to lead the patient to avoid as much as possible movements of the affected limb, the repose of the muscles may render them for a time incompletely paralyzed. The muscles under these circumstances become flaccid and diminished in volume.

The DIAGNOSIS of sciatic neuralgia involves its discrimination from muscular rheumatism and from the affection of the hip-joint commonly known as morbus coxarius. Muscular rheumatism here, as in other situations, differs from neuralgia in the limitation of pain to the affected muscles, in the diffusion of tenderness over a considerable space—namely, a space corresponding to the number of muscles affected—and in the fact that paroxysms of pain are excited exclusively by movements of the affected muscles.

Morbus coxarius is distinguished by the pain in the hip-joint produced by pressure upon the great trochanter and by flexion and extension of the thigh. Moreover, febrile movements, general debility, emaciation, etc., in conjunction with the local symptoms, point to the existence of chronic inflammation within the joint.

The term sciatica, as commonly used, is applied to cases in which pain is referred to sacral nerves, although the sciatic nerves may be unaffected. Pain of a neuralgic character in the nerves composing the sacral plexus is often symptomatic of lesions within the pelvis and abdomen, such as aneurismal, carcinomatous, or other tumors, enlargement of glands, etc. and of lesions of the sacrum and vertebral column and those occurring within the spinal canal. Here, too, as in other situations, it may be dependent on neuritis. This is to be inferred from the speedy occurrence of paralysis and atrophy of the muscles to which the nerves are distributed.

The coexistence of two or more of the foregoing different neuralgic affections or their successive occurrence is frequently observed. Proximate or inosculating nerves may be simultaneously or successively affected. Thus, trifacial and cervico-occipital neuralgia are not infrequently associated, and this is true of sciatic and crural neuralgia. A cure or spontaneous cessation of neuralgia in one situation is likely to be followed by the development of the affection in another situation. These facts go to show the dependence of neuralgia on constitutional or general morbid conditions.

[Coccygodynia.

The term "coccygodynia" is applied to a variety of neuralgia characterized by intense paroxysmal pain in the region of the coccyx. It is more common in women than in men, and is often associated with symptoms of hysteria. It is often reflex, as proved by the relief which sometimes follows the removal of sources of irritation in the genital organs. In intractable cases the coccyx has been removed, and occasionally with permanent relief.—H.]

Dermalgia.

Neuralgia is sometimes limited to the skin. Cases are occasionally observed in which pain is felt on the surface of the head, trunk, or extremities, together with notable tenderness on pressure, the nervous trunks being free from pain or tenderness. This form of neuralgia has been called *dermalgia*. Under this heading may be placed the form of neuralgia described by Weir Mitchell as incident to injury of nerves, and called by him *causalgia*. This is characterized by a burning pain in the soles of the feet and palms of the hands. I have reported an instance of *causalgia* affecting the soles of the feet, occurring without any injury of a nervous trunk or any other symptom; also, a case in which a paroxysmal burning pain was referred to the abdomen and lower limbs.¹

Myalgia—Muscular Rheumatism.

Neuralgia affecting sensory nerves in muscles may be distinguished as *myalgia*. Under this head I shall enumerate certain local affections which it has been customary to embrace under the name *muscular rheumatism*. The term *rheumatism*, as applied to these affections, is manifestly inappropriate, and it is desirable that the name in this application should become obsolete. The *myalgic* affections were designated by Valleix by the suffix *dynia*, added to the name of the muscle or group of muscles affected. This designation, having the same derivative meaning as words ending in *algia*, is appropriate.

Myalgia is of frequent occurrence as an acute and a chronic affection. The symptomatic features of the acute affection are as follows: The development is usually gradual. A dull pain is at first felt in certain muscles, which increases, and at length becomes more or less severe. The pain is comparatively slight when the affected muscles are at rest. In certain positions the patient may be nearly or quite free from suffering. A constant pain of a contusive character is often felt when the muscles are at rest, and this may be aggravated by spasmodic pains occurring from time to time. In movements which involve contraction of the affected muscles, the pain is severe, cramp-like, and sometimes so excruciating that the patient can hardly repress loud groans or cries. Voluntary movements which occasion the severe pain are avoided as much as possible, but as it is impossible to maintain rigidly-fixed positions of the body as a whole or of its different parts, the affected muscles are at times thrown into painful contractions, however much the patient may desire to avoid them. Movements occurring during sleep occasion the attacks of pain, and hence the patient is awakened at brief intervals. In some cases the affection changes its seat from certain muscles to others, but oftener it remains fixed in the muscles first affected.

The affected muscles are more or less tender on pressure, the tenderness being diffused over the whole of the space which the muscles occupy, and limited to certain points as in ordinary neuralgia. The tenderness is us

¹ Vide *Clinical Medicine*.

great. Aside from the tenderness, there are no local characters, such as swelling, heat, or redness. The local phenomena are not those of inflammation, as in articular rheumatism. If the local symptoms denote inflammation of the muscles, the affection is not myalgia. Uniform firm pressure over the affected muscles is not only well borne, but it affords relief in cases of muscular rheumatism.

There is little or no constitutional disturbance beyond that occasioned by suffering and loss of sleep. The appetite and digestion may not be impaired, and there is no fever.

In the subacute or chronic form of the affection pain similar to that which belongs to the acute form may be excited only when the affected muscles are tracted with unusual force. The patient experiences suffering when he makes certain violent movements. In other cases pain is excited by particular movements when they are first made after a period of rest, and the pain partly disappears if the movements be continued. The chronic oftener than the acute affection is likely to shift its situation, affecting now certain muscles and now those in another part. If the chronic affection remain fixed in particular muscles, they may become somewhat atrophied in consequence of their being kept as much as possible in a state of inaction.

The DURATION of acute myalgia varies between a few hours and a week. Exceptionally the affection continues for several weeks. The duration of the chronic form is indefinite. It is often a very obstinate affection, persisting many months. The course of the latter is usually marked by remissions and intermissions. In certain situations—namely, the loins, the walls of the chest, and muscles of the scapulæ—the chronic affection is likely to be long lasting.

The following are the principal situations of myalgia in the acute and the chronic form:

1. *The Muscles of the Head.*—Situated in the occipito-frontal muscle, the affection is distinguished from neuralgia affecting the trifacial and the occipital nerve by the pain being referred to both sides of the head, by its being excited by movements of the muscle and comparatively slight so long as the muscle is at rest, and by the absence of tenderness in disseminated points. The muscles of the eye are sometimes affected. Movements of the eye then occasion more or less severe pain. The temporal and the masseter muscle may be affected, causing pain in mastication.

2. *The Muscles of the Neck.*—In this situation the affection, as it commonly occurs, has been known by the name *rheumatic torticollis*. This name is applied to the affection when situated in the muscles of the antero-lateral part of the neck. The muscles on the posterior part of the neck are sometimes the seat of the affection. Valleix applied to the affection in the latter situation the name *cervicodynia*. In this situation the affection is to be distinguished from ordinary occipital neuralgia.

3. *The Muscles of the Back.*—Valleix called the affection in this situation *craniodynia*. Seated in these muscles, the pain is caused especially by movements which approximate the scapulæ.

4. *The Muscles of the Loins.*—In this situation the affection is commonly known as *lumbago*. Valleix designated it *lumbodynia*. This is a frequent seat of the affection in a chronic form. It is to be discriminated from *lumbosacral abscess*, *lumbo-abdominal neuralgia*, and the pains incident to aneurism of the descending aorta.

The Thoracic Muscles.—Here the affection goes by the name *pleurodynia*. In making the diagnosis pleuritis and intercostal neuralgia are to be excluded. This may easily be done by ascertaining the absence of the characteristic characters of the latter two affections. The pain excited by forced

breathing, coughing, and sneezing is not unlike that in pleuritis and intercostal neuralgia. In this situation the pectoral and the intercostal muscles are affected.

6. *Muscles of the Shoulder.*—Valleix entitled the affection here situated *scapulodynia*. It is seated especially in the deltoid muscles, and it is liable to be confounded with arthritis situated in the shoulder-joint.

7. *The Muscles of the Extremities.*—Seated in the extremities, the affection is to be discriminated from neuralgia affecting the nervous trunks, and from the affection commonly known as syphilitic rheumatism.

8. *The Abdominal Muscles.*—The pain and soreness caused by the affection in this situation may suggest as probable or possible the existence of peritonitis. This disease is to be excluded by the absence of the general symptoms and by firm pressure with the palm of the hand being well borne, as in cases of cutaneous hyperæsthesia.

9. *The Visceral Muscular Structures.*—The tongue and the muscles of the pharynx and œsophagus may be the seat of myalgia, giving rise to pain speaking and in deglutition. Examples, however, are extremely rare. Seated in the stomach, intestines, and uterus, as it probably may be, to distinguish the affection from visceral neuralgias is impossible; and in fact to consider it as distinct from the latter is to make a distinction without any essential difference. There is reason to believe that the diaphragm may be the seat of myalgia. It is perhaps more reasonable to consider this as the affection, rather than diaphragmatic pleuritis, in certain cases characterized by the instinctive arrest of diaphragmatic movements in consequence of pain, and by the intense suffering caused by coughing and sneezing, febrile movement and pleuritic effusion being wanting. It may be doubted if the affection be ever seated in the muscular walls of the heart.

In all these situations the most marked diagnostic feature is the connection of cramp-like pain, more or less severe, with the movements which bring into play certain muscles in the parts to which the pain is referred, pain, irrespective of contractions of the affected muscles, being comparatively slight and sometimes wanting. This diagnostic feature distinguishes myalgia from neuralgic affections seated in the different nervous trunks. Another diagnostic feature is the diffusion of soreness over the affected muscles, whereas neuralgia seated in nervous trunks is characterized by tenderness in circumscribed points. Inflammation affecting muscles is distinguished from myalgia by the constancy of pain or the absence of the remissions or intermissions which belong to the latter affection, by the existence of swelling and sometimes redness, by the greater degree of tenderness on pressure, and by the presence of more or less symptomatic fever.

The TREATMENT of the acute form of the affection consists of sinapisms, followed by soothing, emollient applications over the affected muscles, rest in the position most favorable to avoid contractions of the affected muscles, and the employment of anodynes either internally or by hypodermic injection. In the chronic form small blisters in succession are useful, but not in the same degree as in cases of ordinary neuralgia. The employment of the induced electrical current I have known to be beneficial in obstinate cases. The constant current has also been found highly efficacious. Friction or shampooing, either dry or with stimulating or anodyne liniments, afford relief and promotes a cure. "Firing" is recommended. The bromide of potassium and of ammonium I have found useful. The hydropathic treatment is said to prove successful in some obstinate cases, water being employed locally and generally. The salts of quinia in full doses are sometimes efficacious, especially when the affection is intermittent. Measures to invigorate the general health are important in chronic cases. If

exist, preparations of iron should be continued for a long time in small doses or until the venous hum disappears from the neck. Anstie recommends as especially useful the muriate of ammonia in doses of from twenty to thirty grains. [Fagge regards lumbago as almost invariably the result of irritation of the kidneys by a hyperacid urine, and states that rapid relief may be frequently given in such cases by alkalies such as the citrate of potassium in full doses at frequent intervals.—H.]

Persons liable to this affection are likely to have an attack after exposure of a portion of the body to a current of air, especially during sleep or when the body is perspiring. The susceptibility to this cause of disease is to be overcome by the daily use of the sponge-bath, by avoiding an over-abundance of clothing, and by becoming habituated to out-of-door exercise in all kinds of weather.

Cephalalgia—Headache.

Pain in the head is a symptom occurring in many affections, such as active cerebral congestion, cerebral meningitis, cerebritis, the essential fevers, acute dyspepsia, syphilitic periostitis of the head, intracranial tumors, etc. etc. It is frequently due to neuralgia affecting either the cervico-occipital nerves or the supraorbital division of the fifth pair. Pain limited to one side of the head, or hemicrania, may be due to neuralgia affecting the nerves just named. According to Valleix, idiopathic cephalalgia or headache is in all cases resolvable into hemicrania (migraine). This opinion does not seem to me to be correct. In certain cases the pain does not follow the direction of these nerves, it is not limited to one side of the head, disseminated tender points may not be found, and in its behavior the affection differs from neuralgia affecting these or other of the nervous trunks and branches. Hence, cephalalgia or headache may denote a functional neuropathic affection distinct from hemicrania. The seat of the affection when confined to one side in certain cases has been supposed to be the branches of the trifacial nerve which are distributed to the dura mater. It has also been supposed that the sensory filaments entering into the composition of the cerebral membranes and of the brain may be the seat of neuralgia.

Cephalalgia is extremely common. It occurs in paroxysms, lasting usually from twelve to twenty-four hours, in some cases being of shorter duration, and occasionally continuing for two or three days. There are few persons who do not occasionally experience an attack after childhood or adult age, and there are very many who are subject to attacks recurring sometimes at regular, but usually at irregular, intervals for many years or during the lifetime. A host of persons suffer from it who either do not consider it of sufficient importance to resort to medical treatment, or, having found medical treatment ineffectual, resign themselves to it as an irremediable malady.

The pain in different cases or in different attacks in the same case differs much in degree. An attack is often not severe enough to prevent habitual occupation, but in some instances the intensity of the pain is such that the patient is unable to be about, and perhaps is obliged to take to the bed. The pain is sometimes referred to the forehead, sometimes to the occiput, and sometimes to the whole head. The character of the pain as described by patients differs. It is sometimes sharp or lancinating, like the pain in neuralgic paroxysms; and in other cases it is a dull, heavy pain. Patients sometimes say that they feel as if the head would burst. Firm pressure upon the head, especially over the temples, often affords momentary relief. Frequently **bing** or shampooing the scalp with considerable force diminishes the pain. **re** is frequently an abnormal sensitiveness to light and sounds, and in

severe attacks the patient seeks perfect quietude in a dark room away from all noise. The appetite during the attack is either impaired or lost. The odor of food is often disagreeable. Nausea and vomiting occur in a certain proportion of cases, and then it is common to call the affection *megrin* or *sick headache*. Without nausea or vomiting the affection is commonly known as *nervous headache*. The face is in some cases flushed, the eyes are suffused, and the temperature of the head is raised; and in other cases, especially if nausea and vomiting occur, the face is pallid and the head may be cool. Free vomiting, although the stomach may not contain any aliment, is sometimes followed by relief.

Accompanying the foregoing local symptoms is more or less general debility or prostration. There is rarely fever, the pulse is generally small and feeble, and the surface of the body cool. Occasional shiverings are not uncommon. Disturbed action of the heart, or palpitation, is not uncommon during the attack.

The attack gradually passes off, sometimes with the occurrence of frag evacuations from the bowels or an abundant secretion of urine or a slight perspiration. The attack is often developed in the morning, pain being experienced on awakening from sleep, and it may continue until after sleep is obtained on the following night. Persons subject to the affection are able sometimes to predict its advent by a feeling of lassitude, depression of spirits, or a sense of indefinite discomfort. After the attack has passed off, there is frequently, for some time, a sense of soreness in the head, with more or less general debility. Often, however, the mental faculties are unusually clear and the spirits are buoyant after recovery from an attack.

The affection involves a constitutional predisposition. Persons are subject to periodical attacks of headache, as of asthma or epilepsy. The predisposition existing, various exciting causes may determine an attack, such as mental excitement, deprivation of sleep, bodily fatigue, exposure to the sun's rays, and dietetic imprudences. Not infrequently attacks occur without any obvious exciting causes. Women are more subject to the affection than men, and it often occurs at the menstrual period. The predisposition varies in degree in different cases, as shown by the frequency or rareness of the attacks. The predisposition frequently ceases after the age of forty or fifty; and persons who have experienced attacks more or less frequently from adult age up to the periods of life just named, thereafter are exempt from their recurrence. This may be stated as a rule, but, unhappily, there are not a few exceptions.

The affection is neuralgic in its character, but it is difficult to determine its precise seat. It is a reasonable supposition that it involves a toxical agent in the blood. Cephalalgia, it is well known, is produced by different toxical agents—namely, opium, alcohol, strychnia, quinia, and the accumulation of urea. Assuming the correctness of this supposition, the nature and source of the toxical agent or agencies are unknown. It has been conjectured that the immediate causative condition may be either spasm or paralysis of the muscular fibres of the arteries within the skull from an influence exerted through the vaso-motor nerves. The pallor and coolness of the face and head in some cases, and the redness and heat in other cases, sometimes bilateral and sometimes unilateral, afford support to this conjecture; and it is not an incongruity that anæmia and congestion alike may give rise to the cephalalgia. In accordance with these pathological views, inhalation of the nitrite of amyl has been suggested as an appropriate remedy when the appearances denote anæmia, and ergot when there is congestion. Assuming the existence of spasm or paralysis of the arterial muscles, it is reasonable to suppose that the motor influence depends on a toxical agent acting on the sympathetic nerve. It has been shown that a certain number of cases of migraine are of

origin. In certain cases, migraine is the result of some affection of the nasal mucous membrane, and in obscure cases it is well to make an examination of this region. Other cases of migraine appear to be of a myalgic nature, the occipito-frontalis muscle being chiefly involved.

Periodical headache, as regards successful treatment, belongs among the opprobria of medical art, yet in not a few cases much benefit may be derived from treatment. The treatment embraces measures to be employed at the time of an attack and during the intervals.

If patients be not affected unpleasantly by opiates, an attack may be sometimes warded off or abridged or its severity lessened by a full dose of opium in some of its forms, or of its alkaloids, morphia or codeia. The carbonate of ammonia is sometimes successful in affording relief. A saline purgative, taken at the beginning of the attack, is in some cases an effectual remedy. The bromides given in full doses are sometimes efficacious. This statement will also apply to the hydrate of chloral in doses of fifteen grains, repeated once or twice after an hour's interval if relief be not obtained.

Various palliative measures may be resorted to with advantage. The inhalation of a little of the vapor of chloroform is sometimes an efficient palliative. Evaporating lotions to the head—alcohol, spirits, vinegar, or ether—in some cases afford marked relief. In some cases a towel or napkin wrung out in water as hot as can be borne, and wound around the head, is more efficient than cold applications. Warm stimulating pediluvia are useful. Strong coffee or tea affords marked relief in some cases. Electricity has been found in some cases effective in arresting and preventing the recurrence of the paroxysms. The electrical treatment should not be abandoned until after a fair trial of the faradic and the galvanic current. Guarana, given in the form of powder, infusion, or extract, sometimes is an efficient palliative remedy. This is an uncertain remedy, and generally after a few paroxysms it fails to afford relief. In cases of migraine dependent upon some disease of the nasal mucous membrane local treatment applied to this part has proved effective.

During the intervals remedies which are sometimes useful by way of prophylaxis are—*nux vomica* or strychnia in small doses, arsenic, small doses of quinia, belladonna, caffeine, and the preparations of zinc, especially the valerianate. These remedies may be tried in succession. Hygienic measures are important. In general terms, the liability to attacks is less the more closely the laws of health are observed. Avoidance, as far as possible, of everything which experience shows in individual cases to act as exciting causes is an important part of the management.

CHAPTER VII.

THE NEUROSES.

Chorea.—Hereditary *Chorea*.—Anomalous Muscular Movements.—Local Spasms.—Tremor.—Epilepsy.

CERTAIN of the neuroses or functional affections of the nervous system are characterized by disordered muscular movements. *Chorea* is one of these affections. Anomalous movements proceed from disordered volition.

Disorders manifested by involuntary movements are grouped under the names tremor and local spasms. In these groups belong senile trembling or paralysis agitans, writers' cramp, and athetosis. Epilepsy is an important functional affection. The foregoing affections will be considered in this chapter.

Chorea.

The affection called *chorea*, *chorea sancti Viti*, or *St. Vitus's dance* is characterized by irregular clonic contractions of more or less of the voluntary muscles, giving rise to movements which are either involuntary or not under the guidance of the will. The manifestations of the affection are usually first limited to a portion of the body, to one of the upper extremities often than elsewhere, and sometimes they are confined for a time to the fingers of one hand. The movements increase and progressively extend to both upper extremities, the muscles of the face, and frequently to the lower extremities and to the trunk. The appearances consist of frequently-recurring or incessant movements of the parts affected, producing in the face varied and ludicrous grimaces, and in the extremities and trunk grotesque contortions and fantastic gesticulations.

The spectacle afforded by the manifestations of this affection is comical, and it is difficult to realize that it is not a performance for the amusement of observers. The condition has been well designated an "insanity of movement." The condition, however, if the affection be severe, is truly distressing. The incessant activity of the muscles induces fatigue. The patient may be unable to perform the voluntary acts which the wants of the body require, and is completely dependent upon others. Speech may be impaired or lost. Locomotion may be impossible. The isolation is sometimes more complete than in cases in which a considerable portion of the body is paralyzed or several senses are abolished. Want of ability to direct and harmonize voluntary movements is a feature of this affection. Acts of volition give rise to the irregular movements, but movements to a greater or less extent take place without the stimulus of volition; that is, they are involuntary. In the latter respect chorea differs from locomotor ataxia, the movements in ataxia being never wholly involuntary. The movements in chorea are usually suspended during sleep, but they sometimes continue, although always more or less diminished. They are increased generally when the patient is conscious of being observed and under any emotional excitement. The movements are frequently more marked on one side of the body, and this is generally the left side. They are sometimes confined to this side, and the affection is then called *hemichorea*. The choreic manifestations are confined to the voluntary muscles. The sphincters are rarely affected; and this is true of the muscles concerned in respiration, inclusive of the laryngeal muscles, as also those of the pharynx. In extreme cases the disordered movements are so violent as to give rise to contusions and excoriations unless the patient be properly protected. In consequence of incessant movements it may be difficult or impossible to feed the patient. This severe form of the disease is called *chorea major*, and it is happily very rare.

The affection is not accompanied by fever. If this exist it is due to an intercurrent or coexisting affection. The appetite is usually more or less impaired and the bowels are constipated. Anæmia often coexists. Irritability of temper is a notable feature. The mental faculties are weakened. The grimaces give to the physiognomy an appearance of idiocy, and if the affection becomes chronic patients fall into a condition of apparent imbecility. The mind fails in these cases from the deficiency of exercise of the faculties. If the speech be lost, it is difficult to estimate the amount of

intelligence which is preserved. The power of the affected muscles is more or less diminished, and this impairment of power or incomplete paralysis is more marked on the side more affected with the chorea. Anæsthesia of the surface on one or both sides of the body is sometimes observed; oftener, however, there is hyperæsthesia, which is especially marked in the tract of nerves. Tenderness along the spinal column exists in a large proportion of cases. There is an exaggerated susceptibility to reflex excitations, and the electrical excitability of both the muscles and skin is abnormally increased. Pressure upon tender points over nervous trunks excites the choreic movements.

Endocardial murmurs are not infrequently found in cases of chorea. If these be aortic or pulmonic, accompanying the first sound of the heart, they are to be regarded as inorganic or anæmic murmurs. They do not constitute evidence of endocarditis. Nor is a mitral murmur in this affection always evidence of endocarditis. I have observed a mitral systolic murmur during the continuance of chorea, and the disappearance of the murmur after recovery from the chorea.

As one of the neuroses, this affection of course has no ascertained anatomical characters. In cases which have proved fatal morbid changes, not uniform in character or seat, have been found in the nervous centres. Minute embolic obstructions in the corpus striatum have been observed by J. Hughlings Jackson and Bastian in hemichorea. The opinion is held by many that there is a pathological connection between it and rheumatism. The statistical researches of Sée and Henri Roger in France appear to show that in a considerable proportion of cases chorea either follows or is coincident with rheumatism. The same results have not been obtained by the analysis of cases in Germany. Endocarditis appears to coexist in a certain proportion of cases without other evidence of rheumatism; but it is probable that in some of these cases the existence of endocardial inflammation has been incorrectly inferred from physical signs. It is certain that endocardial inflammation does not exist in a sufficient number of cases to afford any ground for the theory of Kirkes that chorea is caused by the passage into the blood of the inflammatory products of endocarditis. It is perhaps correct to say that there is no essential pathological connection between rheumatism and chorea, but that in children the former predisposes to the latter disease.

[The relationship between chorea and rheumatism was investigated by the collective investigation committee of the British Medical Association in 1887, its report being based upon a study of 439 cases. Of these, 116 (26 per cent.) were preceded by definite attacks of acute or subacute rheumatism. There were 26 other cases in which there was a history of vague pains "believed to be rheumatic," and if these cases are included, the percentage of antecedent rheumatism amounts to 32.5. This association is so frequent as to warrant the belief that there is some etiological relationship between the two affections.]

The seasonal relations of chorea and rheumatism have been minutely studied by Morris J. Lewis of Philadelphia.¹ Among the conclusions at which he arrived is the following: "It is more than probable that 'weather' is one of the most important predisposing causes of both the diseases studied in this paper, although precisely which meteorological factor is the baneful one does not clearly appear. No one element of 'weather' explains fully the fluctuations of these tracings for chorea, although in the barometer and norm statistics the relationship appears to be closer than to any other etiological factor or factors that have as yet been advanced." Briefly stated, *vis*'s tables, based upon a study of 1383 cases, show that "chorea in the

¹ *Trans. Association of American Physicians*, vol. vii., 1892.

United States is essentially a disease of the spring, and that the fewest attacks occur in the autumn."—H.]

The CAUSATION is obscure. It is common to suspect the presence of worms in the alimentary canal, but there is little evidence that the affection is caused by worms. It is sometimes traced distinctly to fright or to violent mental excitement, as a fit of anger. Its development is favored by anæmia, and in most cases patients are anæmic. There is reason for suspecting sexual excitation as a cause in some instances. It may be produced by unconscious imitation. This has been shown repeatedly by its prevalence in schools. It occurs occasionally in pregnancy (*chorea gravidarum*).

Chorea occurs especially between ten and fifteen years of age. It rarely occurs at less than six years of age. It may occur at any period of life. Henri Roger has reported a case occurring in a female aged eighty-four years. Graves observed a well-marked case in a male aged seventy-two years. On the other hand, cases have been observed in infants shortly after birth. Girls are more liable to it than boys, the ratio being as three to one.

The DURATION varies from a few weeks to several months. The average duration is between two and three months. In the vast majority of cases the termination is in recovery. After a variable duration the affection tends intrinsically to this termination. In a very small proportion of cases it becomes chronic and is incurable. Life may be destroyed by intercurrent affections which, in general, do not suspend the choreic phenomena. A fatal result may take place without any superadded disease, the patient being worn out by prolonged irritation, loss of sleep, and inanition. The incessant movements sometimes give rise to contusions and excoriations which may lead to erysipelas and abscesses, and these may contribute to a fatal result. Occurring in pregnancy, it often leads to abortion or premature delivery, and hence is not without danger.

Relapses are likely to occur after intervals varying between a few months and two or three years. As a rule, the relapses are shorter than the primary attacks.

A number of remedies has been advocated as effecting a cure of this disease. In general, when different methods of TREATMENT of any disease are found to be successful, it is a fair inference that the disease ends favorably from an intrinsic tendency. This is undoubtedly true of chorea. Of the diverse remedies indicated, none can be relied upon for promptly arresting the course of the disease, and it is doubtful if any exert a special curative agency. It by no means follows, however, that much benefit may not be derived from judicious treatment. The greater part of the remedies are doubtless more or less useful, and the physician is to exercise judgment in adapting them severally to individual cases, and in employing them successively in the same case.

Rational indications, in the first place, are to be sought for in coexisting disorders or morbid conditions. If there be symptoms, aside from the chorea, pointing to rheumatism, remedies addressed to this condition are called for. Anæmia in a large proportion of cases calls for appropriate treatment. Constipation, if present, claims attention. Purgative remedies are among those advocated as efficacious in curing the disease. Causes of peripheral irritation, especially those of sexual origin, should be removed.

Of remedies, other than purgatives, which experience has shown to be useful, the more important are—arsenic, the carbonate and prussiate of iron, zinc, strychnia, opium, cannabis indica, and various antispasmodics. Of the efficacy of arsenic there is abundant and strong testimony. Fowler's solution is the most eligible preparation. Beginning with three or four drops 3 or 4 times daily, the doses should be gradually increased until the charac-

observed. Of the preparations of iron, the carbonate and prussic acid have been supposed to exert a curative effect, aside from their usefulness in reference to coexisting anæmia. Of the preparations of zinc, the sulphate has been especially advocated as curative in this affection. Strychnia has been used by Trousseau, who preferred the sulphate dissolved in syrup. The treatment with a very small dose—namely, one-twenty-fifth of a grain—once daily—and increased the dose very gradually. Opium was also used by Trousseau as a curative remedy. He gave it in a full dose, inducing slight narcotism, which is to be maintained for several days. He stated that this method of treatment is often extraordinarily successful. The efficacy of cannabis indica testimony is borne by many. Cimicifuga racemosa of this country has been a popular remedy, and its value is testified by many eminent physicians. Conium pushed to its physiological limits has been employed with benefit. Of antispasmodic remedies, those which have been found especially useful are hyoscyamin, valerian, asafoetida, and opium. Keeping the patient daily under the influence of chloroform for an hour or more has been found serviceable. This measure is hardly to be recommended save in cases in which the movements are unusually violent and intractable. In chorea major it may be necessary to anæsthetize the patient in order to introduce the stomach-pump for purposes of alimentation. The application of ether spray to the spine, for four or five minutes at a time daily or on alternate days, has been found efficacious. The testimony respecting the efficacy of electricity is conflicting. Benedikt and Jaccoud claim success from galvanization of the spine. Beard and Rockwell have found electrolysis uniformly successful. The result of galvanization of the limbs in a few cases was unsatisfactory in their hands, and also in the hands of Meyer. This discrepancy may be perhaps in a measure explained by differences as regards the mode of employing both the direct and the interrupted current, and also by differences as regards the period of the disease at which treatment was entered on, bearing in mind that this disease may be of a self-limited duration. The bromides, in my experience, have not met the expectations which I had been led to form of their usefulness in this affection.

Physical measures are certainly not less important than medicinal remedies. Abstinence from food as nutritious as possible is desirable. Daily exposure and, if practicable, exercise in the open air are highly important. The cold sponge-bath provided it be not dreaded by the patient and it be followed by brisk friction and the shower-bath, with the same provisions, is admissible. On the other hand, the tepid bath as a palliative measure is highly useful. In the Hôpital de la Pitié in Paris for many years much reliance has been placed on gymnastic exercises for the cure of chorea. Of course these are practicable only in the cases in which the ability to co-ordinate movements by the will, or more or less impaired, is not lost. The exercises consist of systematic movements performed under the direction of assistants and enlivened by music.

After the choreic movements have ceased, more or less inability to execute fine movements, together with muscular weakness, remains, and the efforts of the disease are to be removed by exercise. The power of re-educating the muscles is to be acquired as in infancy, but it is acquired

more slowly. For details concerning gymnastic exercises, vide papers by M. Sée and by M. Blache in the *Annales de l'Académie de Médecine*, Paris, 1855. For a summary of these details, vide *Neurology of Children*.

[Hereditary Chorea.

This disease differs from ordinary chorea in several fundamental particulars. In the first place, it is decidedly hereditary, having been traced in five generations of the same family. Secondly, it rarely manifests its presence before adult life, and often not before the age of forty. Finally, it is attended with decided symptoms of mental impairment, beginning with loss of memory and gradually advancing to childishness and dementia. Suicidal proclivities are also frequently observed. The disordered movements of the face and upper extremities are like those of chorea, but the distinguishing feature of the disease is the gait or walk, which seems to be composed of a series of efforts to retain the equilibrium. On attempting to walk the patient looks as if he were about to fall on his face, but takes a few rapid, stumbling steps forward and thus recovers his balance. This manœuvre is then repeated, so that, as above stated, the walk consists of repeated efforts to maintain the balance of the body. Another point of distinction between hereditary chorea and ordinary chorea is that no association has been observed between the former and rheumatism.

Thus far there have been but three post-mortem examinations of hereditary chorea recorded.¹ In the first there was a subdural hemorrhagic cyst; in the second there were pachy- and lepto-meningitis; and in the third there were multiple tumors of the dura mater. These lesions indicate a state of continuous irritation of the cerebral cortex, and are entirely different from any anatomical alterations described in connection with ordinary chorea.—H.]

Anomalous Muscular Movements—Local Spasms—Tremor.

Certain abnormal muscular movements are considered, incorrectly, as denoting varieties of chorea. Persons sometimes without motive or purpose, impelled apparently by an irresistible impulse, perform extraordinary acts. One of these is leaping suddenly and violently, and sometimes jumping upon chairs or tables. Such movements have been considered as denoting a variety called *chorea saltatoria*. A patient subject to epilepsy was brought to me for examination, a young man aged about twenty, who at variable intervals had paroxysms of jumping vigorously for a few seconds. He declared he was unable to avoid these movements. In other cases there is a propensity to run, and the patient unexpectedly, when walking, rushes forward at a rapid pace for several minutes. These movements have been considered as denoting another variety, called *chorea festinans vel procursiva*. Rotating and vibrating movements are performed in other cases (*chorea oscillatoria*). Moving the head and body alternately backward and forward, constituting what has been called *salaam convulsions*, belongs in the same category. In a case which came under my observation the patient, a young married woman, had for several months during her waking hours constantly pounded some object before her with both hands. In another case a young unmarried woman had frequently-recurring paroxysms in which for several hours she rotated the head rapidly, and also at times she performed rapid projectile movements of the tongue. This patient for three years maintained the position of emprostotonos in sitting, walking, or standing, always ceasing to maintain it when recumbent.

These movements, although abnormal, proceed from the action of the will. They denote a species of mental aberration. They are manifestations of delirious volition, resembling in this respect certain of the convulsive movements in hysteria. They are sometimes connected with cerebral disease.

¹ *Annual of the Universal Medical Sciences*, 1890.

In most cases they are purely functional. In some cases it is undoubtedly true that patients are unable to resist the impulse which impels to the abnormal acts, but a morbid propensity to excite wonder and interest doubtless enters into the rationale in some cases.

The treatment embraces remedies and hygienic measures to invigorate the nervous system, together with efforts to overcome the propensity which gives rise to the abnormal movements.

Allied to the cases just referred to are those in which twitching of certain parts becomes habitual. Thus some persons acquire the habit of jerking the head, raising the shoulders, or making other motions, especially under mental excitement. In many, if not most, of these cases the habit may be overcome by persevering efforts before it becomes confirmed. Convulsive movements of certain of the muscles of the face, producing sometimes notable grimaces, are involuntary and closely allied to chorea. These often become confirmed and irremediable. Spasm of the eyelids is called blepharospasmus. When the angles of the mouth are raised the peculiar expression is significantly styled risus caninus, or the sardonic grin. The convulsive movements or spasms of the muscles of the face, called by Romberg mimic or histrionic, may be either clonic or tonic. They are oftener the former. The involuntary grimaces which are sometimes produced occasion much mortification. The clonic spasms come in paroxysms which generally last but an instant. They are especially liable to occur under mental excitement. Sometimes they interfere with mastication and articulation. They are almost always unilateral. Involuntary or spasmodic movements of the head, with or without grimaces, characterize some cases. In a case at Bellevue Hospital there was violent jerking of the head from side to side at intervals of a few seconds, and with these there were rapid lateral oscillations of the eyeballs. Aside from these symptoms there was no evidence of cerebral disease. They followed a debauch. The patient soon left the hospital, the movements continuing. In another case the head was moved spasmodically to the left side at short intervals, with some contraction of the facial muscles on that side. Notable improvement in this case took place under the use of the bromide of potassium. Pressure over the branches of the trifacial nerve and at certain points on the cervical portion of the spinal column sometimes has an inhibitory effect upon facial spasms. These are known as "pressure-points." They may be found in local spasms situated elsewhere, and the galvanic current applied at these points not only has the same inhibitory effect as pressure, but it may prove curative. These pressure-points should be sought after in all cases of local spasm. Pressure at certain points is found in some cases to increase the spasms instead of having an inhibitory effect. Hypodermic injections of morphia are sometimes an effectual method of treatment if the spasmodic affection have not been of long duration. The injections should be made at the "pressure-points." Facial spasms often continue, and become permanent in spite of treatment. Electricity and counter-irritation are chiefly to be relied upon, and should be faithfully tried.

An affection characterized by inability to co-ordinate the muscles engaged in the act of writing has been called *chorea scriptorum*, or *writers' cramp* (*graphospasmus*). Whenever the act of writing is attempted, the flexor muscles especially, but sometimes the extensors of the thumb and fingers, either become rigidly contracted or contract irregularly, and guidance of the pen is impossible. Persons who employ certain muscles constantly in other acts are sometimes similarly affected. Thus, pianists and violinists are no longer able to play, printers cannot compose, tailors and seamstresses

lose the power of guiding the needle, and turners are unable to move the lathe with the foot. In all these instances other movements, calling into exercise the same muscles, are performed without difficulty. In the treatment of writers' cramp and allied affections discontinuance of acts which occasion the spasm is essential. The period of rest should extend over several months. If this be resorted to early, recovery may be hoped for. Galvanic electricity is useful. If discontinuance of writing cannot be enforced, as in cases in which the livelihood of the patient depends on writing, the habit should be acquired of using the pen with the left hand. This is sometimes only a temporary resource, as the affection is liable to occur in the left hand after some use. Changing the size of the pen and adopting contrivances to change the action of muscles which are co-ordinated in writing will sometimes enable writers to continue their occupation. The affection consists in impairment of the power of co-ordination for the performance of certain acts, and it is a consequence of the long-continued performance of these acts. It is a fair inference from these facts that it is a central, not a peripheral, affection. If timely and complete rest be not resorted to, recovery is not to be expected.

Painful contraction of muscles, irrespective of affections of which this is a symptom, such as tetanus, epidemic cholera, etc., and not produced by any obvious cause, is known as *cramp*. Some persons are liable to suffer much from cramp of the muscles of the leg or feet, occurring especially at night. A method of treatment proposed by Bardsley of Manchester, England, is said to be generally successful. This consists of sleeping on an inclined plane, the bed being twelve inches higher at the head than at the foot.

Under the name *essential or idiopathic spasm of the muscles of the extremities* (*contracture essentielle ou idiopathique des extrémités*) French writers describe an affection characterized by tonic contraction occurring with either intermissions or marked exacerbations. This affection has also received the name of intermittent tetany or tetanilla. It occurs especially in young subjects between the age of seventeen and twenty-five and in children between one year and three years of age. Females more than males are subject to it. The puerperal state and lactation predispose to it. It is observed as a sequel of certain diseases, such as the continued or eruptive fevers, articular rheumatism, and chorea. In children it appears to be connected with dentition, intestinal worms, and gastric disorders. The spasm or cramp affects first the muscles of the upper extremities, especially the flexors of the forearm. It extends generally to the lower extremities, and here the extensors are the muscles most liable to be affected. The hand is often firmly closed, the fingers concealing the thumb, which is in close apposition to the palm, and the flexion may embrace both the phalanges and the metacarpal bones; or, more rarely, the fingers are separated and partially flexed, so as to give rise to the claw-like appearance. Sometimes the position of the fingers is like that in the act of writing. Exceptionally, the extensors of the wrist are affected. The contractions are powerful. Generally they are bilateral, but they are sometimes confined to one side. In some cases the spasm extends to the muscles of the arm, shoulder, thigh, trunk, and neck, together with those of the jaws. In these cases the affection simulates tetanus. It has been called intermittent tetanus. In tetanus the trismus is primary, whereas in this affection it is secondary. Moreover, in this affection the associated symptoms denoting gravity of disease are wanting. The intermissions sometimes observe the laws of periodicity governing the different types of intermittent fever. The affection belongs among the neuroses; that is, it is a functional affection, the duration varying generally between one week and three weeks. Relapses

often occur. The spasm sometimes leads to paralysis of the muscles which are affected. The affection tends to a favorable termination. Cases, however, have been observed in which a fatal result has been due to paralysis following spasm of the muscles concerned in respiration and to spasm of the glottis. The indications for treatment relate to the pathological conditions with which it is associated. Quinia in full doses is indicated if the affection be intermittent. Belladonna, opium, or the hypodermic injection of morphia may be resorted to for palliation of the pain and spasm.¹

A peculiar affection of the voluntary muscles was first described by Thomsen in 1876 as occurring in a number of members of his own family. The affection is sometimes called *Thomsen's disease*. It has received from Strümpell the name *myotonia congenita*. It is a rare affection, but a number of cases have been reported. The affection appears to be congenital, existing throughout life. It affects frequently several members of a family, and apparently with preference the male members. The characteristic of Thomsen's disease is a peculiar stiffness and tension of the voluntary muscles, amounting to a continued tetanic spasm. This tension is most evident when the patient begins to use the muscles after a period of repose. It lessens and may disappear after the muscles have been for some time in use. The muscular stiffness is increased by psychical excitement. Rapid muscular movements involving precision may be impossible. In most of the cases hitherto observed the muscular development has been excessive. Upon electric excitation the spasm of the muscles is longer than in health, continuing after the circuit is opened. This indicates some congenital anomaly in the muscular structure. Sensibility is intact, and there are no noteworthy symptoms other than those mentioned. No benefit has hitherto been derived from any therapeutic measures.

Tremor—that is, alternate contraction and relaxation of muscles in rapid succession—is a symptom of certain lesions of the nervous centres, especially of multiple or disseminated sclerosis of the brain and spinal cord. It is not infrequently incident to advanced age, and it is then observed especially in the upper extremities, but in some cases constant lateral motions of the head take place during waking hours, and they do not always cease during sleep. The *senile trembling*, as it is called, although not dependent on any known lesions, is irremediable. Tremulousness, especially of the hands, occurs in early and middle life as a result of the abuse of alcohol, the habitual use of opium, nicotism, sexual excesses, and other causes which tend to depress or disorder the nervous system. Under these circumstances it may be purely functional. The trembling sometimes extends to the lower extremities and to the trunk.

The treatment in cases of tremor from these several causes of course involves, as the first and most important measure, the withdrawal of the causes. Other measures indicated are those which have reference to associated disorders and the general condition of the system.

The affection known as *paralysis agitans*, sometimes called Parkinson's disease from an English author who described the affection in 1817 under the name shaking palsy, belongs in the group of affections characterized by tremor rather than among the paralytic affections. It is to be included with the neuroses, inasmuch as it has no ascertained anatomical characters. Diverse morbid changes have been found after death in different cases, but in some cases no changes have been discovered.

¹ Vide *Traité de Pathologie interne*, par Jaccoud.

It is an affection of middle or advanced life, the age being very rarely less than forty years. Men much oftener than women are affected. These are all the facts at present known respecting the etiology.

The tremor consists of feeble, rapidly-recurring, rhythmical movements, at times, under mental excitement or physical exertion, much increased in range and force. The movements generally begin in the fingers and hands, they extend gradually over the upper extremities, and after variable periods the affection invades the lower limbs, the facial muscles, the muscles of articulation, those of the head, and sometimes the trunk. They are in some instances for a long time or permanently unilateral. The muscles which are involved retain their normal electrical excitability. Paresis follows the tremor, the latter preceding the former for a considerable or long period. Stiffness of certain muscles, especially of the flexors, is gradually induced. The head and the trunk incline forward; the elbows stand out from the chest; the forearm and hands are moderately flexed; the thumb and forefinger are sometimes in the position of holding a pen; and the fingers may be distorted as in cases of chronic rheumatism. The lower limbs are often correspondingly affected. They are knock-kneed, the feet have the appearance of talipes equinus, and there is virtually incomplete paraplegia. Festination, or a tendency to run forward, is sometimes observed. The tremor, as a rule, either ceases or is much diminished during sleep.

This affection is to be distinguished from tremor incident to cerebro-spinal sclerosis. The differential points are as follows: In sclerosis, paralysis is either coincident with or antecedent to the tremor; the tremor is excited by volition; it begins in the lower limbs; and is not very infrequent at less than forty years of age. *Per contra*, in paralysis agitans, paralysis does not precede the tremor or accompany it at an early period; the tremor is not dependent on volition; it begins in the upper limbs; and persons less than forty years of age are exempt from this affection.

The independence of volition distinguishes the tremor from chorea. The muscular movements are shorter in paralysis agitans than in chorea. The greater degree of tremor, and often the age, serve to distinguish this affection from senile trembling. The tremulousness from alcoholism and other causes which are readily ascertained in individual cases is excluded without difficulty.

As regards the pathology, it is to be said, as of other functional affections, that the existence of morbid changes is logically certain, but their nature and their seat are yet to be ascertained. The affection is probably not myopathy or peripheral, but whether the morbid condition be seated in the brain or spinal cord, or in both, is an unsettled question.

It is also an unsettled question whether recovery ever takes place. If the few reported instances be not open to distrust, it is certain that the probability of recovery is so small as to be almost nil in any individual case. The affection, however, is not incompatible with the duration of life and fair general health for an indefinite period. Patients generally die from intercurrent affections. The affection proves fatal, *per se*, by inducing general paralysis after many years' duration, death taking place by exhaustion.

The objects of TREATMENT are the prevention of the continued progress of the affection and more or less amelioration as regards the tremor. Various remedies in the hands of different observers have appeared to be not without considerable effect in certain cases. The objects of the treatment are of sufficient importance to render the trial of these various remedies a duty, without abandoning a case as offering no encouragement in the way of improvement. Elliotson claimed to have effected a cure by the carbonate of iron; Brown-Séquard, by the chloride of barium; and Reynolds and Remak,

by galvanization of the spine. Arsenic, administered hypodermically, has been found highly useful by Eulenburg. Charcot and others have given hyoscyamus with benefit. Strychnia was advocated by Trousseau. The iodide of potassium in large doses proved beneficial in a case observed by Villemain. Other remedies are—opium, belladonna, ergot, the Calabar bean, curare, chloral hydrate, and the bromides. None of these can be expected to have more than a palliative effect. Measures to improve and invigorate the general health are perhaps more likely to be of real benefit. Among these, the sponge-bath and the cold pack are to be included. Bandaging the limbs and applying to them the tincture of aconite, small doses of strychnia being also given, diminished the tremor considerably in a case under my observation.

Mercurial tremor denotes trembling movements of the limbs, the muscles of the face, the tongue, and sometimes the trunk, due to poisoning by mercury. The tremor occurs especially when the patient makes voluntary movements, in this respect being analogous to chorea. This affection, formerly not infrequent, of late years is rarely seen, in consequence of improvements in mechanical processes involving the use of mercury and the better observance of precautionary measures. The inhalation of vaporized mercury is most likely to give rise to it, but it has been produced by the use of mercury as a medicine and by mercurial inunctions. In the only case which has fallen under my observation the gums were swollen, reddened, and spongy, and the teeth had been loosened. These appearances, together with other symptoms of the mercurial cachexia, and generally knowledge of the fact of exposure to mercurial poisoning as incident to the occupation of the patient, will lead to the diagnosis.

Recovery may be expected under the use of tonic remedies with an invigorating regimen, provided the continued introduction of mercury into the system be prevented. The iodide of potassium is supposed to effect the elimination of mercury from the body.

A variety of spasmodic movements was described by Hammond in 1871, and designated *athetosis* (*ἄθετος*, "without fixed position"). It is characterized by persistent irregular movements of the fingers and toes and inability to retain them in any fixed position. The movements are wholly independent of volition. The patient can rarely arrest them by an act of the will, even for an instant. In most instances the affection is confined to one side (*hemiathetosis*), but in some instances both sides are affected (*bilateral athetosis*). It may affect either the fingers or the toes separately, or both conjointly. In rare instances spasmodic movements of either the face, neck, or forearm are associated. The movements of the fingers and toes are constant during waking hours, and sometimes continue, although diminished, during sleep. If they cease during sleep, the fingers rest in abnormal relative positions. The abnormal movements resemble those of chorea, but differ from them by their slower rhythm and greater regularity. They are also distinguished from choreic movements by affecting chiefly or exclusively the fingers and toes. In many cases more or less anæsthesia was present on the affected sides. The muscles of the forearm involved in the movements may become hypertrophied.

In a large proportion of cases *hemiathetosis* is a sequel of hemiplegia. The movements of the fingers and toes are on the paralyzed side. Some writers consider that lesions involving the posterior third of the posterior division of the internal capsule are especially liable to be followed by *athetosis*. Others think that the lesion is to be sought for in the motor cortical tract of the brain. Further observations are needed to determine the path-

ology of this affection. Athetosis may occur as a primary affection without paralysis. Although bilateral athetosis is not associated with well-marked paralysis on both sides, there is often general muscular weakness. The affection in this form occurs in idiots or those who are congenitally feeble-minded. It doubtless proceeds from a cerebral affection, although it has been observed in connection with locomotor ataxia.

Experience has furnished few data for a favorable prognosis. Gnauck has reported a cure effected by the constant electrical current and the use of bromide of potassium. Gowers and Oulmont have found this agent essentially beneficial.¹

The anomalous movements described by S. Weir Mitchell under the name "post-paralytic chorea,"² and by Charcot under the name "post-hemiplegic hemichorea,"³ are analogous to those of athetosis. The terms athetosis and post-hemiplegic chorea have been used to describe the same affection. As already remarked, athetosis may occur independently of hemiplegia. Charcot places the lesion of post-hemiplegic chorea in the posterior part of the internal capsule and the surrounding brain-substance. The choreic movements may, however, follow lesions of other parts of the brain.

Epilepsy.

Epilepsy is a chronic paroxysmal affection. The paroxysms are characterized by loss of consciousness, and in the most characteristic cases by convulsive movements extending over more or less of the voluntary muscular system. Convulsions analogous to those of epilepsy are symptomatic of different cerebral affections, of uræmia, of injuries of the head, and they may be caused by certain toxic agents; for example, strychnia. These are to be distinguished as epileptiform convulsions. Epilepsy, as one of the neuroses, is a functional affection; that is, it is not necessarily connected with any appreciable lesions. Related to the affection, sometimes preceding its development, and sometimes occurring in those who are epileptics, are attacks in which convulsive movements are slight and sometimes wanting. Epileptic attacks in which convulsions are slight or wanting constitute that form of the disease which is called mild epilepsy, or *epilepsia mitior*, also by French writers *le petit mal* and *epileptic vertigo*. They may be distinguished as *epileptoid attacks*. In distinction from *epilepsia mitior*, the common form with general convulsions is called *epilepsia gravior*, or *le grand mal*. This form is to be first considered.

In the majority of cases a paroxysm occurs without premonition. The loss of consciousness is as sudden as if produced by a stunning blow upon the head. The person falls, and hence the affection has been popularly known as the "falling sickness." In a minority of cases there is a brief warning of the approaching fit. Generally the premonition consists in a sensation which the patient is unable to describe. The sense of a "cold vapor" emanating from some part of the body and mounting to the head has been called the *aura epileptica*. This sensation was first described by Galen, and, as remarked by Herpin, "the commentators of Galen and those who copied from them handed down the phrase, until the existence of an aura seemed to be accepted as an ascertained fact." It is a traditional error to consider such a sensation as a frequent warning of an epileptic paroxysm, and it is certainly extremely rare for the patient to experience any sensation

¹ Vide *Real-Encyclopädie*, Wien und Leipzig, 1880, art. "Athetose."

² *Am. Journ. of Med. Sciences*, Oct., 1874.

³ *Leçons sur les Maladies du Système nerveux*, Paris, 1877.

emanating from a particular part of the body. The onset of the paroxysm is then marked by a loud, short, and piercing shriek or cry, which from its intensity and unnatural character is sometimes truly terrific. The face at the time of the seizure becomes notably pale. The direction in which the fall takes place is almost always forward on the face. The face is not infrequently lacerated or bruised by the force of the fall, and severe burns are sometimes caused by falling upon heated stoves or into the fire. The convulsive movements at once begin. These are at first tonic; that is, the muscles are forcibly contracted, and the contraction persists for several seconds. The muscles of the face, neck, arms, forearms, the lower extremities, the abdomen, and chest are involved, and have a tetanic rigidity. In most cases the muscles on one side of the body are more affected than those of the other side, and sometimes, although very rarely, the convulsions are limited to one side. The tonic convulsions last for a period varying between a few seconds and half a minute or somewhat longer. The convulsions then become clonic; that is, the muscles present forcible contractions and relaxations in rapid succession. The face is hideously distorted, the head is moved upon the trunk, the upper and lower limbs and the body jerk with violence. The tongue is sometimes caught between the teeth and is wounded by the tonic contraction of the muscles of the lower jaw. This more frequently happens during the clonic convulsions. Respiration is nearly suspended by the tonic convulsions and is irregular and difficult during the clonic. A quackling noise accompanies the respiratory acts. The face during the convulsions becomes deeply congested and livid. Convulsive masticatory movements are accompanied by the ejection of foamy saliva, frequently commingled with blood from the wounded tongue or from a portion of the cheek caught between the teeth. The violent clonic convulsions continue for a period varying between half a minute and three minutes. The period to the observer seems to be much longer, but if noted by a watch it is rarely found to exceed three minutes, and generally it does not last more than a minute. The convulsive movements now become less rapid and violent, the embarrassment of respiration diminishes, the patient utters a deep sigh, and the paroxysm, so far as the convulsions are concerned, is ended. The paroxysms in different cases, and different paroxysms in the same case, differ much as regards the violence of the convulsive movements and the extent of the muscular system involved. The convulsions are sometimes specially marked in the face and upper extremities, and they may be limited to these parts. Paroxysms differ also as regards duration. The violence of the convulsive movements of the muscles of the shoulder is sometimes sufficient to produce luxation of the humerus. A case in which this repeatedly occurred has fallen under my observation. During the convulsions the urine and feces are sometimes expelled, and an emission of semen may take place. The pupils during the paroxysm are dilated, and they do not contract on exposure to a bright light. The eyelids, however, close when the conjunctiva is touched, showing the preservation of the reflex function.

After the convulsions have ceased consciousness may be speedily regained, and the patient may only experience a sense of fatigue, with usually a disposition to sleep; but in most cases the state of coma continues for a variable period. Frequently the respiration for some time is stertorous and the lips are puffed out with expiration. The patient remains in this state for a period varying between a few minutes and half an hour; the pupils are still dilated and do not contract on exposure to light, and he cannot be roused from the comatose state. Gradually he emerges from this state, opens his eyes, appears confused, and some time elapses before he is able to appreciate his situation and reply to questions. If he attempt at once to walk he reels like a person intoxicated. Occasionally the patient passes from the apoplectic state into

one of delirium. He talks incoherently, manifests hallucinations, and sometimes the delirium assumes the form of mania, during which he may be dangerous to himself or others. After recovery of the mental faculties there is complete inability to recall anything which has occurred during the paroxysm.

The paroxysms recur after intervals which are extremely variable in different cases. The intervals may extend over many months or years. On the other hand, they recur in some cases daily and even many times daily. When a paroxysm has once occurred, other paroxysms are almost sure to follow sooner or later. In most cases the paroxysms at first are more widely separated than after they have repeatedly recurred; and they become, as a rule, more and more frequent, until the affection is confirmed. In some cases the recurrence is periodical. In women sometimes paroxysms occur regularly at the menstrual period. Periodicity, however, is not the rule, the intervals generally varying considerably in the same case; but in certain cases of confirmed epilepsy about the same number of paroxysms take place in successive periods of a quarter, a half, or the whole of a year. Exceptionally, the recurrence of the paroxysms becomes less frequent after a time, and a patient who for several years has been subject to paroxysms after short intervals may afterward have long intermissions. Occasionally, having recurred more or less frequently for months or years, they cease altogether for a considerable period, and then return with not less, and perhaps greater, frequency than before.

In some cases paroxysms occur in rapid succession during a day or during several successive days. This condition constitutes the so-called *status epilepticus*. As many as one hundred and even a larger number of paroxysms have been known to occur during twenty-four hours. In a case under my observation paroxysms took place at intervals of a few moments for fourteen consecutive days. The patient recovered, and the paroxysms did not again recur for several months. When a series of paroxysms thus occurs, the mind is notably impaired for a time. The patient is childish and perhaps idiotic for several days, but gradually recovers the habitual state of the mental faculties. Hemiplegia occasionally follows a series of paroxysms. This occurred in the case just referred to. The paralysis in such cases is usually of brief duration.

Epileptic paroxysms occur at all hours of the day or night. They are likely to occur during the night. In some cases for a greater or less period they occur only at night. In these cases the affection may have existed long before the fact is ascertained. I have known a case in which, the paroxysms never occurring in the daytime, the existence of the affection was for a long period concealed from the patient. It is a curious fact that the paroxysms are usually suspended during the course of an acute disease. A patient, for example, subject to daily paroxysms became affected with typhoid fever. During the career of the fever no paroxysms occurred, and among the events denoting convalescence was the return of the epilepsy.

It was for a long time believed that the morbid condition giving rise to epileptic paroxysms was seated in the medulla oblongata and pons Varoli. This view still has its advocates, but there is an increasing tendency to refer the origin of epileptic paroxysms to the motor area of the cerebral cortex, and it must be admitted that there are weighty arguments in favor of the latter hypothesis. The fact that loss of consciousness is a constant factor in the epileptic paroxysm, and that it may occur without convulsions, favors the cortical theory of epilepsy. It has been shown experimentally that irritation of the motor cortical area causes paroxysms in no way distinguishable from epilepsy in human beings. In experimental epilepsy, as well as in

any cases of human epilepsy, it has been noted that the convulsions proceed from one group of muscles to another in an order corresponding to the relative situation of the motor centres in the cortex. Thus, if the spasm begin in the face, the arm is next affected, and then the lower extremity. Extirpation of a motor centre in the cortex prevents the development of epileptic convulsions in the muscles whose cortical centre is destroyed. Injury or disease of the motor cortex is very frequently followed by typical epileptic paroxysms. In incomplete epilepsy or petit mal the manifestations are for the most part psychical. The facts mentioned give great plausibility to the cortical theory of epilepsy.

As regards the immediate cause of the epileptic paroxysm we possess no positive knowledge. Epileptiform and true epileptic paroxysms may be caused by various intracranial lesions, such as tumors, syphilitic affections, meningitis, and fracture of the skull. With the exception of these cases, epilepsy is to be regarded as a neurosis without any known anatomical basis. Except in symptomatic epilepsy, post-mortem examination has failed to reveal any lesion to which the epilepsy could reasonably be attributed.

It is very generally believed that the immediately exciting cause of an epileptic paroxysm is cerebral anæmia resulting from vaso-motor spasm. This view is rendered probable by the known effects of sudden cerebral anæmia from hemorrhage, from ligation or compression of the arteries carrying blood to the brain, by the notable pallor of the face at the beginning of an attack of epilepsy, together with the appearance of the fundus of the eye as observed by means of the ophthalmoscope. While the efficacy of cerebral anæmia as an exciting cause of the epileptic paroxysm cannot be doubted, it is not certain that it is operative in all cases of epilepsy. The experiments of Brown-Séquard and others on animals show a pathological connection between peripheral irritations and epileptiform convulsions. Such a connection exists in some, but not by any means in all, clinical cases.

In a large proportion of the cases of epilepsy no sources of centric or of excentric irritation are apparent. That under these circumstances the epileptic paroxysms are due to the action of an internal and at present unknown toxical agent seems to me the most rational hypothesis. Epilepsy, according to this hypothesis, is a toxæmia analogous to uræmia, the toxical agent being produced at variable intervals, the quantity and the continuance of its production not being sufficient to endanger life; and in this respect the contrast with uræmia being striking. If this pathological view be correct, knowledge of the nature and source of the toxical agent, which may perhaps be acquired, will, as we may hope, render this disease controllable.

Epilepsy is classed among the hereditary diseases. It has, however, been customary to consider the existence of other nervous affections in parents or progenitors as evidence of an inherited predisposition. Heredity, limited strictly to this disease, does not often enter into the causation. While the possibility of the transmission of the disease to offspring should not be ignored, it is to be borne in mind, as a fact which may be of inexpressible comfort to many persons, that an epileptic parentage by no means entails this or any other disease on descendants either proximate or remote. It would be easy to collect instances of families in which the husband or wife were subject to epilepsy, whose children and grandchildren were free from the disease and in all respects healthy.

Age is of considerable weight in the causation. In a small proportion of cases the disease either exists from birth or is developed in infancy. In nearly one-third of the cases it dates from two to ten years of age, and in a somewhat larger proportion from ten to twenty years. The number of cases

in which the development is between twenty and thirty years is much less, and at a later period of life the number is comparatively small. In the great majority of cases at the beginning of the disease the age is between two and twenty years.

Of particular causes little is positively known. It is certain that intemperance as regards the use of alcohol may give rise to it. Epileptic paroxysms occur not infrequently in drunkards, and cease to recur in cases in which reformation of intemperate habits is effected. It is one of the occasional effects of lead-poisoning. Venereal excesses, and especially habits of masturbation, have been supposed to be not infrequent causes. The supposition is highly probable, but an accumulation of facts establishing this causative connection is desirable. A female patient, twenty-three years of age, unmarried, who had been subject to paroxysms occurring almost nightly for two years, stated to me, voluntarily, that she was taught to masturbate at six years of age, and continued the practice almost daily until she was fourteen. At this age she became convinced of the sinfulness of the habit, and discontinued it. She was afterward tormented with sexual desires, and experienced the venereal orgasm almost nightly during sleep. She was led to disclose this private history by a conviction, at which she had arrived of her own accord, that it was important with reference to the source of the epilepsy. To what extent the antecedent history in cases of epilepsy would furnish corresponding facts can only be conjectured. The number of instances in which congenital phimosis exists in epileptics, with cessation of the paroxysms after removal of the prepuce, show a causative connection. Epilepsy has been known to occur in persons affected with tænia, and to cease after the expulsion of the worm.

In persons subject to epilepsy the paroxysms in the great majority of cases occur without obvious exciting causes. The causes determining the attack, as a rule, are intrinsic. Persons not infrequently are able to judge, by experience, from certain indefinite sensations that they will ere long have a paroxysm. The sensations disappear after the paroxysm has occurred, and it is not uncommon for persons to feel better after recovery from the immediate effects of a paroxysm than for some time prior to its occurrence. It has been supposed that the aura which sometimes precedes the paroxysm denotes the existence of an exciting cause emanating from the part to which the aura is referred. It is more correct to regard the aura as a peripheral sensation dependent upon some central irritation. A case has fallen under my observation in which the patient, a female, experienced the first paroxysm during the first act of sexual congress after marriage. Subsequently, a paroxysm occurred at each marital connection, but after a time paroxysms took place without this exciting cause, and the patient became a confirmed epileptic. It is a remarkable fact that an attack may occur from imitation. An instance of this has fallen under my observation. A woman subject to epilepsy had a series of paroxysms in quick succession. Her female attendant while these paroxysms were in progress first manifested hysterical phenomena, and finally she experienced a distinct epileptic paroxysm. She had never before had an attack of epilepsy, nor did another paroxysm take place, the person remaining within my observation for several years afterward. It is well known that dogs, cats, and other domestic animals are liable to epilepsy. Prof. Dalton has related to me the following interesting illustration of the effect of imitation in the canine race: A dog not previously affected with epilepsy was in company with another dog which was subject to this affection. The latter being seized with an epileptic paroxysm, the former immediately afterward had a similar attack. This occurred under Prof. Dalton's observation.

The DIAGNOSIS of epilepsy in its ordinary form rarely offers much difficulty.

case is, in general, readily ascertained when it has become confirmed. In which the practitioner has not an opportunity of witnessing any paroxysms, he may generally obtain sufficient information respecting active features to feel sure of the diagnosis. The prominent points are—the sudden seizure, the cry at the beginning of the paroxysm, loss of consciousness, the tonic and clonic convulsions, embarrassed respiration from the mouth of frothy saliva often mixed with blood, and the duration of the fits. An examination of the tongue, if repeated has occurred, in some cases shows cicatrices, resulting from the use of this organ, which are quite diagnostic.

Attention is to be discriminated from hysterical convulsions, but these points of difference which are usually sufficiently marked. The convulsions are not purely automatic, as in epilepsy, but proceed from conscious volition. They are of longer duration than the convulsive movements of a paroxysm of epilepsy, and they are developed gradually. Foam from the mouth does not accompany hysterical convulsions, and the pupils are dilated. Epilepsy, however, may be developed in persons subject to hysteria, and the two affections may be associated.

When a patient not known to be an epileptic, in the comatose state succeeds the convulsions, apoplexy might at first be suspected; but convulsions which precede this state have been observed by any one, and respecting their occurrence suffices for the diagnosis. If the convulsions have not been observed, the appearance of foam and blood upon the face is diagnostic. The age of the patient is to be considered, and the occurrence of hemiplegia, which often occurs in cases of apoplexy and rarely in epilepsy.

Uræmic convulsions, or eclampsia, occurring in children, in pregnant women or in connection with Bright's disease, are to be discriminated by the antecedent and coexisting symptoms. Judging from the common and associated nervous phenomena, uræmia and epilepsy might easily be confounded. Uræmic convulsions, however, are rarely of as brief duration as those of epilepsy. Examinations of the urine will suffice for this diagnosis; it is, however, to be borne in mind that directly after an attack of epilepsy the urine contains a trace of albumen. A paroxysm of epilepsy in an infant or child often with good reason occasions anxiety to the parents, and may prove the beginning of epilepsy. It is not always practicable to determine this point at once. There is more reason to apprehend epilepsy than when the convulsions are not otherwise to be accounted for. Their recurrence affords the only positive proof that they are not epileptic.

It is desirable to determine whether epileptic paroxysms be connected with lesions affecting the cerebro-spinal system, or whether they be idiopathic. With reference to this point, symptoms denoting lesions are to be sought for in the intervals between the paroxysms. Persisting pain in the head, paralysis of the face, or disturbance of the intellect greater than the epileptic paroxysms afford, are symptoms pointing to cerebral lesions. Lesions are to be suspected if the epileptic paroxysm succeed an injury of the head.

Epilepsy is one of the affections sometimes simulated by malingerers. The appearances which are presented in epileptic paroxysms may be voluntarily produced, but a malingerer must be very well acquainted with the disease to represent accurately the phenomena in the manner in which they succeed each other, and certain of the phenomena are beyond the power of the will. To determine a case of deception, let it be ascertained if the face become at first pale and afterward deeply congested and if a cry be uttered, if the fall be forward on the face, if the convulsions be at first tonic and afterward clonic, if foamy saliva be ejected from the

mouth, and if the tongue or cheek be wounded by the teeth. Let the pupil be examined, for these cannot be voluntarily dilated and their mobility on the approach of light cannot be prevented. Let the duration of the fit be noted, and the convulsions will be likely to be unduly prolonged. Let it be ascertained if, accompanying and succeeding the convulsions, there be insensibility to pricking, burning, or pinching the skin. Let the attention be directed to the time and place in which the paroxysms take place. Malingerers will not select the night or a situation in which they will not be observed. They are not likely to fall in a way or in a position to receive injury. The aspect of confusion and shame which is manifested on recovering consciousness after an attack of epilepsy is not easily feigned.

Epilepsy may continue for a long time before its existence is ascertained if the paroxysms occur only at night. The disease is to be suspected when patients complain of awakening from time to time with headache, lassitude, and a wounded tongue. Under these circumstances the diagnosis is to be settled by causing the patient to be watched during the night.

Owing to the terrible nature of the malady, and the apprehension felt by those in company with an epileptic lest a paroxysm may occur, persons are naturally sensitive with respect to themselves or their relatives being said to have epilepsy. For this reason there is sometimes a disposition to conceal the nature of the paroxysms even from the physician. To avoid the depressing effect upon the mind of the patient which a knowledge of the disease is likely to produce, it is sometimes judicious to refrain from calling it epilepsy. In the case of a lady who was under my observation for many years the nature of the disease was never communicated to her. The paroxysms, which were often frequent and severe, were always called nervous attacks, and she finally died of an intercurrent affection without knowing that she had been an epileptic. In this case ignorance of her disease enabled her to participate in many of the enjoyments of life from which, owing to her sensitive nature, she would have shrunk had she been aware that she was affected with epilepsy.

The PROGNOSIS in cases of epilepsy, as regards immediate danger from the paroxysms, is always favorable, and epilepsy does not give rise to any particular disease or diseases of a dangerous character. Epileptics, as a rule, are not short-lived, and in the majority of cases death arises from other diseases, to the development of which the epileptic paroxysms have not contributed. In another point of view, however, the prognosis is most unfavorable—namely, as regards the persistence of the malady. In the vast majority of cases the disease becomes confirmed, and as a rule the intrinsic tendency is to increasing frequency of the paroxysms.

In another point of view the prognosis is unfavorable—namely, as regards the mental condition. To a certain extent the disease tends intrinsically to impairment or disorder of the faculties of the mind. Many epileptics, especially if the paroxysms recur at short intervals, sooner or later fall into imbecility. To a greater or less extent this is due to causes other than the intrinsic tendency of the disease. If epilepsy occur in early life, the mental faculties are not developed by education and those occupations which involve their exercise, and in the cases in which the disease occurs at a later period the mental faculties progressively fail from disuse. The unhappy sufferer from this terrible disease is likely to lose interest in those objects or pursuits in life which incite to the exercise of the mental faculties. This explanation in part of the apparent effect of epilepsy on the mind has an important practical bearing.

Reference has been already made to mild attacks having an evident relationship to ordinary epilepsy, which may be called *epileptoid attacks*. It is

important for the practitioner to recognize and appreciate the significance of these attacks. They are considered by French writers as belonging to a variety of epilepsy which they call *petit mal*, in contradistinction from the ordinary form, which they call the *grand* or *haut mal*. These attacks sometimes precede the development of ordinary epilepsy, and they sometimes occur intercurrently in persons who are confirmed epileptics.

The epileptoid attacks are multiform. A sudden loss of consciousness for a few seconds occurs in some cases, during which the body may remain fixed, the person apparently being lost in deep abstraction, the mental faculties resuming their operation as if nothing had taken place as soon as the attack passes off. In a case of confirmed epilepsy under my observation the patient at one time in the intervals between the paroxysms was subject to frequent attacks of the kind just described. During the attacks she remained fixed in the position in which she happened to be when they occurred. For example, if standing and arranging her hair, the hands were fixed precisely as they were at the instant of the seizure. On some days these attacks took place a great number of times, and the patient did not appear to be conscious of their occurrence. In the fixation of the body and limbs these attacks resemble catalepsy. In the case just referred to the only convulsive movements were of the muscles of mastication. Similar attacks are sometimes accompanied by convulsive movements of other of the facial muscles, of the muscles of the neck, and by slight laryngeal spasm. In some cases the patient falls, but recovers and rises in a few seconds. Loss of consciousness and falling in some cases are unattended by any convulsive movements. Trousseau relates examples of this kind. Of course in such cases epileptoid attacks are to be discriminated from syncope.

In other epileptoid attacks sudden delirium occurs, continues for a few seconds, and passes off, leaving the mind in the condition in which it was at the instant of the seizure. The delirium is manifested in different ways. Trousseau cites a case in which the patient uttered a burst of laughter, and when asked why he laughed he looked surprised, having no knowledge of what he had done. The same author cites examples of persons engaged in conversation, debate, or other occupations abruptly, as if struck by a sudden thought, going into the street bareheaded, and walking until they recovered themselves, when they were able to return and proceed with the matter in which they were engaged as if nothing had happened.¹ The following example came under my observation in one of the wards of Bellevue Hospital: A female patient quietly standing in the ward suddenly uttered a cry, and ran from one end of the ward to the other. The urine was at the same time expelled, leaving on the floor traces of her course. Having reached the end of the ward, she stopped, looked confused, and quietly returned.

The following example of an epileptoid attack is interesting from its presenting very distinctly the *aura epileptica*. A man thirty years of age had been for ten months in disordered health, suffering from palpitation and mental depression. He described paroxysms of frequent occurrence during the time just stated in which he felt a flash, as he termed it, originating sometimes in the chest, sometimes in the abdomen, and sometimes in one of the lower extremities, rising upward, giving rise to a sense of suffocation, and on reaching the head followed by momentary confusion of mind. He had never fallen. In some of these attacks he had felt stiffness of the muscles of the jaws and of the forehead. The attacks were irregular, but had recurred more or less frequently every week for the preceding ten months. On being questioned, he said that the "flash" gave the sensation of a stream of air or gas. He had never read or heard of the epileptic aura. Nine months after-

¹ Vide *Clinique médicale*, tome ii.

ward this patient had recovered his former health, and no longer had the paroxysms above described.

Other attacks consist of convulsive movements of certain muscles without delirium or loss of consciousness. In a case under my observation the patient, a young man apparently in perfect health, first consulted me for the occasional occurrence of convulsive movements of the upper extremities. From time to time the hands were violently jerked, and whatever he might happen to hold at the time was thrown with great force. It was unsafe for him to hold fragile articles. A careful examination in this case revealed nothing abnormal save these convulsive movements. They became more and more frequent, and shortly they extended to the lower limbs, so that he was repeatedly thrown down for an instant, still without loss of consciousness. At length, after the lapse of several weeks, he had a severe paroxysm of epilepsy, and the malady afterward became established. In a case under my observation in 1864 paroxysms occurred daily more or less frequently, in which the head was forcibly drawn toward the right shoulder, and retained there for a few seconds. This affection had existed for five years without eventuating in epilepsy. The paroxysms, however, had increased in frequency and severity, and he appeared to have loss of consciousness for a few seconds, although he did not fall. In other respects the patient was apparently well. Being a young physician, he suffered from the anxiety incident to a knowledge of the fact that these attacks might be premonitory of the graver epileptic paroxysms. Three years afterward he wrote to me that the paroxysms were not more frequent, but more severe, causing him to fall. He stated that they were controlled by large doses of the bromide of potassium. Subsequently he had some paroxysms of well-marked epilepsy. In 1879 he reported to me that neither epilepsy nor the epileptoid attacks had occurred for several years.

In the case of a girl aged twelve years the attacks presented the following features: Almost daily, often at the breakfast-table, she suddenly manifested a changed expression of countenance, appearing as if frightened, sometimes uttered some exclamation as if surprised, and her consciousness was lost for a few seconds. Sometimes the face was distorted. When consciousness returned, she almost invariably asked, "What time is it?" There had never been any convulsive movements of the limbs, but they were sometimes rigid. There was never any spasm of the glottis.

Epileptoid attacks occurring in persons who have never had well-marked epileptic paroxysms are to be considered as denoting a pathological condition which is essentially that of epilepsy. Hence the obvious importance of not overlooking their significance, in order to prevent, if possible, the fully-developed malady which is foreshadowed. Facts showing how frequently epileptoid attacks occur without being followed by the graver form of the disease are wanting, but it is certain that the latter by no means invariably follows. The physician, therefore, should not excite unduly the fears of the patient or friends by predicting that these minor forms are necessarily the precursors of the graver form.

The TREATMENT of epilepsy relates to the management of the paroxysms and to measures for effecting a cure. The latter are to be employed in the intervals. Curative treatment, as in other of the neuroses, may be conveniently considered as rational and empirical.

The rational treatment consists in deriving, as far as possible, indications from an investigation of each case with regard to the state of the system, coexisting disorders, and circumstances which may be suspected of standing in a causative relation to the malady. If the patient be of a full habit or plethoric, dietetic and other measures addressed to this state are rationally

indicated. If, on the other hand, the patient be anæmic, measures of an opposite character are indicated. Disorders of the digestive system, uterine affections, and, in short, morbid disturbances anywhere in the economy, should receive appropriate treatment, as they may possibly be in some way concerned in the development or perpetuation of the malady. The presence or otherwise of tæniæ is to be ascertained. Inquiries with respect to syphilis are not to be forgotten. Phimosis calls for appropriate surgical treatment. [Ocular defects, whether refractive or muscular, should be corrected.—H.] Habits of life with respect to the probable or possible causation are to be scrutinized. Overtasking of mind or body, undue exposure on the one hand, and sedentary habits on the other hand, the facts with regard to mental and moral influences, the abuse of alcoholic stimulants, the immoderate use of tobacco, and especially over-indulgence in venery or the practice of masturbation, are to be inquired into. In brief, an important part of the rational treatment consists in enforcing observance in all respects of the laws of health. It is unnecessary to consider the many and varied details which this part of the treatment involves.

The empirical treatment consists in the employment of remedies or therapeutical measures which experience has shown to be sometimes curative. The number of these is large. It would require many pages simply to enumerate the drugs the curative efficacy of which, in certain cases, has been attested by honest and competent observers. The list is so extensive, the testimony with respect to particular remedies is so conflicting, and the instances of incurable epilepsy are so many, that practitioners are likely to enter upon the treatment of a case without much expectation of success. For the reasons just stated the disease is not infrequently allowed to continue without persevering efforts to effect a cure; and this fact may in a measure account for the number of cases in which patients remain hopelessly epileptics. Of the host of remedies which have been employed, many have doubtless proved successful in a certain proportion of cases; but without any disposition to deceive either themselves or others practitioners have often been led to over-estimate the success of different remedies by not making allowance for the following facts: An active remedy will frequently prevent recurrence of the paroxysms for a considerable period. Under the use of a certain remedy a patient passes weeks or months without a paroxysm; he is ready to believe himself cured, and the physician is happy to participate in the belief. Now, sooner or later, the paroxysms in most cases return, and the patient despairs of benefit from treatment or consults another physician. The return of the malady may not be known to the physician, who had supposed that a cure was effected, and in the mean time he may have reported the case as one cured by the remedy employed. Again, the paroxysms cease in some cases to recur for weeks or months or years without any treatment. I have notes of a case in which paroxysms more or less in number every month, and sometimes fifteen or twenty in twenty-four hours, had occurred for sixteen years, a great variety of remedies having been tried without avail; and at length, after all treatment had been discontinued, the paroxysms ceased to recur for ten or twelve years, when they again returned, but at long intervals. Making, however, due allowance for the temporary interruption of the malady either by the treatment or spontaneously, there remain a certain number of undoubted cures effected by different remedies. In view of this fact, cases should not be abandoned without the faithful trial of many remedies. Of the various remedies which have been considered as curative, some within late years and at the present time in most repute are the following: The nitrate and other preparations of silver, preparations of zinc, digi-

talis, opium, the narcotic extracts, especially belladonna, and, above all, the bromide of potassium.

The nitrate of silver has long been a remedy for epilepsy, and its occasional efficacy rests on abundant testimony. That it will not effect a cure in the majority of cases is not a sufficient reason for failing to make trial of it in cases which resist other remedies. Beginning with a fraction of a grain three times daily, the dose may be gradually increased to three or four grains. An effect of the prolonged use of this remedy in some cases is to be borne in mind—namely, permanent blueness of the skin. To avoid this effect, the remedy should be suspended for a time after having been continued for two or three months. The oxide of silver is less likely to produce discoloration of the skin, but is less powerful as a remedy.

Of the preparations of zinc, the oxide has been found curative by different observers, and was advocated especially by Herpin, who claimed that in his hands a cure was effected by this remedy in 26 of 42 cases. The mode of administration advised by Herpin is to give at first from six to eight grains daily in divided doses an hour after each meal. The quantity given daily is to be increased by two grains each week until it reaches forty-five grains, this quantity to be continued for three months. The remedy is not to be discontinued after the cessation of the fits.

The prospect of effecting a cure according to Herpin, by this or any remedy, other things being equal, is proportionate to the small number of fits which have occurred. If there have been more than five hundred fits, the probability of a cure is extremely small. In a few cases under my observation in which the treatment as laid down by Herpin was faithfully carried out the remedy proved unsuccessful. The cases reported by this author, however, afford indubitable evidence of a certain amount of curative power; and with reference to any remedy for this disease there is no known means of determining beforehand whether it will be likely to prove successful in any particular case. In the cases in which I have tried this remedy it has been difficult to continue it long after the maximum of quantity is reached, on account of the strong antipathy to it which the patient acquires. In a paper published after his prize essay Herpin advised the lactate in preference to the oxide of zinc. Babington advocated the sulphate of zinc, and carried the quantity given *per diem*, for several weeks in succession, to thirty-six grains without producing nausea. The phosphate and the valerianate of zinc have been recommended.

The ammoniated copper has been found curative. Of 12 cases treated exclusively with this remedy by Herpin, 4 were cured. The dose is half a grain, increased gradually to four or five grains. The sulphate of copper has also been employed successfully.

Digitalis is said to have been long a remedy of much repute in Ireland for epilepsy, and its efficacy was attested by Sharkey, Crampton, McCormack, and Corrigan. The infusion is the preparation to be preferred. The quantity given daily is to be increased to the amount which is tolerated, and continued steadily for several months.

Opium is among the remedies recommended as sometimes curative, and perhaps it deserves a trial more extended than appears as yet to have been given to it. The evils of the habitual use of opium are to be considered, but with a fair probability of effecting a cure of the epilepsy the physician would be warranted in exposing his patient to this danger.

Of the different narcotic extracts, belladonna has the strongest claims, based on the testimony of different observers. Trousseau was an ardent advocate of this remedy as capable of effecting a cure in a certain proportion of cases, and of frequently ameliorating the condition of epileptics when it fails

to prove curative. Trousseau insists that a fair test of this remedy requires its continuance for a period not limited to months, but embracing several years. His mode of administration was to begin with a small dose of the extract (gr. $\frac{1}{4}$) once daily, to be continued for a month without increase. At the end of each month the dose is to be doubled, until as large a dose as can be conveniently borne is reached. The tolerance of the remedy differs in different cases. After the disease is perceptibly modified the doses are diminished in the same manner as they were increased. Atropine may be employed in lieu of belladonna, the mode of administration being similar. With the use of belladonna or atropine Trousseau frequently combined the employment of the nitrate of silver, the sulphate of copper, and the lactate of zinc.¹

Of all the remedies at the present time known to have any controlling influence over this disease, the bromide of potassium justly takes the lead. This remedy has not proved as successful in effecting permanent cures as was anticipated twenty years ago, when it was first employed in this disease; but in a considerable proportion of cases paroxysms do not recur while the remedy is in use, and when this result is not obtained the recurrence of the paroxysms is often rendered less frequent and their severity is diminished. It has effected permanent cures, making due allowance for occasional spontaneous recoveries, but probably the number of instances is not large. The remedy may be carried to the extent of producing distinct bromism. The doses required differ considerably in different cases owing to difference of tolerance. For an adult a scruple of the salt may be given, at first twice or thrice daily. These doses are to be increased until the desired effect upon the disease is produced, unless bromism be induced, even if forty, fifty, or sixty grains in each dose be reached. Whenever bromism is produced, the remedy should be discontinued for a few days and then resumed. If no effect upon the paroxysms be produced within two or three months, it is useless to continue the remedy longer. Having ascertained the effect produced upon the disease and the tolerance of the remedy, it should not be discontinued, except at intervals, for one, two, or more years; that is, provided the paroxysms be prevented or rendered infrequent. It does not seem to be as yet ascertained how far the other bromide salts share in the efficacy of the bromide of potassium. They should be substituted for the latter if it be not well tolerated. The hydrobromic acid appears not to have the same effect as the bromide of potassium, and it has even been thought to increase the frequency of the paroxysms. It is of course important not to carry the use of the bromide of potassium to the extent of causing an alarming degree of bromism; and the fact that, given too largely or continued in large doses too long, it is a dangerous toxic agent, is not to be lost sight of. The following case is of interest as showing the value of the remedy and the tolerance of large doses for a long time: An epileptic patient came to me about six years ago, and was placed upon the bromide of potassium, which was given pretty steadily for two years, the quantity *per diem* being about a drachm. During this period the paroxysms were infrequent and light. The quantity *per diem* was increased to two drachms, and continued steadily for about two years. During this period he had but a few paroxysms, and they were not severe. Of his own accord, from some misapprehension, he increased the quantity *per diem* to three drachms, which he took for about two years. During this period he was exempt from paroxysms. At the end of the two years he came to see me, and I was struck at once by his appearance. His face had a vacant, idiotic expression, and he walked with a staggering gait like that of a drunken man. Recognizing bromism, I then ascertained the quantity which he had been taking for the past two years. I directed him at once to suspend the remedy. He did so

¹ *Clinique médicale.*

for a week or two, but on account of inability to sleep he resumed the dose of a drachm at night. Meanwhile, he had a severe paroxysm. After a few weeks the bromism had entirely disappeared. He has continued the remedy in the dose of a drachm at night, and for two months there has been no recurrence of the paroxysms.

The fact of syphilis having existed at a period even remote should lead to the employment of the antisyphilitic medication—namely, the iodide of potassium and the bichloride of mercury.

It will suffice to mention some other remedies which are worthy of trial in the cases in which the bromides fail, such as strychnia, or *nux vomica*, recommended in small doses, especially by Marshall Hall; cotyledon umbilicus, an ounce of the fresh juice or half a drachm of the inspissated juice to be given twice daily; indigo, beginning with moderate doses and increasing to the amount which the stomach will bear; valerian in large doses, continued for a long period; musk, camphor, cimicifuga, and the oil of turpentine.

[Remarkable statements have been recently made concerning the curative effect upon epilepsy of Pasteur's antirabic inoculations. Two children who had been bitten by rabid dogs were treated at the Pasteur Institute in Paris, with the result of curing them of epilepsy. Charcot, hearing of this accidental discovery, sent to the Pasteur Institute an inveterate epileptic aged twelve. After six days' inoculation treatment the attacks ceased entirely, and had not returned two weeks later, at the time the case was reported. The beneficial effect is probably due to the nerve-matter contained in the inoculation fluid, for Babes of Bucharest has treated six cases of epilepsy with subcutaneous injections of aseptic nerve-matter from the brain of the rabbit and sheep, and with benefit in every case. This novel addition to the therapeutics of epilepsy demands the fullest investigation.¹—H.]

Van der Kolk asserted that counter-irritation over the nucha by means of wet cupping, setons, and issues proved successful in his hands. Others also have claimed success for these measures.

Under the supposition that the paroxysm depends upon a morbid agency springing from some part more or less remote from the nervous centres, and that the aura indicates the point of departure of this agency, it has been proposed to interrupt the nervous communications with the part by means of ligatures, section of nerves, the actual cautery, and even amputation of an extremity; but in the great majority of cases paroxysms are not preceded by an aura, and when this exists there is no ground for the conjecture that it denotes a causative agency. It is claimed that in some instances in which an aura starts from an extremity, a counter-irritant applied between the starting-point and trunk has succeeded in arresting the paroxysm.

Surgical measures for the cure of epilepsy, in addition to those just alluded to, are—ligation of the carotids, tracheotomy, and, after injuries of the head, trephining. Ligation of one or both of the carotids has been repeatedly tried, but the results do not warrant its being recommended. The same is true of tracheotomy, which was warmly advocated by Marshall Hall. Trephining, when there is reason to believe that the epilepsy may depend on depressed fracture of the internal table of the skull, spicula of bone, or a collection of blood or pus, is a warrantable operation. In 35 cases collected and analyzed by Prof. Stephen Smith, the results of this operation were as follows: "Relieved, but not cured, 3. Immediate relief after operation and no further note of result, 2. Relieved for one month or under when last seen, 3; between one and six months, 3; between six months and one year, 6;

¹ For further details concerning this method, vide *Annual of the Universal Medical Sciences*, vol. ii. A 56.

between one and five years, 3; set down *cured*, but lapse of time from date of operation to time last seen not given, 7."¹

It remains now to consider the treatment called for during the paroxysms. These are rarely witnessed by the physician save when a series of paroxysms occur in rapid succession. The duration of a single paroxysm is so short that if the physician do not happen to be present it ends before he reaches the patient. The instructions to friends or attendants should be to place the patient on a bed if practicable, and not to attempt to restrain by force the convulsive movements. All articles of dress which constrict the neck or chest should be removed or loosened. To prevent wounding of the tongue a roll of linen or a piece of soft wood may be introduced between the teeth. A congregation of spectators around the patient should be prevented, and free ventilation should be provided for. The patient should be kept quiet after the paroxysm has ceased, and be soothed by cooling lotions to the head.

Epileptics should sleep in beds with raised sides to prevent injury from being thrown upon the floor by the convulsive movements if a paroxysm occur during the night. They should be under observation, as far as practicable, during the night, for death from suffocation has resulted from the face being pressed into the pillow during a paroxysm.

When a series of paroxysms occur measures may be employed to prevent their recurrence. Ether, valerian, belladonna, and opium may be given for this object. The most effective measure is the inhalation of four or five drops of the nitrite of amyl at the instant of a premonition or of the occurrence of a paroxysm. This drug arrests the paroxysm by relieving the spasm of cerebral arteries. Patients may be provided with this remedy for the purpose of warding off a paroxysm. A paroxysm may perhaps be postponed, but it is doubtful if it be preventable, by any measures resorted to when premonitions are experienced. In a case under my observation a friend sat by the side of a patient the whole of an afternoon, and when the premonition was felt dashed a little water in the face. The paroxysm was apparently prevented for the time, but it occurred as soon as the effort to prevent it was discontinued.

A highly important point connected with the management of epileptics relates to measures to prevent deterioration of the mental faculties. In so far as impairment of mind proceeds from disuse of the mental faculties, it may be obviated or retarded by taking pains to secure as much exercise of these faculties as practicable. It conduces greatly to an alleviation of the unhappy condition of epileptics for them to participate, as far as practicable, in the interests and social enjoyments of life; and if practicable it is sometimes desirable to conceal from them the nature or the extent of the malady with which they are afflicted. I have known marriage to be advised by the physician in the case of a young woman. Such advice cannot be too strongly censured. There is no ground to expect that the malady will be favorably affected by marriage. With reference to this step, it is the duty of the physician to explain fully to the family of the patient, if not to the patient, the nature of the malady.

The existence of epilepsy is an important fact in certain medico-legal cases. In the transient delirium which sometimes succeeds epileptic paroxysms, and which may be incident to epileptoid attacks, violence to others, and even homicide, may be committed. The occasional occurrence of delirium, lasting for hours or days, in connection with the disease, is to be borne in mind in

¹ Vide article on the "Surgical Treatment of Epilepsy," etc., *New York Journal of Medicine*, March, 1852. Prof. Smith in this article gives a summary of facts with respect to setons, issues, cauterizations and moxas, operations on the scalp, tracheotomy, amputation, operations on the nerves, operations on the arteries, and trephining.

giving medical testimony. An epileptic under my observation, a quiet, docile man, has repeatedly said to me, with an appearance of much concern, that he had fears that he might kill some one. He stated that he was conscious at the moment of an intense desire to kill any one who irritated him.

The treatment of cases in which epileptoid attacks occur, either with or without the occurrence of *epilepsia gravior*, is essentially the same as in cases of the latter form of the disease.

CHAPTER VIII.

THE NEUROSES (CONTINUED).

Hysteria.—*Hystero-epilepsy.*—*Catalepsy.*—*Ecstasy.*—*Somnambulism.*—*Tetanus.*

Hysteria.

THE name hysteria, as commonly used, embraces a multiplicity of morbid phenomena. It is used to denote an abnormal condition of the nervous system and of the mind, entering largely as a morbid element into a variety of affections. The hysterical condition, as regards the mind, involves a morbid susceptibility to emotions and a defective power of the will to restrain their manifestations. A person, whether male or female, is said to be hysterical who weeps or laughs irrepressibly on inadequate occasions and when these emotional acts are incongruous. Frequently these manifestations of opposite emotions occur in alternation and with an abrupt transition. Weeping and laughter are physiological acts when they represent emotions which are natural; that is, excited by adequate causes and not exceeding the bounds which observation shows to be consistent with health. These acts are pathological when they do not represent corresponding emotions or when they proceed from emotions which are unnatural in view of the circumstances under which they occur. The emotions may be real, but morbidly excited or in morbid excess. On the other hand, the hysterical manifestations in some cases simulate emotions which do not exist. Patients sometimes weep violently without experiencing mental anguish, and laugh immoderately without enjoyment. An intelligent and estimable lady in advanced life, who was under my observation for many years, was subject to spells of uttering loud explosive sounds resembling those of laughter, from which she declared she was unable to refrain. They were called, in the family, her laughing or screaming fits. These were the only hysterical phenomena in the case, and it was frequently necessary to administer a full opiate to arrest them.

A tendency to exaggerate subjective symptoms of disease often enters into the hysterical condition, proceeding sometimes from an exaggerated sense of existing symptoms and sometimes from a morbid desire to excite interest or sympathy. It is an important part of the knowledge and tact of the practitioner to make due allowance for this tendency in his investigation of symptoms. In some cases a morbid perversion of the mind leads patients to undertake to practise gross frauds as regards their ailments. They pretend to have extraordinary disorders, and resort to ingenious and persevering efforts of deception. Here, too, the knowledge and tact of the physician are called into requisition. He meets not infrequently with hysterical malin-

gering as well as hysterical self-deception. Owing to the facts just stated, hysteria is associated in the minds of many with either imaginary complaints or imposition; and hence many are loath to consider themselves as affected with hysteria, and the physician learns reserve in the use of this term in his intercourse with his patients.

Other symptoms of the hysterical condition are a painful sense of constriction in the epigastrium and the sensation of a foreign body in the throat, known as the *globus hystericus*. To these a great number and variety of morbid sensations might be added, such as cephalalgia, *tinnitus aurium*, eructations, abdominal tympanites, irregular chills with yawning and stretching, diuresis, twitching of muscles, cramps, etc. etc. The nervous and mental disorder which constitutes what is commonly called the hysterical condition may be associated also with a host of affections. This condition may enter more or less as an element into almost any disease. There are certain affections often found associated with symptoms denoting this condition. It will suffice to enumerate the more important of these, as follows: 1. Neuralgia, especially supraorbital, cervico-occipital, and dorso-intercostal. A form of neuralgia almost pathognomonic is that in which the patient describes the pain as if produced by driving a nail into the head (*clavus hystericus*). 2. Hyperæsthesia of the surface, either limited to certain situations or diffused over the body. Affecting the abdominal walls, this simulates in some cases peritonitis. 3. Anæsthesia, local or general. This is sometimes unilateral (*hemianæsthesia*), and it is generally of the left side. Not infrequently the sensibility to tact remains while the sensibility to pain is lost (*analgesia*). 4. Different varieties of functional paralysis, especially paraplegia and nervous aphonia. [These are often associated with contractures, which in the upper extremities are usually in the direction of flexion, while in the lower extremities the position assumed is usually that of extension.—H.] 5. The so-called hysterical cough. (Vide p. 220.) 6. Hyperæsthesia of the joints simulating grave articular disease. 7. Pain and tenderness over one or both of the ovaries, oftener on the left side. 8. Retention of urine. 9. Notable diminution or suppression of urine (*ischuria*).

What I have called the hysterical condition embraces the milder manifestations of hysteria. Severer forms of the affection are hysterical paroxysms characterized either by convulsive movements or coma more or less complete or delirium. In some cases convulsions constitute the most prominent feature of the paroxysms, coma in these cases usually coexisting. In other cases coma occurs without convulsions, but the coma may precede or follow convulsions, and in some cases delirium is the prominent feature. The severer forms of hysteria, therefore, may be considered as threefold—namely, hysterical convulsions, hysterical coma, and hysterical delirium.

Hysterical convulsions occur in persons subject to the milder manifestations of hysteria, and the latter are frequently premonitions of the former. The development of the paroxysm is generally gradual; the convulsions are preceded by notable distress, referred to the epigastrium, by a sense of choking or suffocation, and sometimes by a feeling as if a solid body or ball ascended from the abdomen to the throat (*globus hystericus*). The convulsive movements are often first manifested in the muscles of the eyelids and eyeballs. Other of the muscles of the face are rarely affected, and hence movements more or less rapid of the eyes and constant nictation are highly distinctive of an hysterical paroxysm if the movements be limited to these facial muscles. These muscles may be alone affected, but frequently the convulsive movements extend to the extremities and trunk.

A distinctive feature of the convulsive movements of the body and limbs is they are not purely automatic. Patients throw their limbs in various direc-

tions; they tumble about the bed with violence, rolling from the bed to the floor, and striking with force against solid substances if not prevented; they struggle with those who attempt to restrain them, and sometimes show a prodigious degree of strength. After making active movements for several minutes they remain comparatively quiet for a time, and the convulsions are then renewed. At times they grasp the throat as if to remove an obstruction, strike the breast, or tear the hair. These movements are in great measure voluntary. They are directed by a delirious volition, in this respect differing essentially from the convulsions of epilepsy or eclampsia, which are purely automatic or involuntary. Automatic movements, however, in certain cases enter more or less into hysterical convulsions. Tonic spasm of the posterior muscles of the trunk, bending the body backward so that the trunk, head, and lower limbs form the arc of a circle, constituting what is known as *opisthotonos*, occurs in some cases of hysteria. The jaws are sometimes firmly closed, as in trismus. In the intervals between the active movements the muscles are often rigid.

Consciousness during the convulsive movements and in the intervals appears to be lost, but generally the patient has more or less cognizance of what is said and done; a fact which the practitioner may often turn to good account in the management. The face is sometimes flushed and sometimes pale. Respiration is often notably disturbed, in some cases being extremely rapid and irregular, in other cases slow and suspirious. It is extremely rare for foamy saliva to be ejected from the mouth or for the tongue to be bitten. The spasm of the larynx and muscles of respiration which characterizes epilepsy is wanting; the nostrils are usually dilated; and nictation and movements of the eyes generally continue. The pulse is frequently but little or not at all affected. The heart, however, sometimes acts with violence and irregularity. The tranquillity of the circulation in some cases is a striking feature. The duration of the paroxysm varies much in different cases. It very rarely, if ever, is limited to a few moments; and it may continue for a period varying from half an hour to several hours. The convulsive movements gradually go off, and the disappearance of the paroxysm is frequently accompanied by cries, groans, sighs, loud weeping, or spasmodic laughter. Copious diuresis often occurs at the termination of the paroxysm.

It is important to discriminate hysterical convulsions from epileptic paroxysms and epileptiform convulsions or eclampsia. The foregoing sketch presents certain points which in general suffice for the differential diagnosis—namely, the evidence of volition in the character of the movements; the gradual development of the attack; absence of convulsive movements of the muscles of the face except those of the eyes; absence of foamy saliva and blood upon the lips; the respiration disordered, but not suspended, by spasm of the larynx and respiratory muscles; the long duration of the paroxysms; the incomplete loss of consciousness; and the occurrence of symptoms denoting the hysterical condition prior to and following the paroxysm. It is a fact, however, not to be lost sight of, that epilepsy or eclampsia may be conjoined with hysterical convulsions.

Hysterical coma enters more or less into the paroxysms just described. It may precede and follow them. It is sometimes accompanied by convulsive movements limited to the eyelids or eyes, but it occurs without any convulsions. In a case of simple, ordinary hysterical coma the patient lies apparently in a state of profound, tranquil sleep. The countenance presents a natural appearance, and the respiration is quiet, with perhaps occasional sighs. The pulse is regular, and is neither accelerated nor retarded, and there is frequently more or less rigidity of the muscles. Attempts to rouse the patient from this state are ineffectual or answers to questions are obtained

with much difficulty and in feeble whispers. The muscles offer resistance to efforts to separate the jaws. The quasi-comatose state continues for a variable period, often for hours and sometimes for days, if not successfully treated. Patients in this state are not completely unconscious. They are cognizant of what is said and done. Sensibility to pain is blunted, but not abolished; pinching or pricking the skin may be borne without flinching, but stronger impressions, such as are produced by the application of a heated hammer or the prolonged cold douche, occasion suffering.

Attacks of this kind occasion great alarm, and the physician will naturally participate in the apprehensions of friends if he fail to determine the nature of the affection. It is to be discriminated from apoplexy, and the diagnostic points are as follows: The attacks do not present the stertor of apoplexy, and hemiplegia is wanting; the pupils respond readily to light; the patient is perhaps known to be subject to hysteria. The symptoms of the hysterical condition precede the coma. The age of the patient will be likely to be under the period when apoplexy is most liable to occur; and in ordinary hysterical coma the nature of the affection is generally speedily declared by the efficacy of certain measures of treatment to be presently mentioned.

Uræmic coma is to be excluded. Antecedent and coexisting symptoms relating to the urine, general dropsy in some cases, and the absence of hysterical premonitions, will suffice for this differential diagnosis. Abercrombie related cases of fatal coma occurring in women which are liable to be mistaken for hysteria, nothing being found after death to account for the coma except cerebral congestion. Williams described these cases in the following terms: "A young female becomes anæmic, and after exhibiting various symptoms of feeble general circulation, with headache, drowsiness, and impaired sensorial functions, suddenly becomes worse, passes into a state of stupor, with dilated pupils, sometimes varied by slight manifestations of delirium, throbbing of the carotids and partial heat of the head, and dies comatose. On opening the head a small quantity of serum is found under the arachnoid and in the ventricles, sometimes with a little lymph (in one case there was none). The vascularity of the membranes is remarkable, but the vessels most distended are the veins, and in the larger of these and in the longitudinal sinus there is a firm coagulum."¹ I had met with cases answering to this description many years ago, before uræmia was as well understood as now. The existence of uræmia in such cases seems now to afford a rational interpretation of the phenomena; yet I have met with a case in which repeated careful examinations of the urine gave no evidence of renal disease.

There is a possibility of confounding the coma dependent on meningitis with hysterical coma. Meningitis is to be excluded by the fact that the coma has not been preceded by the diagnostic symptoms of that disease—namely, pain in the head, intolerance of light, suffusion of the eyes, throbbing of the carotids, etc. The thermometer may aid in the exclusion of meningeal or any other acute inflammation. If an acute inflammation exist, the heat of the body is more or less raised; whereas hysteria, existing alone, does not usually give rise to any increase of heat. By this also meningitis may be excluded in cases of hysterical delirium. Hysteria may, however, be attended by rise of temperature, so that the existence of pyrexia in itself does not positively exclude the existence of hysteria.

Under the head of hysterical coma may be embraced certain extraordinary cases in which the mental faculties, the senses, and sensibility are suspended more completely and for a longer period than in ordinary cases. These cases are likely to occasion much embarrassment in the mind of the young practitioner. As an illustration, in the early editions of this work I have given

¹ *Principles of Medicine.*

with considerable detail an account of a hospital case of which a synopsis is as follows: The patient, a man twenty-five years of age, was admitted in a state of unconsciousness, the previous history not having been ascertained. For seven days he remained most of the time in an unconscious state. The eyes were sometimes open and sometimes closed. He appeared to take no notice. The pupils were mobile, and neither contracted nor dilated. Flies creeping over the face, and even over the conjunctiva, did not disturb him. Drinks introduced into the mouth were retained there for some time, and the greater part escaped. The respirations were perfectly normal; the pulse 76 and regular; the skin was natural, and there was neither distension nor tenderness of the abdomen. He lay motionless, not changing his position, and giving no manifestation of suffering.

The treatment consisted of the cold douche (which had no effect), enemata of turpentine and asafœtida, and fluid nourishment by the mouth. The urine was withdrawn with the catheter. On the fourth day there was marked improvement. The eyes were open and denoted intelligence, but he did not speak or give heed to questions. He took nutriment freely and with apparent relish. On this day he had a paroxysm of violent weeping.

He relapsed into the former condition on the fifth day. Castor oil was prescribed on this day, no dejection having taken place since his admission. He urinated voluntarily while preparations were making to introduce the catheter. The bowels were moved freely after four minims of croton oil had been given. He resisted the administration of the oil as well as of drink and nourishment. The dejections were not passed in bed, but he disposed his body so that they were passed upon the floor. On the seventh day, there being no material change, "firing" was resorted to by means of a hammer heated by boiling water. He bore the heated iron for some time without manifesting pain, but on continuing the application he made vigorous resistance, and at length protruded the tongue when requested, and took brandy and water freely.

On the eighth day the improvement was marked. He took, however, but little notice, and replied to questions slowly in a feeble whisper. On the eleventh day he was dressed, without any effort on his part, and made to sit up. He remained sitting in one position, the eyes fixed in one direction. He protruded the tongue slowly and partially when requested, but did not reply to questions. On the twelfth day there was a marked change. He greeted me with a smile and offered his hand. He walked of his own accord.

He relapsed on the fourteenth day into the former state of unconsciousness, and "firing" was again resorted to. By this measure he was roused sufficiently to take nutriment. He continued in this state until the seventeenth day. On that day he was made to walk about the ward with assistance, and the experiment was tried of leaving him unsupported. After remaining motionless for several minutes he dropped down, but in a way not to receive any injury.

On the eighteenth day he talked and walked about of his own accord. On the nineteenth day he again relapsed into silence and unwillingness to take food. "Firing" was resumed, and by means of this measure he was made to walk into the open air. On the twentieth day he walked about and talked freely. After this date he progressively improved, and he was discharged well at the end of three weeks.

Nothing could be ascertained respecting the cause of this attack. The patient stated after his recovery that he recollected what had occurred during his illness. I did not discover that the mind was exclusively occupied by any dominant idea, as in ecstasy. Consciousness was not lost, but the exercise of the faculties dependent on the cerebro-spinal system was in a

great measure suspended. A morbid moral perverseness appeared to be an element in the case, as in most cases of hysteria, but it is certain that the patient was not a malingerer.

The diagnosis of hysterical coma in this case was based on the symptoms which have been stated, together with the absence of fever, as well as of the evidence of disease of the kidneys or of any other organ. I have met with a few other cases presenting the same characteristic features, and in two of these instances the patients were of the male sex. In one of the cases catalepsy existed. In each case the termination was in recovery.

Hysterical delirium occurs generally subsequent to, or in alternation with, the paroxysms of convulsions or of coma which have been described, but it also occurs alone. It is preceded and followed by symptoms characteristic of the hysterical condition. The delirium is active, and is manifested in some cases by wild, excited talking, the mind passing rapidly from one topic to another. The mind may run on either gay or grave topics, or there may be an incongruous union of both. Patients are sometimes violent. Occasionally they use vulgar and obscene language. In some cases the mind acts under the influence of insane delusions, and these sometimes involve spectral illusions.

Of the pathology of hysteria in the severer forms just described, all that can be said, with our present knowledge, is, that it involves a functional morbid condition affecting the nervous system, especially in its relations with the mental faculties. An important element of the affection is disorder and weakness of the will; the affection, however, is by no means purely mental, but proceeds from a pathological state of the cerebral organs with which the perceptive and emotional faculties, together with the will, are connected. The three forms of hysteria which have been described differ considerably as regards the morbid manifestations, but that they are different forms of one affection is shown by their coexistence or occurrence in alternation, by certain symptoms characteristic of the hysterical condition which occur alike in connection with each form, and by the fact that what we know of the causation applies equally to the three forms.

Hysteria may occur at any period of life, but in the majority of cases patients are between fifteen and twenty years of age. I have known it to be well marked in a girl ten years old. It is of rare occurrence either before the evolution of the sexual instinct or after the period when it may be supposed that venereal desires have ceased; but it sometimes continues into advanced age. The symptoms which characterize the hysterical condition are not very uncommon in males. The name hysteria, therefore, which in its etymology refers to the uterus, is a misnomer.

The causation appears to require a peculiarity of constitution. There are some persons who are constitutionally prone to hysteria, and there are many who are incapable of having it. The hysterical diathesis often exists in members of the same family. A great variety of causes may contribute to the development of the affection, among the more frequent being anæmia, overtaxing of mind and body, mental anxiety or grief, and the prostration incident to various diseases. The influence of causes pertaining to the sexual system has doubtless been much exaggerated; but the agency of excessive venereal indulgence or of masturbation on the one hand, and of continence on the other hand, in certain cases is not to be doubted. Sudden disappointment, affliction from loss of friends, violent anger, jealousy, and other kinds of strong mental excitement, often act as exciting causes of an hysterical paroxysm. A desire to excite in the minds of friends or others anxiety or alarm, and to furnish occasion for interest or sympathy, contributes to that abandonment or perversion of the power of the will which enters into the

paroxysms. The hysterical constitution may be developed, and is often fostered, by the absence of wholesome restraint and discipline in the management of youth, and by an unfortunate habit to which women, more than men, often become addicted—namely, of concentrating unduly the attention on personal sensations and sentiments.

As regards PROGNOSIS, hysterical attacks are proverbially devoid of danger. The practitioner, however, is not to lose sight of the fact that hysteria may be associated with affections which are serious. He should not be too ready to set down morbid phenomena to the account of hysteria; and it behooves him to be careful not to confound hysteria with other affections.

The TREATMENT of hysteria is to be considered with reference—*first*, to the hysterical condition; and *second*, to the paroxysms which have been described.

The hysterical condition calls for remedies to soothe the nervous system, but opiates are to be avoided. Valerian, asafetida, lactucarium, ether, belladonna, hyoscyamus, and the valerianate of ammonia are appropriate remedies. Of these, the first two are the most efficient. The bromide of potassium has in some cases a remarkably soothing effect. Alcoholic stimulants should be recommended, if at all, with great reserve, lest the patient take advantage of the sanction of the physician and resort to them more frequently and freely than prudence warrants. The most important part of the treatment is hygienic. The object is to invigorate both body and mind. With regard to bodily vigor, good diet, abundant exercise in the open air, and regular habits as regards sleep are important. With regard to mental vigor, healthful occupation of mind, and avoidance as far as possible of everything calculated to produce undue development of the sentiments and passions or to excite the imagination, are to be enjoined. The causes which may be suspected in individual cases are to be removed as far as practicable. The patient should be encouraged to endeavor to increase the power of the will to resist a tendency to give way to emotional disturbance. For this purpose the discreditable character of the affection may sometimes be referred to with advantage. The moral management will involve details suited to individual cases, which must be left to the discretion, delicacy, and tact of the practitioner. Cases in which ailments are exaggerated or simulated with a view to excite attention, curiosity, or commiseration are unhappily not infrequent. As the determination of the patients in these cases is not to get well, the varied measures of treatment which are adopted prove of course ineffectual. These cases sometimes tax severely the patience and temper of the physician.

In treating cases of hysterical convulsions it is to be borne in mind that if left to pursue their course, simply preventing the patient from the self-infliction of wounds or bruises, they would end spontaneously; and it would perhaps be as well for the patient if the paroxysm were allowed to exhaust itself; but the anxiety and alarm of friends generally require a resort to measures to arrest the convulsive movements. The prolonged application of the cold douche to the head is generally successful. The head of a patient is to be held over a tub and cold water poured upon it continuously until the convulsions cease and the patient admits being relieved and begs that the measure may be discontinued. Remembering that consciousness is not usually abolished, and that the convulsions depend upon a delirious volition, the physician should take care to state repeatedly that the douche is to be persisted in until the patient is able to express relief, and is to be repeated if the relief be not permanent. It is unquestionable that the efficiency of this measure depends considerably, if not chiefly, on its moral effect. The physician should also give to the friends, within the hearing of

the patient, positive assurances that there is no danger and that the paroxysm will certainly be arrested. After the convulsions cease, if the patient be much distressed, an opiate may be given, either by the mouth or by the hypodermic method, but if valerian, asafoetida, or ether will suffice, it is to be preferred.

In an ordinary paroxysm of hysterical coma the douche, as just described, will almost invariably succeed in restoring consciousness. The same course is to be pursued, with respect to moral management, as in paroxysms of hysterical convulsions. The treatment after consciousness is restored is the same as in cases of convulsions after these have ceased. In cases of prolonged hysterical coma "firing," repeated from time to time, is the most effective measure. Nourishment should be given, forcibly if necessary, and as sensibility and consciousness return the exercise of the will in taking food, sitting up, and performing other voluntary acts should be enforced.

In hysterical delirium, if mild, the remedies which have been mentioned, valerian, asafoetida, etc., with soothing management, may suffice. If the delirium be violent, the tartrate of antimony and potassium, carried to the point of nausea, will be likely to tranquillize the patient.

After the paroxysms have ceased in each of the three forms the treatment resolves itself into that called for by the hysterical condition.

Among the most remarkable phenomena of hysteria is the influence exerted upon anæsthetic parts by the application of various metals. The application of metals for this purpose is called *metallo-therapy*. The main facts were discovered long ago by Burq; but they have been more fully studied in late years by Charcot and his pupils in the Salpêtrière in Paris, where most extraordinary and unusual forms of hysteria are observed. It is found that the application of certain metals to an anæsthetic part restores sensation in this part and often over a wider district, and strangely causes a transfer of the anæsthesia to an exactly corresponding part of the opposite side. The most efficacious metals are iron, gold, silver, zinc, and copper, but others are also employed. Not only metals, but magnets, blocks of wood, mustard plasters, and other agents may produce similar effects. In a similar way have been produced restoration and transference of unilateral loss of vision, hearing, taste, and smell. An explanation of these strange phenomena has not been given, nor is the practical application of metallo-therapy of much importance.

[In all forms of hysteria, but especially in those associated with paralysis and contractures, a course of the Weir Mitchell treatment, consisting of isolation from sympathetic friends and relatives, absolute rest in bed, massage, electricity, and copious alimentation, is often followed by brilliant results. Hypnotic suggestion is another therapeutic resource which deserves a more systematic employment than it has yet obtained outside of Paris.—H.]

Hystero-epilepsy.

Hysteria and epilepsy are distinct affections, but they are not antagonistic to or incompatible with each other. A person may be subject to both, and it may happen that hysterical phenomena may precede or follow an epileptic paroxysm. The term hystero-epilepsy, as used by Charcot and others, however, is applied to cases in which hysteria simulates more or less of the phenomena of epilepsy. In an hystero-epileptic paroxysm hysteria is the primary and essential malady, but in addition there are tonic or clonic convulsions which are automatic. The tongue or cheek may be wounded and foamy saliva escape from the mouth. There may be an aura which, according to Charcot, often has its source in one of the ovaries. Pressure over the region of the ovary sometimes excites, and methodic compression sometimes averts, a par-

oxysm. An important point of distinction between a combination of the two affections and the simulation of epilepsy is that the latter does not involve a tendency to the recurrence of epileptic distinct from hysterical paroxysms.

The prognosis is more favorable than in cases of epilepsy existing independently of this etiological connection, and the treatment has relation chiefly to the hysteria.

[Charcot and his pupils have had marked success in the treatment of hysterio-epilepsy at the Salpêtrière by hypnotic suggestion. In the same institution continuous pressure is maintained over the ovarian region of the hysterio-epileptic by means of a belt fitted with pads. It is said that so long as the truss-like instrument is kept in place the attacks are held in abeyance.—H.]

Catalepsy.

The affection called catalepsy, as this term is now commonly used, is evidently allied to one of the forms of hysteria—namely, hysterical coma. In the cataleptic state the sensory functions, volition, and consciousness are for the greatest part or entirely suspended. So far, the state is essentially the same as in some cases of hysterical coma; but superadded is a peculiar wax-like rigidity of the voluntary muscles, retaining the limbs and trunk in a fixed position, the different parts of the body preserving the positions in which they may be placed by the hands of another. This superadded feature is characteristic of catalepsy.

The cataleptic state is generally preceded by symptoms of the hysterical condition, but it is sometimes developed suddenly; that is, without premonitions. The patient while in this state remains immovable, preserving the position in which the body happened to be at the time of the attack. In some cases the rigidity of the muscles is such that they offer considerable resistance when efforts are made to alter the position of any part, but in other cases the different parts are easily moved. The trunk or limbs are retained in positions which in health would require a strong exertion of the will, and for a longer period than would be possible in health. Thus, the limbs are sometimes kept for a long time extended, or, the patient lying on the back, the lower limbs may be raised and the trunk elevated, so that the body rests only on the sacrum; and this position, which, voluntarily assumed, would soon become insupportable, is preserved for a considerable period. This remarkable feature is more or less marked in different cases; in other words, the catalepsy may be complete or incomplete.

As in cases of hysterical coma, the vital functions may be but little or not at all disturbed. The circulation may be regular, respiration natural, the temperature normal, and, if food be ingested, the processes involved in nutrition may be well performed.

The affection is paroxysmal, but different cases differ widely as regards the frequency and the duration of the paroxysms. They are sometimes short, lasting but a few moments; not infrequently they continue for several days; and they may extend to weeks and even months. In the majority of cases the duration is three or four hours. A single paroxysm only may occur, and, on the other hand, paroxysms have been known to be repeated daily for a long period. A case is cited by Puel in which twelve hundred paroxysms occurred within twenty-eight months.

Catalepsy in this country, exclusive of cases of so-called mesmerism or animal magnetism, must be extremely rare. With pretty large opportunities for clinical observation for more than forty years, I have met with but 2 well-marked cases. The statistical researches of Puel, embracing results of an analysis of 148 cases, showed that the disease is not peculiar to females. Of

these 148 cases, 80 were in females and 68 in males.¹ In one of the cases which I have seen the patient was of the male sex. A large majority of cases are between ten and thirty years of age. The affection, however, may occur at less than ten years and at an advanced period of life. It appears to be induced especially by mental causes. Melancholy, overtaxing the intellect, and violent excitement of the passions favor its development, and causes frequently determining an attack are hatred, jealousy, fright, domestic affliction, reverses of fortune, etc.

The PROGNOSIS is always favorable as regards danger to life. It has, however, been observed to precede the occurrence of insanity, paralysis, and epilepsy.

The principles of TREATMENT are essentially the same as in cases of hysterical coma. The condition of the muscles calls for the use of friction with stimulating liniments. Forcible alimentation may be required if the cataleptic paroxysm be prolonged.

An abnormal state, analogous to that of catalepsy, is among the curious phenomena of hypnotism, formerly known as mesmerism or animal magnetism. The consideration of these phenomena—which of late years have deservedly received scientific attention—does not come within the scope of his work.

I shall content myself with a bare allusion to certain abnormal conditions which properly belong to the domain of psychology. One of these is the condition known as *ecstasy*. In this condition the mind, absorbed in a dominant idea, becomes insensible to surrounding objects. In some cases during the ecstatic state the body remains immovably fixed, as in catalepsy. Extraordinary visual hallucinations occur in some cases. The mental condition differs from that of catalepsy in this: the mind is active, and thoughts or visions which occur are recollected afterward, whereas in catalepsy the action of the mind is suspended and the period passed in the paroxysm is a blank in the patient's memory. Another name for the ecstatic state is *trance*. As in some cases of catalepsy, the respiration and circulation may become so feeble that without close examination life may be supposed to be extinct. If the breathing be not readily ascertained and the pulse be inappreciable, auscultation with the binaural stethoscope can hardly fail to reveal the heart-sounds in such cases.

Another condition is that called *somnambulism*. This condition is incident to sleep. It embraces the mental and physical performances, sometimes very extraordinary, which are observed in sleep-walkers. Similar phenomena are observed in the condition known as the *mesmeric or magnetic sleep*.

Tetanus.

The term tetanus is applied to an affection characterized by persisting rigidity of the muscles of the jaw, and frequently of the greater part of the voluntary muscular system, with paroxysms of tonic spasms, the intelligence being preserved. In the great majority of cases this affection follows a wound or local injury of some kind. It is then distinguished as *traumatic tetanus*, and when not traumatic it is distinguished as *idiopathic tetanus*. Its symptomatic characters are essentially the same whether the disease be traumatic or idiopathic. On account of the large preponderance of traumatic cases it belongs among the surgical affections, and is treated of at length in comprehensive works on surgery. I shall consider it as an idiopathic affection.

Idiopathic tetanus is everywhere rare, and in cold or temperate climates it is one of the rarest of affections. It is less rare in tropical climates. It is

¹ *Mém. de l'Acad. de Méd.*, Paris, 1856. Vide Valleix, *op. cit.*

one of the affections to which newly-born children are subject, especially in tropical climates, but occasionally everywhere. In adults it seems sometimes attributable to exposure to cold, and with this apparent causation it is called by some writers *tetanus a frigore*. It has been conjectured that the disease is sometimes a manifestation of rheumatism.

[At the present day tetanus is universally regarded as an infectious disease caused by the entry into the organism of the "bacillus of Nicolaier." Kitasato was, however, the first to obtain pure cultures of the bacillus and to produce the disease by inoculation in animals. It is thoroughly established that this micro-organism exists in the soil and that it flourishes most abundantly in stables and their neighborhood. In the so-called idiopathic tetanus it is almost a foregone conclusion that the germs have gained access to the body through wounds or abrasions so slight as to have been unnoticed by the patient.—H.]

In many cases idiopathic tetanus is developed abruptly, without premonitions; but in a certain proportion of cases it is preceded by indefinite ailments, such as chilly sensations, sense of fatigue, etc. The muscles first affected are those of the neck and lower jaw. The affection is sometimes limited to these muscles, and it is then distinguished as *trismus*. The jaws are firmly shut by the rigid contraction of the muscles, and hence the affection is known as *lockjaw*. The mouth in some cases cannot be opened by any force which it would be prudent to employ, and drink, nourishment, or remedies can be taken only through the spaces between the teeth. The muscles of the face are frequently involved, giving rise to distortions of the features which are sometimes terrific. The angles of the mouth are drawn backward and upward, giving the expression called *risus sardonicus*. The tongue is sometimes severely bitten by being caught between the teeth. The pharyngeal muscles are not infrequently involved, preventing deglutition.

If the affection extend to the muscles of the trunk, the abdomen becomes retracted and rigid and the respiratory movements of the chest are restrained. The limbs become rigidly extended. The entire body is sometimes immovable and stiff, so that it may be raised by the head or feet as if it were a statue.

Rigidity of the muscles is persistent, but at intervals spasm is added to the persisting contraction. In the paroxysms of spasm or convulsions the body is frequently bent backward by the predominant force of the posterior muscles of the trunk; and in extreme cases the body forms the arc of a circle, resting on the head and sacrum, and sometimes on the head and heels. This is called *opisthotonos*. A much less frequent form of curvature is produced by the predominant contraction of the muscles on the anterior portion of the trunk. This is called *emprosthotonos*. A lateral curvature, still more rare, is called *pleurosthotonos*. The paroxysms vary in duration, and they occur at intervals which vary much in different cases. They are attended with severe pain. The paroxysms may be excited by any mental emotion and by impressions transmitted from the surface of the body. In this respect, as also in the character of the convulsions, they resemble those which take place in cases of poisoning by strychnia.

As already stated in the enumeration of the characters distinctive of tetanus, the intelligence is preserved. Delirium and coma are wanting. In general, the paroxysms are more frequent during the day than during the night. If deglutition be prevented by pharyngeal spasm, the patient suffers from thirst and hunger. Foamy saliva under these circumstances collects and escapes from the mouth. The bowels are usually constipated, but in some cases involuntary dejections occur. Retention of urine may occur, or, on the other hand, it may be passed involuntarily. The circulation may be but little or not at all disturbed, save as an effect of disturbance of the respiration. Respiration

is embarrassed in proportion as the respiratory muscles are affected. The embarrassment is usually great during the paroxysms, and fatal apnœa may be induced. The temperature of the body varies much in different cases. In a certain proportion of cases there is moderate or slight fever. In other cases there is notable pyrexia, the thermometer in the axilla sometimes showing a rise to 110° F. The temperature is measurably an effect of the muscular spasms. The temperature is always raised during exacerbations in which the muscular contractions are increased. Profuse sweating occurs in the exacerbations, and more or less perspiration exists in the intervals. Contraction of the pupil to the size of a pin's point during the exacerbations is often observed, the contraction going off in the intervals. A frequent symptom is pain at the pit of the stomach, piercing through to the back.

The disease sometimes destroys life within twenty-four hours. On the other hand, in rare cases it continues for several weeks, when it is called chronic tetanus. •

In a large proportion of cases the affection ends fatally after a duration varying between twenty-four hours and twenty days, the average duration being not far from ten days. The fatality is somewhat less from idiopathic than from traumatic tetanus. The mode of dying may be by apnœa or by asthenia. The danger of apnœa is in proportion to the amount of embarrassment of respiration. Death by asthenia is caused by the exhaustion incident to long continuance of the rigidity and spasms, together with the difficulty in some cases of alimentation. It has been noticed that in some cases rigor mortis succeeds the spasms during life without any appreciable interval of muscular relaxation.

The distinctive characters of the affection render the DIAGNOSIS sufficiently easy. It is to be distinguished from spinal meningitis and from cerebro-spinal meningitis by the absence of local symptoms denoting inflammation, and from the latter of these affections by the absence of cephalalgia, delirium, and coma. Absence of coma distinguishes it from epilepsy. Moreover, the latter is purely paroxysmal, the muscles not being contracted in the intervals. Absence of characters distinctive of hysteria sufficiently distinguish it from that affection. It is, however, to be recollected that trismus, with or without convulsions, is an occasional manifestation of hysteria, and under these circumstances is unattended with danger. The phenomena produced by strychnia in poisonous doses bear the closest resemblance to those of tetanus, and to discriminate between them is of great importance in a medico-legal point of view. Within late years strychnia has been repeatedly employed for homicidal and suicidal purposes. The following differential symptoms are quoted from Todd :¹

“As regards the Tetanoid State from Strychnine.—a. The rapid supervention of tetanoid convulsions affecting chiefly, and with most intensity, the muscles of the trunk and spine, causing an active and violent opisthotonos rarely met with in tetanus. b. A rigid and tetanoid state of the muscles of the lower extremities, with somewhat less intensity than those of the trunk; the limbs extended and the feet drawn powerfully inward by the action of the tibialis postici muscles. The upper extremities affected also, but in a less degree, and the hands generally semiflexed. c. The trismus existing only imperfectly, and the facies tetanica very slightly or not at all; swallowing perfect, but the mode of deglutition peculiar, the patient snapping at the liquid offered and gulping it down with an effort, in a manner very similar to that in which hydrophobic patients swallow. d. The attacks of opisthotonos very frequent, seemingly exquisitely painful, and ushered in by a cry more or less loud.

¹ *Clinical Lectures on the Nervous System.*

"As regards Tetanus.—*a.* The symptoms coming on *gradually*, and the trismus the earliest, the most prominent, and most important one. *b.* The *facies tetanica* a very characteristic symptom. *c.* The attacks of opisthotonos less frequent, less extensive, and less severe than in poisoning by strychnine. *d.* The extremities the last parts affected, and suffering much less from the tonic spasms than other parts. *e.* Deglutition slow and difficult, and sometimes impossible, owing to the spasmodic closure of the mouth."

To these differential points it is to be added that a fatal dose of strychnia kills quickly, usually within an hour, whereas in fatal cases of tetanus life is prolonged generally for two or three days.

Punctate hemorrhages are very frequently found in various parts of the central nervous system, particularly in the medulla oblongata and spinal cord, after death from tetanus; but these changes are probably secondary, as they are found after death from other convulsive diseases. No morbid changes have been discovered to which tetanus can be attributed. In the present state of our knowledge, therefore, the disease is to be considered as functional, the changes which may be found after death being either secondary or associated by coincidence. With respect to the pathology, the close analogy of the symptomatic phenomena to those produced by strychnia is a strong point in favor of the supposition that the disease involves the presence in the blood of a toxic agent acting upon the spinal cord and the medulla oblongata. The symptoms show an exaggerated reflex excitability of the medulla and the cord as a marked pathological feature of the disease.

The TREATMENT of tetanus by different methods has proved unsuccessful in a large proportion of cases. Among the measures which have seemed to be sometimes successful are—opium given in large doses, aconite, alcoholic stimulants carried to the extent of producing intoxication, and the inhalation of chloroform. Other remedies advocated as sometimes successful are belladonna, cannabis indica, and quinia in large doses. Bloodletting and counter-irritation over the spine have been largely tried, but are not to be recommended. Ice applied to the spine has been found useful. Cold affusion has been employed with success. The high temperature of the body in some cases indicates antipyretic measures of treatment.

In addition to the remedies already named, others more recently employed are the hydrate of chloral, the Calabar bean, curare, and the nitrite of amyl. Cases which have ended favorably under treatment by these remedies have been reported; but clinical facts do not, as yet, warrant positive conclusions respecting the remedial power which they respectively exert over the disease. The great number of remedies advocated as possessing curative efficacy in tetanus suggests a reflection which has been mentioned in other connections: When cases of a disease have ended favorably under a host of remedies it may be reasonably conjectured that the ending in these cases was due more to an intrinsic tendency of the disease than to the remedies used. It remains to be determined in how large a proportion of cases tetanus would end in recovery without any actual medicinal interference.

In the following case improvement and recovery took place after all treatment had been discontinued: A boy seven years of age, the son of a poor washerwoman, came under my observation about a fortnight after the beginning of the disease. He then had every few minutes paroxysms of opisthotonic spasms, with rigidity of the limbs, pronation of the thumbs, erection of the penis, and firm closure of the jaws. The paroxysms lasted two or three minutes; they were accompanied by great embarrassment of breathing; they occurred spontaneously, but were brought about whenever the body was moved. During the paroxysms the body could be lifted like a statue by raising one leg. The angles of the mouth were depressed and the features

expressed great distress. A certain amount of trismus was constant; and the mouth could not be opened sufficiently for the patient to take food freely or to protrude the tongue. The pain was severe during the paroxysms. The mind was clear. He obtained but little sleep. The pulse was not accelerated. The disease could not be referred to any cause.

The case had been treated with morphia, quinia, and the valerianate of zinc. The patient was kept under the influence of chloroform for several hours. The effect was to relax the muscles of the jaw and to lessen the frequency of the paroxysms. Owing to a misapprehension this patient had no subsequent treatment. At the end of ten days he was found to have notably improved, and he shortly recovered. After the trial of the chloroform, nothing was done but to give nutritious food. The improvement was very gradual, slight spasms occurring from time to time after he had convalesced sufficiently to be up and about.

A highly important part of the treatment relates to the quietude of the patient. The body should be moved as little as possible, and all excitement of the mind should as far as practicable be avoided. Light, currents of air, and noise should be excluded. Nutritious alimentation is an important part of the treatment. If deglutition be impossible, food should be introduced by means of a stomach-tube, which may be passed through the nostril.

[Behring and Kitasato have succeeded in conferring upon rabbits immunity from tetanus. The blood-serum of these immune animals will, when injected subcutaneously, not only confer immunity upon others, but will actually cure the disease when produced by inoculation. From the blood-serum of immune animals Tizzoni and Centanni have succeeded in isolating an albuminoid substance, an "antitoxin," which is believed to be the prophylactic and curative principle to which the virtues of the serum are due. Several cases of tetanus which were apparently cured by antitoxin injections have been already reported, and our hope of a specific remedy for this fatal disease undoubtedly lies in the direction indicated by these remarkable experiments.—H.]

CHAPTER IX.

THE NEUROSES (CONTINUED).

Delirium Tremens.—Alcoholism.—Hypochondriasis.—Pathophobia.

Delirium Tremens—Alcoholism.

This affection proceeds from the abuse of alcohol. The various pathological effects of alcohol are considered as incident to a toxic condition, called *alcoholismus* or *alcoholism*. These effects enter directly into the causation of many affections, such as cirrhosis of the liver, fatty liver, epilepsy, muscular tremor, gastritis, pyrosis, and various dyspeptic disorders. Indirectly, alcoholism favors the production of nearly all diseases by lessening the power of resisting their causes, and it contributes to their fatality by impairing the ability to tolerate and overcome them. Taken in sufficiently large quantity, alcohol produces certain immediate effects which belong to the state commonly known as intoxication or drunkenness.

The opportunities of observing these effects are, unhappily, but too common. The coma which exists when a person is profoundly intoxicated—or, in common parlance, dead-drunk—is liable to be mistaken for apoplexy. The differential points have been presented in treating of the latter. Intoxication falling short of coma sometimes comes under the cognizance of the physician under circumstances in which the nature of the difficulty is not suspected by friends, as in women and children. Knowledge of the characteristic phenomena is then brought into exercise. The physician in these cases is sometimes bound by delicacy and prudential considerations to withhold an enunciation of the diagnosis.

The habitual use of alcohol beyond certain limits produces a deleterious influence on the whole economy. In cases of chronic alcoholism the digestive powers are weakened, the appetite is impaired, the muscular system is enfeebled, and the generative function decays. The blood is impoverished and nutrition is imperfect and disordered, as shown by flabbiness of the skin and muscles, emaciation, or an abnormal accumulation of fat. Pain in the limbs and back is a symptom of frequent occurrence. Wilks and other writers have called attention to the occasional occurrence of paralysis, particularly in the form of paraplegia, in drunkards (alcoholic paraplegia). The breath and emanations from the skin have a characteristic odor. The deleterious influence on the mental is not less marked than on the physical powers. The perceptions are blunted, the intellectual and moral faculties progressively deteriorate, until at length the confirmed inebriate, miserably cachectic in body and imbruted in mind, has but one object in life—namely, to gratify the morbid craving for alcohol. He exemplifies a variety of the form of mental derangement called dipsomania, from which recovery is extremely rare.

Delirium tremens, called also *mania a potu*, is an affection incident to alcoholism. It has been a mooted question whether the affection ordinarily known by these names be due to the sudden withdrawal of an habitual amount of alcoholic stimulation, or whether it be a direct consequence of the long-continued action of alcohol on the brain. Both explanations are correct. In a large proportion of cases its development is evidently owing to the use of alcohol being suspended or much diminished. Thus, it occurs in persons who voluntarily undertake to abandon intemperate habits, who are unable to obtain liquor, or who are prevented from drinking by the occurrence of some disease or accident. It is notoriously common among inebriates who are thrown into prison and among those admitted into hospitals. It often follows paroxysms of intemperance in periodical drinkers when the stomach refuses further alcoholic libations. On the other hand, it is sometimes developed notwithstanding the continued use of the habitual amount of alcohol.

The SYMPTOMS attending the access are anorexia, insomnia, muscular tremor, especially tremulousness of the tongue, and notable dejection. This state is known among drunkards as "the horrors." The mental depression is so great as not infrequently to lead to suicide. There is no pain in the head or febrile movement. The pulse is generally feeble and the surface is cool. This stage continues for one, two, or three days.

The development of the disease is characterized by mental aberration of a peculiar character. The derangement is characteristic, although presenting considerable diversity in different cases. The expression becomes wild, and the eyes are either vacant or staring. The movements are quick. The patient is constantly in motion. He talks incoherently. His mind wanders from one subject to another. He fancies that he has important business to attend to, wishes to go out, and requires to be constantly watched. To these manifestations of mental disorder are added illusions of the senses, phantasms, and

hallucinations of various kinds. He sees imaginary objects, such as mice, dogs, cats, lice, snakes, and ferocious animals. He hears noises of animals or men, answers imaginary questions, and often fancies the proximity of persons who are bent on insulting or ridiculing him or from whom he apprehends personal violence. Uncouth and unnatural representations appear to him to be going on. At first he may be able to appreciate the unreality of what he sees, hears, and imagines; but after a time his morbid perceptions become delusions, and, however extraordinary and absurd, they are real to the sufferer. They are sometimes of a character to inspire the greatest possible terror. Thus, patients not infrequently leap from windows and are dashed in pieces, believing that they are pursued by wild beasts or by men who seek their lives. A patient who escaped in his night-clothes under a sense of personal danger ran barefooted over frozen ground for fifteen miles before he was overtaken by men on horses who followed in pursuit. The degree of terror must be fearful to lead to such an amount of physical effort and endurance. In some cases the delusions are ludicrous. Thus, a patient declared that he should be able to sleep, but whenever he fell into a doze there were persons under his bed who tickled his fundament with straws. Under the apprehensions which the delusions excite patients are sometimes violent and dangerous, but they are usually controlled without much difficulty.

The insomnia continues. The patient gets no sleep for two, three, or four days, and sometimes for a still longer period, after the development of the affection. The delirium is always much worse during the night. Tremulousness of the muscles continues, but this is not always a marked symptom, although it enters into the name. Vigilance being a more constant symptom, it has been proposed to call the affection *delirium vigilans* instead of *delirium tremens*. Anorexia continues, the bowels usually are constipated, the skin is cool, the pulse is feeble, and, except under mental excitement, may be but little or not at all accelerated; the patient makes no complaint of pain in the head or elsewhere, and generally declares that he is well.

If the affection end favorably sleep at length occurs. If the patient once become soundly asleep, he will be likely to remain so for many hours, or if he awake the speedy return of sleep may be counted upon. After a protracted sleep, generally the delirium is found to have disappeared. Occasionally it continues, but is diminished, and disappears after renewal of sleep. Sleep appears to be not merely a criterion, but a means of convalescence. After sleeping much of the time for one or two days, convalescence is established, and the patient recovers more or less slowly or rapidly according to the duration of the affection and his physical condition at the time of the attack. If the affection pursue an unfavorable course, the insomnia persists and notable prostration ensues. The condition is not unlike that in an advanced stage of typhus; the delirium continues, with efforts to get out of bed; subsultus tendinum occurs; the pulse becomes more and more frequent and feeble; the skin is sometimes bathed in perspiration; and death takes place by asthenia, although the fatal termination is usually preceded by coma.

The PROGNOSIS is generally favorable. When not associated with other affections a fatal termination is rare. The affection destroys life *per se*, chiefly in cases in which repeated attacks have occurred and the constitution is broken by a long-existing alcoholic cachexia. Occurring after wounds, surgical operations, or accidents, and associated with other affections—as, for example, with pneumonitis—it adds much to the gravity of the prognosis.

The symptomatic phenomena show the affection to be cerebral, but the nature of the morbid condition, as in the other neuroses, is unknown. It is important to bear in mind that inflammation is not involved, nor is there

ground to believe that congestion is an essential element. There is usually some increase of the cerebro-spinal fluid, and the ventricles of the brain may contain an abnormal quantity of serum. The substance of the brain may be œdematous. This condition is sometimes called the wet brain of drunkards. All that can be said of the pathological character with our present knowledge is, that the prolonged toxical action of alcohol on the brain induces a peculiar morbid condition giving rise to those manifestations of disorder which are characteristic of this affection, especially when the use of alcohol is from any cause suspended. There is reason to believe that the morbid phenomena relating to the mind, as well as the progressive impairment of the vital forces, are to a considerable extent due to the insomnia. This is to be inferred from the fact that the delirium generally ceases after sleep has continued for several hours. Inability to sleep is an essential feature of the affection and the chief obstacle in the way of a favorable termination.

In general, the DIAGNOSIS is not attended with difficulty. The characteristics of the delirium render the affection easily recognizable when fully developed; moreover, the known habits of patients generally lead the practitioner to expect it. Tremulousness of the tongue and limbs, with vigilance, if the patient be a drunkard, denotes an impending attack. If now the patient complain of having remarkable visions or manifest illusions of the senses, the development is progressing. The cases in which the practitioner hesitates in coming to a diagnosis are those in which the habits are unknown. The affection may be developed in secret drinkers and in persons who are supposed to be perfectly temperate. I have known a person to be attacked who was supposed by his friends never to taste any alcoholic beverage. As the diagnosis implies intemperance, caution in forming an opinion in some cases is advisable, as well as prudence in expressing the opinion when formed. Of course it is a breach of medical ethics to reveal the character of the affection, save to the patient and, under certain circumstances, to his friends.

Excesses in drinking sometimes occasion a form of delirium differing, pathologically, from delirium tremens, but liable to be confounded with it. The delirium now referred to is an active delirium, characterized sometimes by violence or fury and sometimes by hilarity. It is a form of acute mania due to active cerebral congestion, conjoined with the immediate effect of alcohol on the brain. It is occasioned by a protracted paroxysm of drinking rather than by the habitual use of alcohol. This form of delirium has been distinguished as *delirium ebriusum*. It is accompanied by pain in the head, increased heat, throbbing of the carotids, and febrile movement; in short, by the symptoms of active cerebral congestion. It is of brief duration, ceasing when alcoholic stimulants are discontinued. It thus ceases under the circumstances which frequently occasion delirium tremens. It may be followed by delirium tremens. Aside from the discontinuance of stimulants, it claims the treatment indicated by active congestion of the brain—namely, bloodletting, purgatives, etc., measures not suited to the treatment of delirium tremens.

Finally, with respect to the diagnosis of delirium tremens, meningitis is excluded by the absence of cephalalgia, intolerance of light and sounds, throbbing of the carotids, febrile movement, etc. Acute gastritis, which may present some of the phenomena of impending delirium tremens, is to be excluded by the absence of vomiting, gastric pain, tenderness over the stomach, etc. Gastritis, however, is often present in delirium tremens. Typhoid and typhus fever are excluded by the absence of the diagnostic symptoms other than delirium of these diseases.

The TREATMENT of delirium tremens was formerly by bloodletting and other of the so-called antiphlogistic measures, under the belief that it involved either

inflammation or cerebral congestion. These measures are now abandoned as not only uncalled for, but injurious. Within late years various curative methods of treatment have been advocated on the grounds of success; and in endeavoring to judge of their respective merits it is to be borne in mind that under favorable circumstances the intrinsic tendency of this affection is to recovery. It may be said of this affection, as of others tending in like manner to recovery, that a large proportion of recoveries cannot be cited in evidence of the curative efficacy of any particular method of treatment, but that a large proportion of fatal cases favors the presumption that the treatment was injurious. Excluding cases in which the affection occurs in connection with wounds, surgical operations, and accidents, or with other affections, and the cases in which it occurs in persons whose constitutions are shattered by intemperance, judicious management without therapeutical measures would, in the great majority of cases, prove successful. It does not follow from this statement that remedial measures are not often useful.

The great object of treatment is to procure sleep. Opium has been employed largely for this object. The statistical researches of John Ware showed that the fatality was greater under the opiate plan of treatment than when an expectant or eclectic plan was adopted, and that the fatality is proportionate to the excessive use of opium. Opium used indiscriminately and largely is undoubtedly injurious, but that its moderate employment is useful in certain cases is not to be doubted. The use of opium as advised by Stillé may be safely adopted. This author says: "The best mode of exhibiting the medicine (opium) is undoubtedly to begin with a quarter of a grain or its equivalent, and progressively to augment the dose by small and hourly additions until sleep is produced or a sufficient degree of tranquillity obtained." I have not infrequently found a full dose, repeated, if required, after intervals of several hours, to act very favorably. The remedy should never be pushed to the extent of inducing narcotism, and if on a fair trial it be not found to tranquilize, it should be discontinued.

Cases have been treated satisfactorily by simply continuing the use of alcoholic stimulants in moderate quantity. In general it is injudicious to discontinue entirely the use of stimulants so long as the affection continues. The time for breaking off the habitual use is after sleep has taken place and the patient is convalescent. Stimulants are to be given freely in cases in which the symptoms denote failure of the vital powers.

Tartar emetic in nauseating doses is useful in certain cases. This remedy, if not pushed too far, exerts a sedative influence, diminishes delirium, and disposes to sleep. It is suited to cases in which there is considerable constitutional vigor, and it should be very cautiously given to patients much enfeebled or in cases in which there is a tendency to prostration. Emetics have been advocated as curative, but the evidence of this is unsatisfactory, and they are now very rarely employed. They are objectionable on the score of perturbation. Cathartics are objectionable on the same score. These evacuant remedies have been employed under the idea that they eliminate the alcohol from the system; but the affection is due to the toxical effects of alcohol, not to its actual presence in the system; and, indeed, the attack often appears to proceed from a diminution of the amount of alcohol habitually present.

Cold affusions, the cold douche to the head, and the shower-bath are useful in some cases. They are of doubtful expediency if employed against the will of the patient. He should be induced to concur in the propriety of making trial of them. They may do harm to feeble subjects or if the powers of life be much depressed.

Digitalis has been advocated as a curative remedy. It was introduced by

Dr. G. M. Jones of Jersey, England, who was led to ascertain its efficacy by a patient affected with delirium tremens having taken an ounce of the tincture by mistake. Subsequently he employed it in 70 cases with the loss of only 1 case. No practitioner would have ventured to give this remedy in the doses which experience has abundantly shown may be given without any unpleasant consequences in this disease. The dose advised by Dr. Jones is half an ounce of the tincture, which may be repeated, if required, after an interval of four hours. Many cases in which this plan of treatment has apparently proved efficacious have been reported. I have tried it in a few cases, in one of which it appeared to act like a charm, but in the others no curative effect was apparent.

The inhalation of chloroform in some cases tranquillizes the patient and induces sleep. This is a remedy to be employed with great circumspection. Its effect has been happy in several instances under my observation. In one case the effort to employ it excited such a degree of mania that I was led to desist. The hydrate of chloral may be employed. The use of this remedy calls for circumspection. The bromide of potassium, given in large doses, is a valuable remedy in this disease. This remedy is chiefly relied upon in a large majority of the great number of cases treated at Bellevue Hospital. Hyoscyamin has lately been employed with much success as an hypnotic in this disease.

As regards the measures which have been referred to, and others, they are to be employed according to circumstances proper to individual cases. Each of the measures is suited to some cases, and not to other cases. They are to be employed tentatively, the practitioner being guided by the effect in deciding whether to continue or discontinue them. Not infrequently they may be tried successively in the same case. In short, the appropriate treatment as regards these measures is expectant and eclectic, and they will be employed judiciously or otherwise according to the judgment of the practitioner.

The management in other respects is important. Quietude is to be enforced. Visitors, who are often actuated by curiosity, are to be excluded. The circumstances surrounding the patient should as far as possible be regulated with a view of promoting sleep. Much may be done by the exercise of tact in soothing the patient, combing the hair, bathing the face, resorting to warm pediluvia, etc. I have known muscular exercise carried to the point of fatigue to be useful. Alimentation is highly important. The patient should be encouraged as much as possible to take nutritious and easily-digested food.

It is the duty of the physician, after recovery from this disease, to inform the patient of its character, and to point out the inevitable consequences of the habits which have induced it; and the patient will be aided in an effort to emancipate himself from the slavery of intemperance by remedies and hygienic measures which tend to invigorate the body, thereby strengthening the mental powers.

A craving for alcoholic excitation is a result of habit. It is sometimes induced by dyspeptic disorders, mental depression, or a sense of prostration incident to various diseases, and it is sometimes a constitutional idiosyncrasy. The power to resist it is impaired in proportion as the faculties of the mind are weakened by indulgence. It can be overcome only by sufficiently long-continued total abstinence, together with measures to remove disorders and to promote mental occupation and invigoration of body and mind. There is no drug which has a special curative efficacy. Persuasion, the fear of consequences, and moral considerations are often unavailing. The unhappy slaves of intemperance should be considered as suffering from disease, and should be

treated as patients until the morbid craving is extinguished by prolonged abstinence. In many instances effective treatment is practicable only in institutions established for this purpose.

The "opium habit" is to be regarded in the same light. Generally, instant and complete withdrawal of every form of opiate is perfectly safe and is the preferable course. Under judicious medical treatment and encouragement patients will be more likely to endure the intense suffering from the sudden disuse of opium than to persevere in a gradual diminution of doses during a period of weeks or months.

[An important contribution to the treatment of alcoholism has been recently made by Dr. T. S. Latimer of Baltimore. His cases, 2012 in number, were treated at the Baltimore city jail. "They were cases of almost continuous drunkenness, culminating at short intervals in a severe debauch, leading to some act of violence or to a condition of drunken stupor in which they were picked up on the streets quite helpless and almost or quite unconscious." Of these "2012 cases of chronic alcoholism with acute explosions, 87 of which were maniacal, under circumstances of the most depressing character all did well without the use of alcoholic stimulants". . . . "All were treated with potassium bromide—the maniacal cases with 30-grain doses every two hours, and the non-maniacal with the same drug and dose at intervals of four hours. No addition was made to this treatment except in three or four cases in which 10 drops of tincture of digitalis and 5 grains of carbonate of ammonia at intervals of three hours were also given; all recovered."

Latimer's patients were immediately and absolutely deprived of alcohol, the result being in no instance injurious. He therefore logically concludes that the symptoms of delirium tremens are the result of over-stimulation, and that they are not due to the abrupt withdrawal of stimulants. None of the patients were bound or subjected to any physical restraint beyond that attendant upon their being locked in their cells. They spent their time in incessant walking, and the physical fatigue thus excited appeared to induce sleep earlier than would otherwise have occurred. Another advantage of non-restraint is that patients who are bound and at the same time left entirely alone experience a degree of terror far greater than is the case with those whose limbs are unconfined.—H.]

Hypochondriasis—Pathophobia.

Although hypochondriasis belongs in the list of disorders of the mind, the mental aberration is not regarded as amounting to insanity, and patients with this affection are not proper subjects for treatment at lunatic asylums. Cases are not infrequent, and they claim the services of the general practitioner. In view of these facts, it is appropriate to consider the affection as one of the neuroses. The name hypochondriasis—which from its derivation is supposed to have reference to morbid sensations sometimes felt in the hypochondriac regions—has very little significance as indicating the character and seat of the affection. The names pathophobia and nosophobia are much more expressive of the malady.

The characteristic feature of the affection is a morbid apprehension of either the existence of, or a liability to, some serious disease. In its mildest form it consists of a feeling of extreme delicacy of constitution or of a peculiar susceptibility to the causes of disease. Existing in this form, it leads to an anxiety concerning health and over-precautions for its preservation. In the severest form of the affection patients suffer from the conviction that they have an incurable malady and that life is in imminent danger. Different

cases represent gradations between these extremes. The mental depression or despair which may be produced by a knowledge of the fact that a serious or fatal disease actually exists does not constitute hypochondriasis. The hypochondriac is the victim of a delusion with respect to his condition; and the mental suffering arising from this error of belief often exceeds that which would be likely to be experienced if the fancied disease really existed. Generally, the hypochondriacal delusion is accompanied by more or less mental depression, and often by marked melancholia, but in some cases patients are resigned and cheerful. Fancied diseases are sometimes the occasion of profound religious sentiment, calling forth the manifestations of pious resignation.

The affection is presented to the practitioner in different phases. In some cases the imagination becomes fixed upon a particular disease, and the patient's belief in the existence of the disease defies all efforts to remove it. Disease of the heart, pulmonary consumption, cancer, syphilis, tapeworm, softening of the brain, and diabetes are among the diseases which in different cases are supposed to exist. The physician may strive in vain by assurances and arguments to dispossess the mind of his patient of the delusion. In support of his conviction the patient sometimes not only exaggerates ailments which are present, but insists on the presence of symptoms which are wanting. The pertinacity and ingenuity with which in some cases patients hold to their faith and strive to convince the physician of its truth are remarkable. Not infrequently the conflict between the physician and patient continues until it becomes intolerable, and each is well pleased to break off the professional relation. Hypochondriacs frequently consult many physicians in succession, finding for a time greater attention and apparent interest in a new medical adviser; and, naturally enough in their mental condition, they become dissatisfied when the patience of the physician becomes exhausted and they have given up all expectation of converting him to their belief. The absurdity of the delusion in some instances is truly surprising. I have known two cases in which the patients, women of intelligence and good sense, for a long time could not be persuaded that they were not affected with cancer of the breast, although nothing was to be seen or felt to give color to the delusion. It is a noteworthy fact that hypochondriasis is not confined to the weak-minded. Persons of education and strong mental powers are as liable to the affection as those who are ignorant and of feeble intellectual capacity.

In another phase of the affection there is not a fixed belief in the existence of a particular disease, but a shifting of the delusion from one disease to another. The physician may succeed in convincing the patient of the non-existence of an imagined disease, but no sooner is this done than the patient's imagination runs upon another disease, and so divers diseases are in turn imagined, until at length the physician is discouraged and may give up the contest. Again, patients sometimes keep the house and take to the bed, complaining of ill-health, prostration, and various morbid sensations, without selecting any particular disease. With cases of bedridden patients who have no definite malady, but a host of subjective symptoms, all practitioners of much experience are familiar. Such cases occur much oftener among women than among men, and the phenomena embraced under the name of hysteria are generally more or less involved.

The CAUSES of hypochondriasis are physical and mental. Some persons are constitutionally liable to morbid apprehensions in this direction. Whenever they are ill with any affection, their mental constitution leads to a sense of danger and to despondency as regards recovery. Not infrequently this state of mind exerts a depressing influence which may interfere seriously with the favorable progress of disease. Persons thus unhappily constituted are likely

to exaggerate the permanent consequences of dissipated habits in early life, specially abuses of the sexual function. Delusions with respect to the latter are fostered by publications and lectures designed by unprincipled persons to produce this effect. Apprehensions on this score, often with little or no foundation, are a source of nefarious profit to a host of charlatans. If a person with a hypochondriacal predisposition either have had or imagine that he may have had syphilis, he is liable to fall into the belief of supposing that his system is irretrievably ruined. This delusion also is encouraged by empirics whose business is to prey upon the fears which they foster and excite. There is a class of wretched hypochondriacs whose minds are absorbed with the idea that they are the hopeless victims of the thoughtless errors of youth, and patients of this class, much as they are to be pitied, often tax severely the temper of the physician. It is to be added that the practice of masturbation, excessive sexual indulgence, and the intemperate use of alcoholic stimulants are undoubtedly sometimes involved in the causation, not merely by an effect upon the imagination, but by contributing to produce a morbid condition of the nervous system.

The reading of legitimate medical works is to be mentioned among the causes of hypochondriasis. Want of mental occupation contributes indirectly to the affection. Persons who have relinquished active pursuits often become hypochondriacs. Success in the acquisition of wealth, when it leads to a determination to forego labor and to enjoy leisure, may thus engender a far greater evil than poverty. On the other hand, the loss of fortune or want of success in the pursuits of life, and severe affliction of any kind, are sometimes concerned in the causation of this affection. These various causes may produce the affection in those who are not, as well as in those who are, constitutionally predisposed to it; but of course their efficiency will be marked in proportion as the predisposition is strong.

The morbid physical conditions often existing in cases of hypochondriasis, and more or less concerned in its causation, are various. Among these may be mentioned anæmia, neurasthenia, and dyspeptic disorders. The latter, there is reason to believe, are frequently, to a considerable extent, effects of the morbid condition of the mind.

The DIAGNOSIS of hypochondriasis must rest on an exclusion of the maladies which are apprehended or imagined and of any serious disease. The different organs of the body are to be interrogated by means of symptoms and signs; and it is obvious that the accuracy of the diagnosis will depend on the ability of the physician to exclude the affections to which the different organs are subject. Subjective symptoms are to be admitted with circumspection and a certain amount of distrust. The incongruity of the previous history and the present condition, as described by the patient, with the laws of any definite disease, exclusive of mental disorder, is often at once significant of the affection under consideration, or the subjective symptoms are incongruous with the physical disorders which may be associated with the hypochondriasis. From want of sufficient knowledge or skill to reach the diagnosis by exclusion practitioners are sometimes misled by the statements of patients, and thus contribute unwittingly to establish more firmly existing delusions.

In a certain proportion of the cases in which some serious disease is either apprehended or imagined the positive assurances of the physician suffice to dispel the delusion. In this way the physician who is confident in his ability to interrogate accurately the different organs of the body has the power of doing much good. The fear of the existence of some grave disease oppresses specially those who are dependent for the means of living upon a certain

measure of health; and a decided opinion, in which they have confidence, is a great blessing to patients of this class.

In cases of confirmed hypochondriasis the first object with reference to **TREATMENT** is the removal of any supposed causes. Over-exertion, mental or physical, is to be avoided if possible; and sexual abuses, intemperance, and any violation of the laws of health are to be inquired into and reformed. Aside from the casual indications, the measures of treatment relate to both body and mind. Any coexisting physical disorders are to be remedied as far as practicable. Anæmia and dyspeptic ailments often claim remedial measures. In addition to the physical operation of remedies, they undoubtedly have a useful moral effect within certain limits. Patients often crave remedies, and it is important not to encourage this disposition; but it is often not judicious to withhold remedies altogether, even when the medicinal part of the treatment is comparatively unimportant. Alcoholic stimulants and opiates should not be prescribed, or if indicated for a temporary object they should be given with great circumspection.

The most important part of the treatment is that which relates to the mind. Arguments, assurances, and combined medical opinions may be brought to bear upon the delusions with more or less effect. It is, however, not always judicious to act upon a determination that the patient shall be at once reasoned out of the affection. It is not wise to attempt to dispel the delusions by ridicule or indifference. A fundamental part of the moral management is to divert the patient's attention from himself. This is to be effected by inducing occupation if the patient have been living a life of indolence, and by well-selected recreations if the patient be of industrious habits. It is more difficult to effect this in cases of hypochondriasis among women than among men. Change of scene and new associations are often effectual, and, wherever practicable, should be advised. With respect to the particular plans to be pursued in different cases, the habits, intelligence, education, and social position are to be considered in each case, and the success of the treatment will depend much on the judgment and tact of the physician.

CHAPTER X.

VASO-MOTOR AND TROPHIC NEUROSES.

Progressive Unilateral Facial Atrophy.—**Scleroderma.** or **Sclerema.**—**Myxœdema.**—**Actinomegaly.**—**Raynaud's Disease.**—**Symmetrical Gangrene.**

Progressive Unilateral Facial Atrophy.

In this rare disease the muscles are not primarily nor chiefly affected, but the atrophy begins at the surface and progresses inwardly, involving the bones as well as the soft parts. The skin is discolored and thinned. The beard, eyebrows, and hair on the affected side become white and often fall out. The subcutaneous fat disappears. The muscles are more or less atrophied, but in a less degree than other structures. The bones and cartilages are atrophied. The atrophy may extend to the tongue on the same side and also to the palate and uvula.

The disease occurs in women much oftener than in men, and very rarely after twenty-five years of age. The left much oftener than the right side of the face is affected.

The contrast between the two sides of the face renders the recognition of the disease easy after it has made considerable progress. It cannot be confounded with facial paralysis, inasmuch as drawing of the mouth to the opposite side is slight or wanting, and the muscular movements are not lost on the affected side.

The disease usually progresses very slowly. In all other respects the patient may be perfectly well.

The pathogeny is undetermined. It is yet to be settled whether the disease be primarily seated in the affected tissues or whether the atrophy be secondary to a neurotic affection. If the neurotic or trophic theory be adopted, it is not settled to what particular nerve or nerves the disease is to be referred. The trifacial, the facial, and the cervical sympathetic have each been supposed to be especially involved. [One of the rare autopsies in cases of hemiatrophia facialis was recently (1888) made by Mendel, who found atrophic changes in the descending root of the trigeminus.—H.]

The disease thus far has proved intractable to treatment. An arrest of the progress is all that can be hoped for. It must be expected that the lesions which have taken place will be permanent. The progress of the disease does not endanger life, but the conspicuous deformity is not a small calamity.

Scleroderma, or Sclerema.

The affection called scleroderma or sclerema, also sclerodermia and scleremia, may be here noticed, as it is analogous, in its pathological character and in certain of its effects, to the disease just considered. Other terms than those already given have been applied to it—to wit, scleremus, scleria, sclerosis, scleroma, and sclerymus, all derived from the Greek word *σκληρος* (hard). Its anatomical characteristic is the production, in the lower portion of and beneath the skin, of dense fibrous tissue in great abundance. This renders the integument notably rigid and resisting to pressure. It is closely adherent to the muscles. It cannot be moved over the muscle or pinched up in folds. The muscles are restrained in their movements by the density of the structures above them, as if a firm bandage were closely applied. More or less wasting of the muscles is caused by the pressure. Pigmentary matter is in most cases deposited in the cells of the rete mucosum, producing a discoloration which is yellowish, yellowish-gray, or dark-brown, and more marked in some situations than in others. These changes may be either limited to certain parts or diffused over the whole surface, but they vary in amount in different places.

The affection is extremely rare. A case under my observation was reported by Dr. Walter De F. Day in the *American Journal of Medical Sciences*, April, 1870. Dr. Day was able to collect for analysis reports of only 33 cases, and the case reported by him was the seventh on record in which there was an examination after death. The affection is not to be confounded with that called by some writers acute sclerema, which is peculiar to infants. The latter is a variety of œdema. The affection under consideration occurs generally in middle life. It occurs much oftener in women than in men. It is a chronic affection, usually beginning insidiously and progressing slowly, but exceptionally it may be developed rapidly with a sudden invasion. The upper part of the body is oftenest first affected, but it may appear primarily in any part.

The affection is not necessarily associated with disease of any of the internal organs, and if uncomplicated it is not incompatible with good general health.

Existing in a notable degree, it obstructs muscular movements by mechanical pressure and restraint, leading at length to more or less impairment of motor power, by inducing atrophy. The surface is usually cool or cold, but the heat at times may be greater than normal. Sensibility is not impaired, and perspiration continues. The duration is variable. It may continue for months and years. A fatal termination is due to some complication or intercurrent affection. It continues in some cases indefinitely without improvement, and in other cases more or less improvement takes place without recovery, but complete recovery may be hoped for. The number of cases reported is, as yet, too few to determine the ratio of recoveries.

Various measures of TREATMENT were employed in the cases which have been reported. It remains to be ascertained what are the remedies, if there be any, which exert a curative effect. In the case under my observation arsenic was given for some time, and it seemed to be of service, but in this case there occurred grave complications—namely, pleuritis, pericarditis, and peritonitis. An analeptic course and tonic medication are rationally indicated, together with alkaline baths and emollient applications to the skin.

Myxœdema.

This remarkable affection, which was first described in 1873 by Gull, received the name myxœdema from Ord, to whom we owe the most complete study of the disease which has hitherto been made. The disease is characterized by an infiltration of the connective tissue of the body with a gelatinous fluid containing mucin.

Nothing is positively known concerning the CAUSATION. The disease has been observed more frequently in women than in men. It occurs in adult life, rarely at any other period. In a certain number of cases it has followed pregnancy. Mental distress has been thought by some writers to be an element in its causation. The disease seems to be more common in England and in France than elsewhere. In this country only a few cases have been reported.

But little is accurately known of the MORBID ANATOMY. In the few post-mortem examinations which have been made the connective tissue of the skin and the subcutaneous tissue are richly infiltrated with a jelly-like material containing mucin. According to Ord, the fibrillar and cellular elements of connective tissue are increased. This mucous infiltration and new growth of connective tissue are not confined to the skin, but they affect the mucous membranes, the glands, the muscles, the nervous system, and, above all, the outer coat of the arteries. The thyroid gland has been found atrophied, a condition also observed during life in many cases, but not in all. In the late stages of the disease the cortical substance of the kidneys is atrophied—a condition which may be secondary to the changes in the arterial walls.

The peculiar œdema begins generally in the face, producing a characteristic physiognomy. The eyelids, the lips, the *alæ nasi*, the cheeks—in fact, all of the features—are swollen. The œdema which causes the swelling differs from ordinary œdema in its firmness and resiliency. It does not pit on pressure and does not gravitate. The face acquires a dull, expressionless appearance, with an absence of all the finer lines of the features. The œdematous skin has an anæmic, alabaster-like appearance, with the exception of the cheeks, which present reddish spots or a more diffuse dull pinkish hue.

Next to the face, the hands are most markedly affected with the mucous œdema. They become swollen and shapeless, an appearance which has been described by Gull as “spade-like.”

The same condition as that affecting the face and the hands may extend over the whole body, so that the skin everywhere is swollen.

The skin is usually dry and rough in consequence of the absence of perspiration.

As already remarked, in a large proportion of cases the thyroid bodies are atrophied. Ord mentions also the occurrence of tumefaction, with marked resilience of the skin, just above the clavicle.

In the majority of cases there are nervous symptoms no less characteristic than the mucous œdema. For a long time these symptoms consist only in a progressive hebetude affecting all mental and physical actions. The mental processes are slow and labored, but they may be for a long period correct. Speech is slow and conducted with a monotonous, and often hoarse, voice. All muscular movements require a long time in their execution, and they are often attended with a slowness of co-ordination which may suggest ataxia. Sensation is normal, save a certain tardiness in perception.

After a time mental aberration is likely to appear, and this is manifested in various forms of insanity attended with hallucinations.

Ord speaks of the frequent occurrence of two subjective symptoms referable to the special senses—namely, a persistent unpleasant taste and a persistent unpleasant smell. In some cases the occurrence of salivation has been noted.

The hair often falls out, and the teeth frequently decay. The appetite may be normal, but after a time it is generally disturbed. There is usually anæmia, which may be very profound. Albuminuria is common only in the later stages of the disease. The bowels are generally constipated. There is not only a subjective sensation of coldness, but the temperature of the body is actually lowered, ranging from 94° to 98°. Sometimes there is a difference in the surface-temperature of the two sides of the body.

The DURATION of the disease is long, varying between three and twenty years or more. The prognosis is unfavorable, but instances of improvement are not uncommon, and cases of recovery have been reported. Death may be due to gradual exhaustion, to uræmia, or to some complication. Bulbar paralysis has been observed as a complication.

There are various theories as to the nature of the disease, but they are all very hypothetical. A plausible assumption is that myxœdema is due to some trophic nervous disturbance; but attempts to define the nature of the tropho-neurosis have not been successful. Some have surmised disease of the sympathetic system, others disease of the medulla oblongata.

Of considerable interest is the possible relation between myxœdema and atrophy of the thyroid gland. The facts bearing upon this relation are as follows: Extirpation of the entire thyroid gland in human beings for goitre has in some cases been followed by a peculiar cachexia, with mental disturbance, and even with firm œdema. This cachexia has been called *cachexia strumipriva*. The extirpation of the entire thyroid gland in dogs is nearly always fatal. Horsley has produced by the extirpation of the thyroid gland in monkeys profound anæmia and an œdema similar to myxœdema. The affection known as cretinism bears some resemblance, particularly in the mental symptoms, to myxœdema, and cretinism seems to be in some way connected with disease of the thyroid gland. Finally, myxœdema is often associated with atrophy of the thyroid gland.

[The fullest investigation of the subject of myxœdema was made by the Clinical Society of London in 1888. Their report, which is based upon an analysis of 109 cases, concludes as follows: "Finally, it may be stated that there is strong evidence that myxœdema, sporadic cretinism, endemic cretinism, cachexia strumipriva, and the operative myxœdema of animals are

severally species of one genus; that such clinical differences as exist between them are due to causes already sufficiently set forth; and that the one pathological fact common to all these conditions is the occurrence of morbid processes or of operations involving the annihilation of the function of the thyroid body."

It is not yet settled exactly how atrophy or ablation of the thyroid gives rise to myxœdema. In explanation of the pathogeny of the disease two theories have been advanced. In accordance with the first, the thyroid gland elaborates some material which is essential to the healthy metabolism of the tissues, and especially to those of the nervous system; according to the second, the gland eliminates from the blood one or more substances which are noxious to the organism, and especially to the nerve-tissues.

TREATMENT.—It is of the utmost importance to protect the patient from cold. With this object in view, removal to a tropical climate should be recommended. The influence of cold in accelerating and that of heat in retarding the development of myxœdema is well shown by the results of two series of experiments (total excision of thyroid) upon monkeys by Victor Horsley. "In the first series no special after-treatment was carried out, and the average duration of life after the operation was twenty-four days. In this series the symptoms characteristic of *acute* myxœdema developed. In the second series of experiments special precautions were taken to keep the animals warm: after excision of the gland they were kept at a temperature averaging 90° F. The average duration of life in the second series was 125 days. In this series the symptoms characteristic of *chronic* myxœdema were developed."

Hot baths, friction, and general massage have been of marked benefit in several carefully-observed cases. A remarkable case is reported by Dr. John Thomson¹ of Edinburgh, in which recovery from an apparently hopeless condition was brought about by the systematic employment of hot baths, friction, and prolonged exposure of the body to the heat of an open fire. Jaborandi and its alkaloid pilocarpine are the only drugs from which benefit seems to have been derived. The committee of the London Clinical Society speak of their beneficial influence in myxœdema as undoubted, and attribute it to their action on the functions of the skin.

In 1890, Prof. Victor Horsley suggested that myxœdema be treated by transplantation of the thyroid of a healthy sheep into the subcutaneous tissues of the patient. This suggestion was first carried out by Lannelongue of Paris; later by Walther of the same city, and by Fenwick, Collins, Harris, Wright, and Macpherson of Great Britain. In Fenwick's case death occurred five days after the operation, the disease having been too far advanced for a fair trial of any kind of treatment. Of the remaining six cases, there are but four in which the progress of the patient after the operation was recorded. Of these four, in two there was a more or less prolonged period of improvement, while in the other two the improvement was only temporary.

The treatment of myxœdema with hypodermic injections of thyroid extract was first employed by Dr. George Murray, a pupil of Horsley. Murray, observing the rapid improvement which follows the transplantation of the thyroid, concluded that it must be due to the absorption of thyroid juice remaining in the gland, rather than to a secretion of the latter in its new and abnormal situation.

Up to May 18, 1893, according to Beadles,² 100 cases of myxœdema had

¹ *Trans. Medico-Chirurgical Society of Edinburgh*, vol. vii. p. 50.

² *Journal of Mental Science*, July and October, 1893.

been treated by Murray's method or some modification of it, and, with the exception of two cases, they have all been followed by remarkable improvement.

The next step in the therapeutics of this disease was the administration of the thyroid *per os*, and it appears to have been first taken by Prof. Howitz of Copenhagen, who, in March, 1892, fed a myxœdematous patient with the thyroid glands of calves. Four months later, Dr. Hector Mackenzie employed this method of thyroid feeding, with the result that in less than three months the patient subjected to it had improved to such an extent as to be "scarcely recognizable." The thyroids in the last-mentioned case were pounded and given in a little brandy. An extract of the thyroid and a substance called thyroïdin, obtained by precipitation with alcohol from the glycerin extract of the finely-minced gland, have also been administered, and apparently with results equalling those obtained by the ingestion of the crude gland itself.

This treatment, successful though it be, has one drawback: it must be kept up indefinitely. No sooner is the thyroid treatment withheld than the patient shows signs of relapse. As remarked by Beadles, however, "the taking of an occasional dose is surely a hardship not hard to bear, even were it necessary for the remainder of the patient's life."

The various methods thus far employed in the treatment of myxœdema are the following:

1. Thyroid grafting.
2. Subcutaneous injection of an extract of the thyroid gland.
3. Ingestion of an extract (aqueous or glycerin) of the thyroid gland.
4. Ingestion of thyroid gland, raw or slightly cooked.
5. Ingestion of a dry extract obtained from the thyroid gland, in the form of a powder, tabloid or capsule, or pill.
6. Ingestion of thyroïdin.

In this country the treatment of myxœdema with thyroid preparations has been carried out by F. P. Kinnicutt, J. J. Putnam, M. Allen Starr, and doubtless by many others.¹—H.]

[Acromegaly.

Acromegaly (derived from *ἄκρον*, extremity, and *μέγα*, large), first minutely described and named by Marie in 1886, is a dystrophic affection characterized by enlargement of peripheral portions of the body. The parts chiefly affected are the feet, hands, and face, and the enlargement is principally caused by hypertrophy of the osseous tissues. The facial alterations are so characteristic that patients affected with this disease, no matter what their nationality, come to bear an extraordinary resemblance to each other. The alterations consist, for the most part, of hypertrophy of the nose and inferior maxilla. The former is enlarged in all its dimensions, and each constituent of the organ—the bones, the cartilages, and the derma—takes part in the hypertrophy. Even the walls of the blood-vessels are thickened, the lymphatics dilated, and the mucous membrane œdematous and infiltrated with leucocytes. It is the hypertrophy of the inferior maxilla which is chiefly concerned in giving the face its characteristic expression. The bone is enlarged in all its dimensions, sometimes to such an extent as to entitle it to be called colossal. The distance from the angle to the symphysis is increased (in a case reported by C. L. Dana it measured 5½ inches), so that in well-marked cases the lower lip and teeth project beyond the upper—prognathous type. The downward slope of the ramus is also greater than normal; or, in other words, the angle formed by the body and ramus is more than normally obtuse.

¹ Vide *Trans. Association of American Physicians*, vol. viii., 1893.

Macroglossia is a condition common to all well-marked cases, the enlargement of the tongue being chiefly due to hypertrophy of the interfascicular connective tissue.

The first signs of acromegaly generally appear in the hands, which become hypertrophied in the directions of breadth and thickness rather than in length. All the tissues of the hand—the bones, muscles, connective tissue, and skin—participate in the enlargement, but there is no deformity of the phalangeal joints. The nails do not enlarge correspondingly, and therefore appear abnormally small. They are flattened and widened and often marked with longitudinal striations. The feet are affected in the same manner as the hands—that is to say, they are enlarged chiefly in the directions of breadth and thickness. Cases are now and then met with in which the feet and hands are enlarged as to length also. The enlargement of the hands is perhaps the most striking feature of the disease, and is often so great as to cause them to be compared to spades and “battledores.” Dorso-cervical kyphosis is a constant symptom, and is sometimes so great as to cause the chin to project forward and downward so as to approach the sternum or even to rest upon it. There is generally combined with this antero-posterior curvature a certain degree of scoliosis, as well as a compensatory lordosis in the lower dorsal and upper lumbar regions.

The bones of the chest, clavicles, scapulæ, ribs, and sternum are all hypertrophied, and the same is true of the costal cartilages. The antero-posterior diameter of the thorax is enlarged, apparently at the expense of its transverse diameter, and the downward slant of the ribs is increased, so that when the patient is sitting with the head bent forward the lowermost of these bones may rest upon the crest of the ileum.

In most cases the thyroid gland is diminished in size, but has also been found enlarged. The thymus is sometimes persistent or enlarged, and in either case gives rise to percussion-dulness in the upper sternal region.

A long list of symptoms is referable to the nervous system, and may be classified as cerebral, vaso-motor, and sensory. Among them may be mentioned polydipsia, polyuria, glycosuria, hyperidrosis, cutaneous anæsthesia, and loss of the senses of taste and smell. Disturbances of vision, especially in the form of hemianopsia, have been frequently observed. In women the menses are suppressed at an early period of the disease, and sterility is absolute. Duchesneau¹ queries whether this may not explain why heredity is so little concerned in the etiology of the affection. In males diminution or extinction of sexual desire is the rule. Trophic disturbances of the skin in the form of keloid growths or molluscum fibrosum have been observed too frequently to be regarded as mere coincidences. The appetite is generally preserved and is sometimes voracious. One of Dana's patients² “ate twenty-seven plates of ice-cream at one sitting, thereby winning a wager that he could eat more than two men.”

Of the subjective symptoms above mentioned, cephalalgia is undoubtedly the most constant, and is often the sole thing complained of. In a typical case reported by Marie³ the patient travelled from Spain to Charcot's clinic on account of persistent headache. He appeared to attach no importance to the abnormal increase in size of his hands and feet, the deformities of his spine and thorax, and the marked alterations in his physiognomy. In this case the cephalalgia which was the sole complaint came on two or three hours after the patient had fallen asleep in the recumbent position, but did not supervene when he slept in the sitting posture.

¹ *Contribution à l'Étude de l'Acromégalie*, Paris, 1892.

² *Journal of Nervous and Mental Disease*, Nov., 1893.

³ *Nouvelle Iconographie de la Salpêtrière*, tome i., 1888.

The changes in the muscular system are worthy of notice. It is highly diagnostic of the disease that, with enormous hands, deep chest, and other signs usually indicative of strength, the patient is decidedly feeble. This muscular feebleness increases until, in late stages of the disease, he may be compelled to remain in bed from this cause alone. This muscular inability is caused by progressive atrophy.

ANATOMICAL ALTERATIONS.—Besides the enlargement of the bones and overlying parts above mentioned, the persistence of the thymus, the alterations of the thyroid, the macroglossia, and the deformities of the spine, there remains to be mentioned a lesion which is believed by Marie and others to be concerned in the pathogenesis of the disease. The lesion referred to is hypertrophy of the pituitary body, or, as some prefer to call it, the hypophysis cerebri. This so-called gland, which normally weighs but a few grains (from five to ten), has been found in cases of acromegaly as large as a hen's egg, and even larger. Enlargement of this body occurs far too frequently to be regarded as fortuitous. Souza-Leite in his classical thesis speaks of it as constant, but in rare cases it has been absent. On the other hand, hypertrophy of the hypophysis has been observed without coincident acromegaly. On the whole, it must be admitted that there is an intimate connection between enlargement of the hypophysis cerebri and acromegaly, and the question, as yet undetermined, is whether the former is a cause or a consequence of the latter. Marie draws a parallel between disease of the hypophysis and acromegaly on the one hand and disease of the thyroid and myxœdema on the other.

DIAGNOSIS.—The only affection with which acromegaly is likely to be confounded is that to which Marie has given the name of hypertrophic pulmonary osteo-arthritis ("ostéo-arthropathie hypertrophique pneumique"). James Ross¹ does not recognize the distinction drawn by Marie between them, but to the writer they seem to be separate conditions. In pulmonary osteo-arthritis the jaw is not enlarged; kyphosis is not constant; the fingertips are swollen and bulbous, and the nails curved like the beak of a parrot; and, finally, the articular ends of the long bones are enlarged to such an extent as to impede the movements of the extremities. As implied by the adjective "pulmonary," these deformities are associated with lesions of the respiratory organs—the lungs and pleura. The points of distinction between osteitis deformans (Paget's disease), leontiasis ossea, and gigantism are obvious. Until quite recently acromegaly was unrecognized. The present tendency is to include under this head affections which bear to it but a partial resemblance, such as circumscribed osseous hyperplasias and gigantism. The former are congenital and generally unilateral, while in the latter the different parts of the body preserve their relations to each other.

PROGNOSIS.—The prospect of recovery from the outward manifestations of the disease is hopeless. The osseous changes are irremediable. Life may, however, be prolonged for years, the patient eventually succumbing to progressive asthenia or dying more suddenly with signs of cerebral compression. The powers of resistance to intercurrent acute disease are, as a matter of course, greatly impaired.

TREATMENT.—Little is to be said under this head. Antipyrin, exalgine, and caffeine have been used with more or less success to relieve cephalalgia. The strength is to be maintained by a nourishing diet—in some cases, per-

¹ *International Clinics*, April, 1891.

haps, by restraining the tendency to boulimia. Duchesneau, acting on the hypothesis that the disease may be due to suppression of the function of the hypophysis cerebri, suggests the hypodermic injection of extracts of this "gland."—H.]

[Raynaud's Disease—Symmetrical Gangrene.

This affection is characterized by extreme pallor and coldness of peripheral portions of the body—fingers, toes, nose, ears—on exposure to cold, followed by intense venous congestion of the same parts, and eventually, if the circulatory disturbances continue, by well-defined areas of dry gangrene. The above are the essential clinical features of the disease, but, in addition, hæmoglobinuria and scleroderma have been observed in a few cases. The affection was first described by Maurice Raynaud in 1862 in a thesis containing a report of 25 cases, of which 20 were of the female sex. The disease is most prevalent in early life, the great majority of Raynaud's cases occurring between the ages of eighteen and thirty. The same observer also noted 5 cases of the affection in children between three and nine years of age. He has therefore suggested the term "juvenile gangrene" as an appropriate name for the disease, but it will doubtless continue to be called by the name of him who first accurately described it. The term juvenile gangrene is further inapplicable because it might be supposed to imply that the affection is limited to the young. This, however, is far from being true. In two typical cases now under the writer's observation the ages of the patients are fifty-five and seventy-seven respectively. The chief theories of the cause of Raynaud's disease are (1) that it is due to an endarteritis obliterans; (2) that it is due to peripheral neuritis; (3) that it is the result of vascular spasm. The last is the theory of Raynaud himself.

The early age of many of the cases, the intermittent character of the symptoms, and the great rarity of the disease as compared with endarteritis suffice to exclude the latter as a causative factor in its production.

There is little to support the theory that peripheral neuritis is the cause of Raynaud's disease. In the first place, the rarity of the latter and the frequency of the former militate strongly against it. Secondly, the cases in which neuritis has been found post mortem may be examples of mere coincidence, or, more probably, the neuritis is secondary to the local circulatory disturbance. A degree of asphyxia sufficient, in its severer forms, to produce gangrene might, in its lighter grades, readily lead to degenerative and inflammatory changes in the nerves of the affected part.

The theory of arteriole spasm is certainly the one which is most in accordance with the clinical phenomena. The disease is most frequently observed in females and in the young—i. e. in those whose vaso-motor system is most impressible. It occurs in paroxysms, and is excited by exposure to the surest exciter of vascular spasm—cold. Finally, in several cases, during the paroxysm there has been dimness of vision which was shown by the ophthalmoscope to depend upon a contraction of the central retinal artery and its branches. This, more than any other observation, tends to corroborate Raynaud's view that the disease known by his name is due to an "enormous exaggeration of the excito-motor energy of the gray parts of the spinal cord which control the vaso-motor innervation." The symptom hæmoglobinuria is in all probability due to a "local asphyxia" of the renal vessels.

The SYMPTOMS consist of pallor and coldness, both subjective and objective, of the affected parts, constituting the stage of *local syncope*. This is

mediately followed by the stage of *local asphyxia*, characterized by lividity and cyanosis of the same parts accompanied with paræsthesiæ, such as numbness and tingling, or with severe pain. Ecchymotic spots and vesicles may appear and may become the starting-points of dry gangrene. The uricle is a favorite site of the latter, but it may also attack the fingers and toes and cause the loss of one or more phalanges. The lesions, whether vascular or gangrenous, are remarkable for their symmetry. Hæmoglobinuria has been already mentioned as a symptom of the disease, and it must be acknowledged that it is difficult, if not impossible, to draw a line of demarcation between certain cases that have been described as examples of paroxysmal hæmoglobinuria and genuine cases of Raynaud's disease.

DIAGNOSIS.—Genuine cases are distinguished by the presence of the two stages above mentioned—"local syncope" and local asphyxia—followed sooner or later by gangrene. The latter may be limited to a sphacelus scarcely larger than a pin-head on one or both ears. Large areas of spreading gangrene dependent upon endarteritis obliterans or following an injury are not to be included in the category of Raynaud's disease. Neither are cases of mere local syncope of the hands—the so-called *digiti mortui*. As is well known, the latter symptom is occasionally seen in Bright's disease, and is caused by a vascular spasm which is trivial when compared with the tonic contraction of the vessels in Raynaud's disease.

PROGNOSIS.—Notwithstanding the apparent gravity of its symptoms, the affection is not *per se* a dangerous one. As remarked by Raynaud, the system in the course of time seems to acquire a species of tolerance (*accoutumance*) of the disease.

TREATMENT.—Exposed parts of the body should be protected from cold and woollen underclothing should be worn the year round. If the patient's means permit, the winters should be spent in a warm climate. Exposure to the morning air before breakfast should be carefully avoided in all climates. Raynaud in his later researches¹ reports good results from the continuous electrical current applied to the spine and extremities. "The action exercised by the current on the cord appears to consist in an enfeeblement of the reïto-motor power, whence there results a corresponding relaxation of the flex vascular contractions."—H.]

SECTION SIXTH.

DISEASES AFFECTING THE GENITO-URINARY SYSTEM.

CHAPTER I.

CONGESTION OF THE KIDNEYS.—ACUTE AND CHRONIC BRIGHT'S DISEASE.

Active Congestion of the Kidneys.—Passive Congestion of the Kidneys.—Parenchymatous Degeneration of the Kidneys.—Fatty Degeneration of the Kidneys.—Acute Bright's Disease.—Chronic Bright's Disease.

A LARGE proportion of the affections of the genito-urinary system do not fall within the scope of this work. Excluding the affections peculiar to females, diseases of the male generative organs and of the bladder are to be excluded as belonging to surgical rather than to medical practice. The diseases which remain are chiefly those affecting the kidneys. Abnormal changes in the urine are highly important as denoting morbid conditions relating to the kidneys and the blood. These changes constitute important symptoms in various diseases. They are not to be considered as individual affections, and in general it suffices to notice them in connection with other symptomatic events which make up the clinical history of different diseases. In an important disease which, in the present state of our knowledge, it is convenient to regard as a urinary affection, it is certain that the abnormal change in the urine expressed by the name of the disease is merely a symptom. The disease referred to is *glycosuria* or *diabetes mellitus*. This disease will be included among the diseases to be considered in this section. The same statement may probably be applied to the disease distinguished as *diabetes insipidus*, and also to *endemic hæmaturia* and *hæmoglobinuria*.

Active Congestion of the Kidneys.

Active congestion of the kidneys may be due, *first*, to the action of irritants, and *second*, to vaso-motor paralysis. These two forms of active congestion are widely different from each other. The former, when of sufficient intensity to give clinical evidence of its existence, is almost invariably accompanied by inflammatory or degenerative changes in the kidneys; the latter has no tendency to lead to inflammation; the former is accompanied by the excretion of urine similar to that of certain forms of acute nephritis, the urine being albuminous, bloody, and usually diminished in quantity; in the latter the urine is abundant in quantity, non-albuminous, and of low specific gravity.

In the inflammatory variety of active congestion the kidneys are enlarged, of a dark-red color, engorged with blood, and ecchymosed. Certain drugs which exert an irritant effect upon the kidneys are usually assigned as the most important causes of this form of active congestion. Such drugs are cantharides, turpentine, oil of mustard, cubeb, copaiba, nitrate of potash, chlorate of potash, and carbolic acid. Of these drugs, cantharides, taken

either internally or applied externally in the form of a blister, provokes the most marked urinary symptoms. In cantharides-poisoning the urine is diminished in quantity and may be suppressed; it is usually, but not always, stained with blood; it is albuminous, and it may contain hyaline and blood-casts as well as epithelial cells. A peculiarity noted in some cases has been the spontaneous coagulation of the urine. Gelatinous fibrinous clots, either pale or red, may form in the bladder and interfere with micturition, or similar coagula may form in the vessel after the urine is voided. It has been shown by experiments that a true diffuse nephritis is produced by cantharides. It is probable that an inflammatory condition likewise exists when similar symptoms follow the ingestion of the other drugs named. The treatment consists in removal of the cause, rest, and the administration of diluent and of mucilaginous drinks. Camphor in doses of two to five grains will often afford relief.

The existence of vaso-motor nerves of the renal arteries has been demonstrated by physiological experiment. These nerves are contained in the splanchnics. Paralysis of these nerves causes dilatation of the arteries in the kidneys and consequent afflux of a larger amount of blood to these organs. Some also assume the existence of vaso-dilator nerves of the kidneys. It is fully in harmony with the results of physiological experiment that this increased flow of blood through the kidneys is attended by the excretion of a large quantity of pale urine. We may assume that renal hyperæmia due to vaso-motor influence may be produced in man by causes acting upon the peripheral nerves as well as by those acting on the nerve-centres. We possess little positive knowledge as to this variety of renal hyperæmia in man. It has been inferred to exist, from the characters of the urine, in certain diseases of the brain. Hyperæmia of the kidneys from vaso-motor influence is assumed to exist in many cases of diabetes insipidus, of hysteria, and of emotional disturbance.

Passive Congestion of the Kidneys.

Passive or venous congestion of the kidneys is one of the characteristic events in the general venous congestion which attends certain pulmonary and cardiac diseases. Passive congestion of the kidneys may also be caused by thrombosis of the vena cava ascendens, but this occurrence is so rare that it does not demand further consideration here. Thrombosis of one of the renal veins has been observed more frequently, but in the cases hitherto recorded no notable congestion of the kidney has been observed. Passive congestion of the kidney, therefore, may be considered as almost invariably accompanied by general venous stasis.

Pulmonary disorders are less important than cardiac diseases in the etiology. In advanced emphysema and in certain cases of fibrous phthisis there is chronic congestion of the kidneys. The various cardiac diseases which lead to general venous congestion—valvular lesions, fatty degeneration, and myocarditis—are the most frequent and important of the causes. Mitral lesions may be especially emphasized in this connection. It will be remembered that the symptoms of venous stasis do not appear until the stage of non-compensation, and are intense in proportion to the failure of heart-power. It is also important to bear in mind that in proportion as the tension in the veins increases the blood-pressure in the arteries sinks.

The appearances presented by the kidneys after prolonged passive congestion are quite characteristic. The condition is sometimes called cyanotic induration of the kidneys. These organs are usually somewhat enlarged, their consistence is extremely firm, the capsule is non-adherent, and the surface is

smooth. Upon section both the cortical and the medullary substance present a dark bluish-red color, the pyramids being darker than the cortex. The dark-red color and the firm, almost stony-hard, consistence of the kidneys are the most distinctive features. Upon microscopical examination the parenchyma and the interstitial tissue are usually unchanged. Fatty degeneration of the epithelium and increase of the interstitial tissue are found sometimes, but not as a rule.

Chronic passive congestion of the kidneys is accompanied by the symptoms of the primary disease. There are generally evidences of venous congestion in other parts of the body. Edema of the lower extremities is usually present. The only symptoms which can be referred, with any certainty, to the condition of the kidneys are changes in the urine. The quantity of urine is diminished; its specific gravity is increased; its color is darker than normal; it contains a moderate quantity of albumen, and usually some red blood-corpuscles, a few small hyaline casts, and a few epithelial cells. The urine upon standing often throws down an abundant sediment of the urates. According to Bartels, the excretion of uric acid is greater than in health. The amount of albumen is not great, rarely reaching two parts in a thousand. The quantity of blood does not generally suffice to color the urine perceptibly. The small quantity of urine may be referred to the diminished rapidity with which the blood flows through the glomeruli. The albuminuria is attributed, by some writers, to increased blood-pressure in the glomeruli; and by others to changes either in the capillary walls or in the epithelium of the glomeruli in consequence of an insufficient supply of arterial blood. Passive congestion of the kidneys is never a cause of uræmia. The diminished excretion of urine may perhaps increase the general dropsy. The treatment is directed to the primary condition, and not immediately to the kidneys. The indication is to strengthen the force of the heart's action, thereby increasing the arterial tension and relieving the venous stasis. By the administration of digitalis the urinary symptoms are often improved, and they may entirely disappear as the power of the heart's action increases. The reader is referred to the article on Valvular Diseases of the Heart for a consideration of the treatment applicable to the disturbances of the circulation which cause the manifestations of venous congestion.

Parenchymatous Degeneration of the Kidneys, Fatty Degeneration of the Kidneys.

These degenerations occur in the different forms of Diffuse Nephritis, in connection with which they will be again mentioned. Many of the slighter grades of so-called catarrhal nephritis and of parenchymatous nephritis belong, in reality, to the category of these degenerations. The degenerations may occur independently of any inflammation of the kidney, in which case they are generally without much clinical importance. It is desirable not to include under the name of Bright's disease these degenerations when unattended by any inflammation.

The cortical substance of kidneys in the condition of parenchymatous degeneration or cloudy swelling is somewhat swollen and of an opaque grayish color. The surface of the organ is smooth and the capsule is easily detached. The consistence of the kidney is diminished. Upon microscopical examination the epithelial cells of the convoluted tubes are found swollen and filled with albuminous granules which, in considerable part, dissolve in acetic acid. As these cells are normally very granular, it is not easy to detect with the microscope the slighter grades of this form of degeneration. The macroscopical appearances are often more distinctive than the microscopical.

inflammation of the kidney, the most important causes of parenchymatous degeneration are infectious and febrile diseases and certain poisons. Of the first group of causes may be mentioned pyæmia, diphtheria, and the exanthematous and the continued fevers; of the second group, phosphorus, arsenic, antimony, and the mineral acids. Parenchymatous degeneration also follows extensive burns and irritating agents applied to a large surface of the skin.

Fatty degeneration is often combined with parenchymatous degeneration (fatty degeneration). It is a usual sequence when the action of the poison is long continued or intense. In well-marked cases of fatty degeneration the cortical substance is more swollen than in the preceding condition. The enlarged and pale cortex presents yellowish streaks and hemorrhages are usually present in the fatty degeneration of phosphorus poisoning. The microscope shows in the epithelial cells of the convoluted tubules an accumulation of fatty molecules larger and more refractive than the albuminous granules of parenchymatous degeneration, from which they more differ by their insolubility in acetic acid and their solubility after treating the specimen previously with alcohol. Both in parenchymatous and in fatty degeneration the glomeruli are unchanged. The fatty degeneration, in addition to those of parenchymatous degeneration, occurs in anæmic conditions, especially pernicious anæmia and leucocythæmia, especially chronic pulmonary tuberculosis; chronic alcoholism, according to Wilks and Moxon, diabetes. In old age and in obesity a moderate fatty degeneration may be met with. Jaundiced kidneys are likely to be fatty. No attempt is made to discriminate between parenchymatous and fatty degeneration of the kidney. Many of the causes of parenchymatous degeneration are also causes of nephritis.

Parenchymatous degeneration of the kidneys is usually attended by albuminuria. As already remarked, this condition is held by some to be a mild form of acute Bright's disease or to be the first stage of the varieties of that disease. This form of degeneration is transitory, and it readily subsides as its causes disappear. It is not at all the slight albuminuria so often present in simple parenchymatous degeneration of the kidney in reality depends upon these degenerative changes in the renal epithelium. It is perhaps referable in some way to the primary condition which causes the degeneration. It is not that extensive fatty degeneration of the kidney may exist, as in the case of phosphorus-poisoning, without any albuminuria or other appreciable symptoms. These observations justify the separation from Bright's disease proper of these non-inflammatory degenerative changes. In the forms of jaundice of sufficient intensity hyaline casts are present in the urine, often without any albuminuria. It is uncertain whether the presence of these casts have anything to do with changes in the renal epithelium.

Acute Bright's Disease—Acute Diffuse Nephritis.

The memorable researches of Richard Bright, published in 1827, disclose the kidney characterized by albuminuria and general dropsy have been named Bright's disease. It will be seen that the renal changes which characterize the different forms of this disease are various, although not so many as the names which have been proposed for them. Not every case of albuminuria can be considered as one of Bright's disease. We do not include under the name the renal changes which have already been considered in this work, namely, simple parenchymatous degeneration, fatty degeneration,

and hyperæmia of the kidneys—although each of these alterations may form an important element in Bright's disease. These changes are attended either by moderate albuminuria or by none whatever; and if any dropsy be present, this is not referable, as a rule, to the alteration in the kidneys. By almost universal consent Bright's disease is regarded as a nephritis; that is, as an inflammation of the kidneys. This nephritis affects both organs, and is therefore described as diffuse, in distinction from the circumscribed renal inflammations, such as suppurative nephritis. The great majority of cases of Bright's disease are furthermore appropriately called diffuse nephritis, on the ground that all the constituents of the kidneys—namely, the interstitial tissue, the Malpighian tufts, the uriniferous tubes, and the blood-vessels—are involved in the inflammatory process. But the term "diffuse" must not be understood as implying that the morbid process affects the kidney tissue uniformly. Some parts of the kidney are always more diseased than others. Bright's disease is divided into an acute and a chronic form.

Acute Bright's disease has received various names, such as parenchymatous nephritis, acute tubal nephritis, acute desquamative nephritis, catarrhal nephritis, croupous nephritis. These names are all objectionable, as they imply theories concerning the nature of the disease which are either unproven or erroneous. The designation acute Bright's disease is the simplest, and involves no doubtful hypotheses. If it be desired to employ an anatomical term, acute diffuse nephritis is the one least objectionable.

ANATOMICAL CHARACTERS.—The morbid appearances in acute Bright's disease vary considerably in different cases. The kidneys may present so little variation from their normal aspect that the disease can be recognized only by microscopical examination. As a rule, however, these organs are enlarged, moist, and somewhat softened. The surface is smooth, and presents red patches alternating with opaque grayish or yellowish-white portions. The red patches correspond to hemorrhages or to spots of congestion, and the pale portions are either relatively or absolutely anæmic. Upon section the swelling is seen to involve chiefly the cortex, which presents the same mixture of colors. Red points corresponding to congested Malpighian bodies, or more frequently to hemorrhages, are observed. The Malpighian bodies may appear swollen and abnormally pale. In some kidneys the hyperæmic and hemorrhagic portions predominate, and in others the pale opaque appearance prevails. It is thus possible to distinguish red kidneys and pale kidneys of acute Bright's disease, and between these types there is every possible variation. In the majority of cases of acute Bright's disease the kidneys are hyperæmic. If the disease approach a chronic stage, the hyperæmia usually gives place to a whitish or yellowish color, but some hemorrhages usually remain.

Upon microscopical examination the alterations are sometimes found to be astonishingly slight, even when during life the urine was quite albuminous and contained blood and casts. In these cases, which are generally mild and do not terminate fatally from the kidney disease, the inflammatory alteration affects chiefly the capillaries of the glomeruli. These altered capillaries allow the escape of an albuminous fluid and the passage of red and white corpuscles through their walls. These inflammatory products are exuded into the space between the glomerulus and Bowman's capsule, whence they pass into the tubes and escape with the urine. There may be cloudy swelling of the epithelium of the Malpighian tufts and of the convoluted tubes. The interstitial tissue presents no inflammatory changes.

When death occurs from the renal affection itself the changes are generally more marked. Here, too, the affection of the glomeruli is of great importance. To the naked eye the Malpighian bodies often appear swollen and pale.

The capillaries of the glomerulus frequently contain in their meshes desquamated and proliferating endothelial cells mingled with white and some red blood-corpuscles. Both the epithelium of the glomerulus and that lining the capsule of Bowman swells up, proliferates, and, often with an admixture of white blood-corpuscles, forms a crescentic mass of cells filling up the space between the compressed glomerulus and the capsule. These changes constitute the affection called glomerulo-nephritis, which is an important element in many, and almost the sole alteration in some, cases of acute Bright's disease. A similar accumulation of leucocytes and of desquamated endothelium may occur in the intertubular capillaries. The epithelium of the convoluted tubes is swollen and filled with an abnormally large number of albuminous, mixed with some fatty, granules. Colloid drops, granular material, and desquamated and disintegrating epithelial cells are found in some of the convoluted tubes. Hyaline casts are found here and there in the convoluted tubes, and in still larger number in the loops of Henle and the collecting tubes. Emigrated white blood-corpuscles are found not only in the tubes and the Malpighian bodies, but also in the interstitial tissue. In the latter situation they are generally collected in groups, especially around the veins and the Malpighian bodies. In most cases of acute Bright's disease of any severity hemorrhages are present, partly in the intertubular tissue, but chiefly within the capsules of Bowman and within the convoluted tubes.

It is not possible to draw a sharp line of demarcation between the inflammatory and the purely degenerative changes in the kidney. The same causes may produce both changes. As has already been remarked, in most cases of slight or moderate albuminuria attending various infectious diseases the sole change in the kidney is a parenchymatous or fatty degeneration of the epithelium. These cases are classified by many writers as parenchymatous nephritis. If, however, the symptoms, especially the changes in the urine, are during life sufficiently severe to warrant the diagnosis of Bright's disease, it is believed that in addition to these degenerative changes in the epithelium actual inflammatory lesions are present in the blood-vessels, particularly in the glomeruli.

Anasarca and serous accumulations in the pleural, pericardial, and peritoneal cavities are usually met with to a greater or less degree in the bodies of those dead of acute Bright's disease. Sero-fibrinous pleuritis and pericarditis are not infrequent. Pneumonitis, both in the lobar and in the lobular form, is one of the recognized complications. Increase of the cerebro-spinal fluid with cerebral œdema, or even with meningitis, is likewise to be mentioned in the enumeration of complications.

CLINICAL HISTORY.—Subcutaneous œdema is a very frequent but not a constant symptom. It is usually the first symptom pointing to the existence of this affection. The œdema is generally first observed on the face, particularly on the eyelids and around the eyes, but it is speedily apparent in the lower extremities, and sometimes occurs first in the latter situation. Coincident with the appearance of the dropsy is more or less febrile movement, frequently preceded by chills or shiverings, together with thirst, anorexia, pain and tenderness in the loins. Pain and tenderness over the kidneys are, however, rarely marked and are often wanting. Vomiting is a frequent symptom at the beginning of the affection. The skin is dry and the countenance becomes pallid. The dropsy increases and becomes general, varying considerably in amount in different cases. In some cases the anasarca is great, the limbs, scrotum, penis, or external labia becoming enormously swollen. In other cases it does not exceed a moderate amount. More or less dropsical effusion usually takes place into the peritoneal and

the pleural cavity. Hydrothorax sometimes occurs to such an extent as to occasion great suffering from dyspnoea and to endanger life.

The examination of the urine is essential for the diagnosis of acute Bright's disease. The quantity is usually diminished, and it may be very scanty. Suppression sometimes occurs. The specific gravity generally exceeds that of the urine in health. The total quantity of urea excreted in twenty-four hours is much diminished. The urine contains albumen¹ in considerable, and frequently in great, abundance. The amount of albumen is usually between $\frac{1}{4}$ and 1 per cent. by weight, but it may exceed this proportion. In some cases the urine has a reddish-brown, smoky appearance from the presence of blood. A certain number of red blood-corpuscles are present in nearly all cases, although not always in sufficient number to color the urine. It is possible to distinguish two types of urine in acute Bright's disease—the one bloody, and the other free from blood. As a rule, in this disease a considerable sediment forms in the urine. The microscopical examination of this sediment shows red and white corpuscles in varying proportion; and the one variety may be abundant in the absence of the other. The red corpuscles may appear normal or as clear pale rings, or they may be shrunken. Disintegrated red corpuscles and granules of hæmatoidin may be observed. Epithelium of the urinary passages and of the kidneys may be present. Granular matter and micrococci are also among the frequent constituents of the sediment. The most characteristic objects are cylindrical bodies known as casts. These are formed in the uriniferous tubes of the kidney. Casts vary between $\frac{1}{100}$ and $\frac{5}{16}$ of an inch in diameter. A number of varieties are distinguished. Those which belong to acute Bright's disease are blood-casts, epithelial casts, and hyaline casts. Granular casts and fatty casts indicate a more advanced change in the kidneys than usually belongs to acute Bright's disease; but in some cases of the acute disease granular, fatty, and even waxy casts are found in the urine. Hyaline casts are pale cylinders with delicate contours, and are so transparent that an inexperienced observer readily overlooks them. The addition of some coloring agent, such as iodine or eosin, is of assistance in searching for them, as they readily stain with most coloring matters. Their chemical composition is not known. They are often described as fibrinous, but they do not conform to the reactions of fibrin. They are probably of an albuminous nature. They vary in size. Small hyaline casts are those most frequently met with in the acute form of the disease. Blood-corpuscles, epithelial cells, and granular material are often attached to these casts. Epithelial casts are composed of desquamated epithelial cells of the renal tubes. Some of the so-called epithelial casts are composed of white blood-corpuscles. Blood-casts are made up of red blood-corpuscles. These last two forms of casts often possess a hyaline basement-substance to which the cells and corpuscles are attached. There may be some oil-globules in the sediment free or attached to the casts or contained in cells. In the majority of cases there are many casts, but sometimes they are so scanty as to require careful search for their detection.

Coma and convulsions occur in a certain proportion of cases. These are symptoms of uræmia. Owing to an insufficient elimination by the kidneys of urinary constituents, these may accumulate in the blood to an extent sufficient for the manifestations of their toxic effects upon the brain. Vomiting and purging may precede, or occur without the cerebral symptoms of uræmia, being due to a vicarious elimination of urea and other excrementitious substances through the gastro-intestinal mucous membrane. Epistaxis and

¹ Both serum-albumen and globulin are usually present in combination in albuminuria, the former predominating. Other forms of albumen (paralbumen, hemialbuminose) and peptones may be present, but it does not appear that any special diagnostic importance attaches to these latter forms of albumen.

may occur in uræmia. Impaired vision and amaurosis are among the symptoms of uræmia occasionally observed. Blindness, which may be present when it occurs in acute albuminuria is generally sudden; but it is of temporary duration, and recovery is complete. The ophthalmoscopy under these circumstances, shows no morbid appearances within the field of vision. The morbid condition is central. It is otherwise, as will be seen, in the chronic disease, occurring sometimes in the acute affection, but oftener in cases of Bright's disease. The amaurosis which is not associated with albuminuria is appreciable with the ophthalmoscope is called uræmic amaurosis. It is especially in cases of acute albuminuria developed in connection with pregnancy and pregnancy.

Complications considered as occurring sufficiently often to show not merely a connection, but a pathological connection with the affection, are bronchitis, inflammation of serous membranes, especially pleuritis and pericarditis. Cerebral oedema is an occasional complication.

In the course of the affection the symptoms may present considerable variation on different days. The quantity of urine, the amount of albumen, and so with respect to the oedema, the effusion into the cavities, the febrile movement. If uræmic effects and important complications occur, the affection continues for a period varying between a few days and two months, the average duration being about four weeks. The period of convalescence is denoted by a notable diminution or disappearance of dropsy, cessation of febrile movement, return of appetite, and normal secretion of urine. Albuminuria usually continues, but in a slight degree, after the dropsy has disappeared. At length the urine becomes normal and casts disappear from the sediment. The latter sometimes continue to be found for some time after the albumen has disappeared. The affection may end in complete recovery or it may eventuate in a chronic form. The latter is rare. As a rule, if the patient be not cut off by poisoning or the complications which are liable to occur, the recovery is complete and permanent.

PATHOLOGICAL CHARACTER.—As both kidneys are diffusely inflamed in Bright's disease, it is to be inferred that the irritant which excites the inflammation is contained in the circulating blood. In many cases, as in the chronic disease secondary to toxic influences (cantharides, turpentine, mercury), or infectious diseases, the relation between morbid blood-changes and renal affection is clear. In other cases, as when the disease follows a cold, this relation is obscure. The kidneys are peculiarly exposed to the action of noxious substances, as it is mainly through these organs that wastes and excreta are excreted from the body. As it is through the glomeruli that water and doubtless many of the solid constituents of the urine pass, it is believed that inflammatory irritants act first of all upon the glomeruli, and in the mildest cases of the disease only upon them and the epithelium, with which also irritants contained in the urine must come in intimate contact. In more severe cases all of the constituent elements of the kidney share in the inflammatory process. The diminished quantity of urine in acute Bright's disease may be explained by the lessened circulation and the slow circulation in the glomeruli, these changes in the urinary system being incident to all acute inflammations. [Compression of the vessels of the glomerulus by the products of inflammation within the capsule also tends to diminish the excretion of water.—H.] The white corpuscles found in the kidney and in the urine are the natural result of inflammation. The red corpuscles doubtless escape, at least in the early stage of the disease. The albuminuria may be referred partly to inflamma-

tory alterations in the walls of the renal capillaries, and partly to changes in the epithelium, particularly of that covering the glomeruli. Changes in the blood-pressure may also be concerned in the causation of albuminuria.¹ As to the mode of production of hyaline casts, there is discrepancy of opinion. According to one view, they are formed from altered epithelial cells which have coalesced with each other; according to a second, they are produced by secretion of hyaline material from the epithelial cells; according to a third, and the most probable view, they result from a coagulation of albuminous material which has escaped from the blood-vessels into the tubes.

The most important of the effects produced by the renal disease upon the general system are dropsy and uræmia. The dropsy is usually referred to the hydræmia which results from the withdrawal of albumen from the blood and the diminished excretion of water. This explanation of the dropsy is not satisfactory in all cases. There is reason to believe that in some cases the anasarca is best explained upon the assumption that some alteration exists in the walls of the cutaneous and subcutaneous vessels, which renders them more permeable to the passage of albuminous fluids. Cohnheim assumes this alteration to be of an inflammatory nature, and to be produced often by the same causes which excite the nephritis.² The uræmia is the result of the accumulation of urinary constituents in the blood.

CAUSATION.—This affection may occur at any period of life, and even young infants are not exempt from it. It occurs oftener in males than in females. As already stated, in the majority of cases it is a sequel of scarlatina. It may occur during the progress of scarlatina or follow directly the stage of desquamation, but it is most likely to occur in the second or third week after the date of convalescence. It is an important question whether this sequel proceed exclusively or chiefly from an agency pertaining intrinsically to scarlatina, or whether it depend on extrinsic causes, such as the action of cold. It occurs in cases in which the utmost care is taken to place the patient beyond the agency of extrinsic causes, but it is probable that the latter are frequently involved. It may be developed in a person much exposed to the scarlatinous infection without any affection of the throat or an eruption, the person having already experienced an attack of scarlatina many years previously. I have notes of several cases exemplifying the facts in this statement.

Exclusive of the cases in which it is a sequel of scarlatina, it occurs in various other pathological connections. It is an occasional sequel of diphtheria and of epidemic cholera. It sometimes occurs during the development of pulmonary tuberculosis, in the course of articular rheumatism, in syphilis, in

¹ Writers are far from being agreed as to the causation of albuminuria. Increased blood-pressure in the glomeruli has usually been considered an important cause. Rubeberg has advocated the view that the cause is in all cases diminished pressure. The truth seems to be that the blood-pressure is not an important factor in the production of albuminuria. Diminished rapidity of the circulation in the glomeruli is considered by many to be an efficient cause. The view advocated by Cohnheim is that the usual cause of albuminuria is to be found in changes in the epithelium covering the glomeruli. This view is consistent with the preceding, for slow circulation produces alterations in these cells by depriving them of their proper supply of nutriment. The real difficulty is to explain why albumen is not present normally in the urine. All other capillaries in the body, so far as known, allow an albuminous fluid to transude under normal circumstances. The walls of the glomerular capillaries differ from those of other capillary blood-vessels in the fact that they are not composed of distinct endothelial cells; at least such cells cannot be demonstrated by staining with nitrate of silver. Perhaps structural peculiarities in these walls may explain the absence of albumen in normal urine.

² This view must be considered hypothetical. It is elaborated by Cohnheim in the second volume of his *Allgemeine Pathologie*, Berlin, 1882.

s of typhoid and typhus fever, yellow fever, erysipelas, relapsing fever, lobar pneumonia, acute yellow atrophy of the liver, pyæmia, septiæmia, endocarditis, dysentery, carbuncles and suppurative processes in different situations, smallpox, and measles. Albuminuria and general dropsy arising in pregnancy depend, in a certain proportion of cases, on this affection, but in many of these cases changes in the kidney are very slight or nearly absent. As a primary affection it occurs especially in persons addicted to intemperance. In these cases it is sometimes difficult to say how much causative agency is to be attributed directly to the action of alcohol and how much to the exposure incident to intemperance. It is observed infrequently to become developed after lying on the ground in a state of intoxication. In a case which came under my observation it followed excess-indulgence in beer without any exposure to cold. It is sometimes attributable to exposure to cold irrespective of alcoholic indulgence. It may be caused by extensive burns. Other causes are cantharides, turpentine, phosphorus, carbolic acid, iodoform, the mineral acids, arsenic, the nitrate of silver, and mercury, taken internally. Finally, it may be mentioned that acute convulsions are not uncommon in chronic Bright's disease. It is thus seen that with regard to etiology most cases may be distributed into three groups: those in which the disease is caused by toxic agents; 2d, cases in which incident to infectious diseases; and 3d, cases in which it is referable to lesions acting on the skin, as cold and burns.

DIAGNOSIS.—The existence of albuminuria is not, in itself, adequate proof either of the affection under consideration or of the chronic affections of the kidneys which remain to be considered. Albumen may be present in the urine in a small or moderate quantity, and for a brief period in the course of a great number of diseases. It is found not infrequently in the urine of persons who are apparently in perfect health. Munn found albuminuria in a proportion of 11 per cent. of persons applying for life insurance, this being the only evidence of any disease.¹ In general, the diagnosis is easily made, being based on the occurrence of anasarca developed rapidly, accompanied with febrile symptoms, and an examination of the urine generally showing albumen in abundance. Dropsy is an early symptom in the great majority of cases, but it is sometimes wanting. The diagnosis is then to be based on symptoms pertaining to the urine in conjunction with general symptoms. In addition to the presence of albumen in the urine, the quantity is usually notably lessened; it frequently has a smoky or sooty appearance from the presence of red blood-corpuscles, and it is sometimes distinctly bloody. The sediment of the urine, examined microscopically, is found to contain, in greater or less abundance, the casts which have been described. The presence of these, in conjunction with other characters pertaining to the urine and the general symptoms, render the diagnosis positive. Etiological conditions are also to be taken into account in the diagnosis. It is to be borne in mind that acute Bright's disease not infrequently occurs as an intercurrent affection in the course of the chronic form of the disease.

PROGNOSIS.—The danger in cases of this affection is from uræmia and the complications which are liable to occur. Coma and convulsions always denote imminent and great danger to life, but recovery may take place notwithstanding these effects of uræmia. Pleuritis, pericarditis, peritonitis, meningitis, and pneumonia, developed in the course of the affection, are likely to prove fatal. Effusion of the lungs may prove a cause of death. Dropsical effusion into the pleural cavities may take place to such an extent as to destroy life.

¹ Vide article by Dr. John Munn in the *N. Y. Med. Record*, March, 1879.

An instance of death from this cause has not fallen under my observation, but I have repeatedly met with cases in which the dyspnœa seemed to denote imminent danger to life.

Exclusive of uræmia and serious complications the prognosis is favorable. The affection does not tend to disorganize the kidneys. It is a self-limited affection, seldom continuing more than two months, and in some cases ending in from one to two weeks. It very rarely assumes a chronic form. Cases of the chronic affections which remain to be considered, as a rule, do not originate in an acute attack.

Uræmic poisoning is to be apprehended when the urine is scanty; in other words, when the quantity of urea and other excrementitious substances eliminated by the kidneys is small. Suppression of urine lasting twenty-four or forty-eight hours places the patient in imminent danger, and if it continue is a fatal symptom. Danger from uræmia is not passed, although the albumen may have disappeared from the urine, if the sediment still contain casts. I have known fatal uræmic convulsions to occur under these circumstances.

TREATMENT.—The treatment embraces the following leading objects: 1. Diminution of the intensity of the renal inflammation, promotion of resolution, and restoration of the excretory function of the kidneys. 2. Diminution or removal of dropsical effusion. 3. Elimination of urinary constituents through the skin and gastro-intestinal mucous membrane if uræmia exist or be threatened.

With reference to the first of these objects, warmth and rest of the surface are important. The patient should keep the bed in order to maintain both warmth and rest. The diet should be unstimulating. Water and other bland liquids should be allowed as freely as the thirst dictates. Dry cupping over the loins is the best method of revulsion or counter-irritation, and if the patient be not feeble or anæmic the scarificator may be employed. General bloodletting is advisable only in cases in which patients are full-blooded and attacked when in good health. As a rule, after scarlatina, in intemperate persons, and whenever the system is enfeebled from any cause, this measure is inadmissible. Fomentations over the region of the kidneys by means of moistened cloths covered with oiled muslin and several thicknesses of flannel or the spongio-piline are useful. Saline laxatives are useful by way of depletion.

With reference to the dropsy, either saline cathartics or the more active hydragogues are indicated in proportion to the amount and situation of the dropsical effusion. In cases in which suffering and danger are incident to hydrothorax, the fluid may be withdrawn by aspiration. Elaterium is the most prompt and reliable hydragogue. I have repeatedly obtained, by means of this remedy, effectual relief in a few hours when the pleuritic effusion was sufficient to occasion alarming dyspnœa. Gamboge, podophyllin, jalap with the bitartrate of potassa, and sulphate of magnesia or soda are efficient hydragogues. Diuretics are not to be relied upon, and the kidneys will not be likely to respond to them. Moreover, they are considered by some as inadmissible because their action on the kidneys may increase the inflammation. They are, however, recommended as safe and frequently useful by others. A rational indication for their use is afforded by the fact that the renal tubes are obstructed; and a free secretion of urine will be likely to remove the obstruction by washing away the contents of the tubes. So far as my experience goes, digitalis and the saline diuretics do no harm and are often useful.

Measures for the vicarious elimination of urea are indicated whenever the diminished quantity of urine and its low specific gravity show the elimination by the kidneys to be greatly deficient. By timely meeting this indication uræmic poisoning may be forestalled. Of course measures for this object

are urgently indicated when symptoms denoting uræmic poisoning are present. Hydragogue cathartics are the most efficient, and next to these the hot-air bath. The pilocarpine, given hypodermically, in some cases produces profuse perspiration and is a potent eliminative remedy. It may be conjoined with the use of the hot-air bath. Both hydragogues and sudorifics are to be employed in alternation if uræmic coma or convulsions have occurred. If the indication be not urgent, salines and sudorific remedies may suffice. An eligible sudorific remedy is the liquor ammoniæ acetatis in half-ounce doses thrice daily. The statement concerning the use of diuretics with reference to dropsy of course is equally applicable to their use for the elimination of urea. They are not to be relied upon for the elimination of urea when uræmia exists or is threatened. Under other circumstances diuretics may be employed, selecting those which do not act as irritants of the kidneys. The bitartrate of potassa, the infusion of digitalis, and the decoction of broom are eligible diuretics. With reference to a diuretic effect pure or distilled water should be taken as a drink as freely as possible without inconvenience. Dickinson says: "Of all diuretics, water is the best;" and my own experience has led me to think that this statement is not too strong.

Uræmic coma and convulsions call for measures of treatment in addition to those which are eliminative in their operation. Venesection may be employed if not contraindicated by the condition of the patient exclusive of the uræmic symptoms. For the arrest of convulsions, either chloroform inhalation or the chloral hydrate given by the mouth or rectum is indicated. Morphia may be administered by subcutaneous injection, but not in toxic doses. These are palliative measures to be pursued until elimination has been effected by hydragogues and sudorifics or as long as the coma and convulsions continue.

During convalescence care as regards diet, exercise, and exposure to cold is important. Tonic remedies, and especially preparations of iron, are generally indicated.

My clinical records furnish illustrations of complete recovery from this affection when the dropsy was excessive, when life was threatened by hydrothorax and œdema of the lungs, and also after the occurrence of uræmic coma and convulsions.

Chronic Bright's Disease—Chronic Diffuse Nephritis.

It is not easy to make a convenient and correct classification of the different forms of chronic Bright's disease. In different cases of this disease the kidneys present a great variety of morbid appearances as regards size, color, character of the surface, etc. Kidneys affected with chronic Bright's disease may be small, of normal size, or enlarged; they may be red, yellow, white, or mottled; their surface may be smooth or granular; waxy degeneration exists in some and not in other cases. The large kidneys usually are pale in color and of smooth surface, and the small kidneys are generally red or mottled and of granular surface; but the exceptions to these rules are many. There are three modes of classification which deserve special mention. There is, first, the classification of Frerichs, adopted in its leading features by Granger Stewart. This divides Bright's disease into three stages: *first*, a stage of inflammation; *second*, a stage of degeneration; *third*, a stage of atrophy. This classification is founded on theory, and is opposed by clinical and pathological observations. It is certain that in the majority of atrophied kidneys the disease is chronic from the beginning, and there is no reason to suppose that the condition of these kidneys is preceded by either of the other stages;

nor are most cases of the so-called second stage ushered in by an acute attack. There are cases of Bright's disease which pass through the three stages of Frerichs, but this sequence of events is so rare that it cannot serve as a basis of classification. This division of Bright's disease into stages is generally abandoned.

Another classification is based on a view wholly opposed to the preceding. Bright's disease, according to this second view, is a general name for a number of independent diseases. This doctrine is advocated by many English writers, and since Bartels' work on diseases of the kidney it has been widely adopted in Germany. It is without doubt more generally accepted at the present time than any other classification. The distinct affections which are thus recognized as included under the name Bright's disease are: 1, acute Bright's disease; 2, chronic parenchymatous nephritis; 3, chronic interstitial nephritis; 4, waxy degeneration of the kidney. It is admitted that these affections are often combined with each other. This classification is in many respects a convenient one. It is certainly proper to separate acute from chronic Bright's disease; but on pathological as well as on clinical grounds there are serious objections to the sharp distinctions drawn in the foregoing classification between parenchymatous nephritis, interstitial nephritis, and waxy degeneration. In so-called chronic parenchymatous nephritis there exist interstitial changes of the same nature as those found in chronic interstitial nephritis; and in the latter there are also parenchymatous changes. There is no proof of the assertion that the disease begins in one case in the parenchyma and in the other in the interstitial tissue of the kidney. Waxy degeneration of the kidney may occur without inflammatory alterations, but in that case the degeneration is not extensive and is of little clinical importance. The waxy kidney is, in the great majority of cases, accompanied by a true nephritis. In many cases usually described as chronic parenchymatous nephritis there is waxy degeneration in addition to the nephritis.

A third classification is the one adopted in this work. It embraces all of the different forms of chronic Bright's disease under the name chronic diffuse nephritis. This classification recognizes the fact that in all of these forms there are both interstitial and parenchymatous changes. It does not consider the preponderance of parenchymatous alterations in one case and of interstitial alterations in another as a satisfactory reason for distinguishing a parenchymatous from an interstitial nephritis, especially as there may exist every possible degree of combination between these two changes.

It has been fully demonstrated that certain morbid conditions of the kidney in chronic diffuse nephritis are associated with characteristic clinical phenomena. These different morbid conditions are perhaps best designated by indicating the gross appearances of the kidneys in which they are present, as, for example, the small granular kidney, the large waxy kidney, etc. This method of division has disadvantages, but is perhaps as good as any which our present knowledge enables us to make. Whether the varieties of chronic Bright's disease are to be regarded as distinct affections or as different manifestations of one and the same disease is, in a measure, a matter of individual judgment. If chronic diffuse nephritis embraced only typical cases of large white kidney on the one hand and typical cases of small granular kidney on the other hand, there would be no impropriety in regarding these as distinct diseases; but there is every grade of transition between the large and the small kidneys. There are large kidneys with the clinical history of the small, and *vice versa*; and there are large kidneys which, except as regards size, may present all the pathological changes of the small. For these and other reasons which might be adduced it is better to regard the types of diseased kidney which are to be described not as independent affections, but as differ-

manifestations or varieties of the same disease—namely, chronic diffuse nephritis.

The two influences of greatest importance in determining the character of the kidney found after death from chronic Bright's disease are the duration of the disease and the presence or absence of waxy degeneration. When the disease has lasted for several years, it is almost certain that the small granular kidneys will be found after death. When the affection terminates less than a year from the onset (a point by no means easy in all cases to determine), some form of large kidney will usually be found on post-mortem examination. The waxy kidney, however, even when of several years' duration, is, as a rule, large and pale. It may, however, be small and granular. It must not be inferred from the fact that the small kidneys run a more prolonged course than the large that the former represent a late stage of the disease. In the majority of small kidneys the process of contraction or atrophy is to be considered as in operation from the onset of the disease.

The three main forms of chronic diffuse nephritis are: 1. The simple large kidney (red, mottled, or white); 2. The small granular kidney; 3. The waxy kidney. The waxy kidney is usually enlarged. It is therefore convenient to consider two forms of large kidney—one with and the other without waxy degeneration. Mention will also be made of the occurrence of waxy degeneration in small kidneys.

1. *The Large Kidney without Waxy Degeneration.*—This form is less frequent than either the large waxy kidney or the small granular kidney. It is a variety met with in the rare instances in which acute Bright's disease passes into the chronic stage. It is not, however, generally preceded by the acute disease. It runs, as a rule, a more rapid course than any other variety of chronic diffuse nephritis, its duration being rarely more than a year and a half. It presents two modifications according to the color of the cortical portion of the kidney. In one the cortex is red or, more usually, mottled with red and white (large red or mottled kidney). In the other the cortex is pale or large white kidney). The kidneys are enlarged, less frequently of normal size. A normal-sized kidney is reckoned among the large in distinction from the small kidneys). The surface is smooth. The capsule is easily detached. The swelling affects chiefly the cortex, which may present many hemorrhagic and congested portions, with opaque whitish or yellow parts, or may be almost wholly of a pale yellowish-white color, with only here and there a hemorrhage or a congested patch, or even without any hemorrhages. In not a few cases the surface of the kidney is granular and the capsule is adherent.

Upon microscopical examination small hemorrhages are found in abundance in the red or mottled kidneys, and, although diminished in number, they are usually but not always present in the pale kidneys. The extravasated blood may be in the intertubular tissue, but is more frequently within Bowman's capsules and in the convoluted tubes. The changes in the interstitial tissue are in the form of more or less circumscribed patches scattered throughout the cortex. In these patches the connective tissue between the tubes and the Malpighian bodies is increased. This new tissue may be rich in cells and indistinctly fibrillated, or it may be poor in cells and fibrous. The epithelium lining the tubes surrounded by the new connective tissue is generally atrophic, and the diameter of these tubes is diminished. In some places the tubes may have entirely disappeared. The glomeruli may be shrunken and fibrous, and the new tissue may be developed, especially around the red glomeruli. Some of the glomeruli present the lesions of a glomerulonephritis as described in the preceding article (p. 816). There is often a growth of new connective tissue in the walls of the arteries, presenting itself frequently in the form of an obliterating endarteritis. In addition to this devel-

opment of new connective tissue combined with atrophy of the tubes, the interstitial tissue may present here and there an infiltration with small round cells and with fatty molecules. Outside of the patches of new connective tissue the convoluted tubes, instead of being atrophic, are frequently dilated. In these dilated tubes the epithelium is generally swollen and contains molecules of fat. In other places no change may be noticeable either in the tubes or in the interstitial tissue. The lumina of the tubes contain also blood-corpuscles, hyaline casts, fatty molecules, and granular matter.

In the large kidneys, in distinction from the small granular kidneys, the changes in the epithelial cells (that is, the parenchymatous and the fatty degenerations) exceed in extent the interstitial alterations. Whether or not there be a form of chronic Bright's disease in which the parenchymatous and fatty degenerations constitute the sole changes is a matter of dispute. It is certain that in the great majority of cases there are interstitial alterations, as described, in addition to the changes in the tubes. It is important to observe, however, that both the parenchymatous and the interstitial changes are scattered in patches throughout the cortical portions of both kidneys, and are not uniformly diffused; also that the most extensive swelling and fatty degeneration of the epithelium are found outside of the patches of new connective tissue, in which, on the other hand, the epithelial cells are usually small and atrophied. It is evident from the description that even in large smooth kidneys there may be (microscopically) atrophied portions resembling those in the small granular kidneys, but not so abundant. This atrophy, with increase of fibrous tissue, is evident to the naked eye in those large kidneys which present a granular surface with adherent capsule. These and other considerations which will appear in the course of this article render it clear that, important as it is to distinguish certain general types or varieties of chronic diffuse nephritis, it is not desirable to separate them from each other by sharp boundary-lines. The pale kidneys differ from the red or mottled kidneys chiefly in a greater amount of anæmia and of fatty degeneration.

A considerable number of the large, non-waxy kidneys of chronic Bright's disease are accompanied by hypertrophy of the left ventricle or of the whole heart. Hypertrophy of the heart does not usually develop in connection with the large kidneys when the renal disease occurs in patients much enfeebled, as by phthisis, syphilis, chronic suppurations, etc. It is in connection with such wasting diseases that the greatest number of the large white kidneys are developed. There is reason to believe that many of the kidneys frequently described as of the large white variety are affected by a waxy degeneration which has been overlooked, and which therefore places them in the following variety.

II. *The Large Kidney with Waxy Degeneration.*—This variety and the small granular kidneys constitute the most frequent forms of Bright's disease. This form embraces a large proportion of the cases developed in connection with phthisis, syphilis, chronic suppurations, and severe cachexiæ. As already mentioned, a considerable number of the large white kidneys belong to this variety.¹ Waxy degeneration of the kidneys is, with very few exceptions,

¹ Some writers regard the large white kidney as characterized especially by fatty degeneration of the epithelium, as free from waxy degeneration, and as unattended by hypertrophy of the heart. This constitutes only one variety of large white kidney. A part of the confusion arises from the fact that there are different forms of diffuse nephritis which may present the appearances of the large white kidneys—namely, 1. The pale kidney of acute Bright's disease, especially of scarlatinal nephritis. 2. The large pale kidney without waxy degeneration and with hypertrophy of the heart. 3. The large pale kidney of chronic Bright's disease, without waxy degeneration and without hypertrophy of the heart. 4. The large pale kidney with waxy degeneration. Most of the large white kidneys of chronic Bright's disease without hypertrophy of the left ventricle are affected with waxy degeneration.

accompanied by waxy degeneration in other parts, especially the spleen and the liver. The kidney is one of the favorite seats of this abnormal deposit. The waxy change in the kidney may be so slight as to be recognizable only upon microscopical examination, or it may be so extensive as to give a very characteristic aspect to the organ. In nearly all doubtful cases its presence or absence can be determined by means of the simple iodine test. For microscopical examination iodine and sulphuric acid and methyl-violet are to be preferred. A slight or moderate waxy degeneration may occur without further parenchymatous or interstitial changes. This simple waxy degeneration, however, is so rare that its occurrence has even been denied. Waxy degeneration of the kidney, when of clinical importance, may be considered practically as associated always with diffuse nephritis. Whether the waxy change be the cause of the nephritis, or whether both be effects of the same cause, are undecided questions which at present do not admit of profitable discussion.

Kidneys affected with waxy degeneration present a variety of gross appearances according to the degree of degeneration and the extent and character of the parenchymatous and interstitial changes. The waxy change may be so slight as not to influence the appearance of the kidney, which then presents some one of the forms of chronic diffuse nephritis. Usually, however, careful inspection will reveal in the glomeruli, and perhaps elsewhere, the characteristic translucent appearance of the waxy material. When a large amount of the waxy deposit exists, we have the characteristic appearance of the waxy kidney. The organ is then enlarged, pale, and anæmic. The consistence is firm. The surface is smooth and glistening. The capsule is not adherent. Upon section the cortex is found to be the part chiefly swollen. It presents the same pale aspect as the surface. The pyramids are bluish-red, as in most forms of diffuse nephritis. The cortical striæ are obscured. The translucent Malpighian tufts are visible. The cortex presents a combination in irregular patches or in striæ of translucent gray portions with opaque white or yellow portions. The latter correspond to the parts most affected by fatty degeneration, and the former to the waxy districts. The more the translucent gray substance predominates, the greater is the extent of the waxy degeneration and the more characteristic of the waxy kidney is the appearance. The more the yellowish parts predominate, the more closely does the appearance approach that of the large white kidney without waxy degeneration.

By the use of iodine it is evident to the naked eye that the favorite seats for the deposit of the waxy material are the glomeruli and the vasa recta. Microscopical examination shows that the capillaries of the cortex and the *membranæ propriæ* of the tubes, especially of the straight tubes and the loops of Henle, are also often affected. The deposit, as a rule, is at first in the middle coat of the arterioles and around the capillary walls of the glomeruli. The walls of the affected vessels become swollen and homogeneous. The lumina of the vessels is gradually diminished, and may be obliterated. In a similar way the walls of the tubes may be thickened and homogeneous. The nephritic changes are in most respects the same as those described for the preceding variety, and need not here be repeated. It is only necessary to add that hemorrhages are usually absent in kidneys affected with waxy degeneration. Fatty degeneration of the epithelium and anæmia of the kidneys are prominent features. The waxy glomeruli present a more homogeneous appearance, fewer nuclei, and less shrinkage than those involved in the other forms of chronic diffuse nephritis. There is nothing characteristic of waxy degeneration in the casts found in the tubes.¹

¹ These casts, often called waxy, may stain red with methyl-violet, but they do not give the characteristic reaction with iodine and sulphuric acid. Formless clumps presenting this reaction have, however, been found in the tubes (Kyber).

Waxy degeneration is not confined to large smooth kidneys. It is not very rare to find large waxy kidneys with irregular surface and partially adherent capsule. Small granular kidneys may also be waxy. Waxy kidneys are very rarely accompanied by hypertrophy of the heart. The coincidence of waxy spleen and of waxy liver with this form of kidney disease is an important element in the diagnosis. There are cases, however, in which the change in the kidney is well marked, while in the liver and in the spleen it is insignificant. It may always be inferred that some degree of waxy degeneration of the kidney exists when this change can be recognized in the liver and in the spleen.

III. *The Small Granular Kidney.*—At least three varieties of this form of kidney may be recognized—namely, one representing an atrophic stage of the large kidney without waxy degeneration; a second representing the same stage of the large waxy kidney; and a third, being the genuine contracted kidney, of which no stage of enlargement exists. The first two are called secondarily-contracted kidneys. Nothing could be more erroneous than the view which once prevailed that the large kidneys in the natural order of events, if recovery do not take place, necessarily pass into a stage of contraction, and that the majority of atrophied kidneys are preceded by a stage of enlargement. The secondarily-contracted kidneys do not usually become as small as the genuine or primarily-contracted kidneys. It is not rare to find small kidneys with waxy degeneration. Many of the small granular kidneys occurring in gout are waxy. It is probable that in some of these cases the waxy degeneration is superadded to a genuine contracted kidney. Many of the small waxy kidneys, however, are better regarded as representing an atrophic stage of the large waxy variety.

While the existence of secondarily-contracted kidneys is admitted, it is the primarily-contracted form which is referred to in the remainder of this article under the name small granular kidney. Other names for this variety of chronic diffuse nephritis are—genuine contracted kidney, small red kidney, granular atrophy of the kidney, cirrhosis or sclerosis of the kidney, chronic interstitial nephritis, and chronic desquamative nephritis (Johnson). There is no serious objection to any of these names except the last. Of all the forms of chronic diffuse nephritis, this is the one which with most propriety may be regarded as a distinct disease, and this is the view now very generally adopted. There are authorities who hold the opinion that renal cirrhosis is not only to be separated from other forms of chronic Bright's disease, but that it is only one manifestation of a general disease affecting the arteries of the body. This view will receive consideration subsequently.

The kidneys in this form are reduced in volume and weight. As in all forms of Bright's disease, both organs are involved, and, as a rule, to nearly an equal extent. The size may be a third that of the normal kidney or even less. There is usually a compensatory increase of adipose tissue around the kidneys. The organs are abnormally dense and resisting. The capsule is with difficulty detached, and when removed it brings away portions of the torn renal substance. The exterior surface presents little irregular elevations or granulations. The granulations usually have a yellowish and the depressions between them a reddish color. In many cases the name small red kidney is appropriate. Sometimes, however, the prevailing color is whitish or yellowish. Upon section it is observed that the cortical portion especially is diminished. This is reduced to a narrow rim over the pyramids. In marked cases the pyramids extend nearly to the external surface, and their sides are almost in contact. Little cysts, varying in size from a pin's head to a pea or even larger, and filled with a thin fluid or with colloidal contents, are frequently observed both on the surface and in the interior. White

lines, due to the deposit of urate of soda in the tubes, are not infrequently seen in the pyramidal portion. They are invariably present when the disease of the kidney is associated with gout. Small kidneys with these deposits were called by Todd gouty kidneys. The same deposit of urates may occur independently of gout.

The microscope shows as the most essential change the production in the cortex of a large amount of fibrillated connective tissue. This new tissue is not uniformly distributed, but is in greater amount in some places than in others, and there are usually parts where no thickening of the interstitial tissue exists. Many of the Malpighian tufts are small and fibrous, and are often placed abnormally close to each other in consequence of atrophy of the intervening tubes and retraction of the new fibrous tissue. The rich development of new connective tissue around the shrunken glomeruli may be especially noticeable. An important change in most cases is the growth of fibrous tissue in the walls of the arteries, both in their adventitia (periarteritis) and in their intima (endarteritis). By the obliteration and partial occlusion thus effected of many small arteries and of capillaries in the glomeruli the circulation through the kidneys must be much impeded; but the blood-vessels are not the only parts that suffer by this new growth of fibrous tissue. The tubes are also compressed, and may be in part obliterated. By this constriction of the tubes in certain places the flow of urine through them is obstructed, and, being dammed back, causes cystic dilatations visible to the naked eye. These cysts consist of dilated tubes and of dilated capsules of Bowman. In the latter form of cyst the glomerulus is compressed or entirely obliterated. Although interstitial changes decidedly predominate in this form of kidney, parenchymatous changes are not wanting. Atrophy of the epithelium is constantly met with in tubes enveloped in connective tissue. Fatty degeneration of the epithelium, although less extended than in the large kidneys, will usually be found in some places. Fat-globules may also appear in the interstitial tissue. The tubes within the new fibrous tissue are small and may be entirely obliterated. Outside of this they are frequently dilated. Hyaline and granular casts are often discovered in the tubes, especially those of the pyramids. There may be some increase of the interstitial tissue of the pyramids, but the changes in these are trifling in comparison with the alterations in the cortex.

One of the most constant accompaniments of the small granular kidney is hypertrophy of the left ventricle, unattended usually by valvular lesion. There may be hypertrophy of the whole heart. The hypertrophy is usually attended by more or less dilatation, but it may be simple. Buhl has pointed out the frequent coincidence of fibrous or chronic interstitial myocarditis in connection with this hypertrophy. Another complication of great frequency and of diagnostic value is the form of retinitis called retinitis albuminurica, the ophthalmoscopic appearances of which will be described in connection with the symptoms. Both the retinitis and the cardiac hypertrophy may occur with other forms of chronic Bright's disease, but they are rarely met with in conjunction with the large waxy kidney. Cerebral hemorrhage and inflammation of serous membranes are also to be mentioned as important complications. Bartels calls attention to the frequent occurrence of thickening of the skull-cap and adhesion of the dura mater to the bone. Dropsical effusions are rather the exception than the rule in this form of Bright's disease.

As has already been said, many writers are inclined to regard the small granular kidney as a disease entirely distinct from the other forms of chronic Bright's disease. Even the propriety of considering renal cirrhosis as a nephritis is disputed. Gull and Sutton first advanced the view that renal cirrhosis is only one manifestation of a widespread affection of the whole

arterial system, to which affection they give the name arterio-capillary fibrosis. The essential change, according to these authors, is a thickening of the outer coat of the arteries. The disease they regard as mainly one of old age. The hypertrophy of the heart, they urge, is to be explained only by this general arterial disease. There are cases which seem to support Gull and Sutton's theory. Extensive atheroma of the arteries (arterio-sclerosis), such as occurs in old age, is usually attended by partial atrophy of the kidney. This arterio-sclerotic atrophy of the kidney is not, however, usually attended by any symptoms of Bright's disease, and it is not probable that this is the form of disease referred to by Gull and Sutton. Widespread obliterating endarteritis, when it involves the renal arteries, leads to atrophy of the kidneys, which may give rise to grave symptoms; but in many cases, probably in the majority, of small granular kidney no arterial changes have been found which can be assigned with any propriety as the cause of the renal disease. There is not, therefore, sufficient basis for the doctrine that this form of Bright's disease is in all cases the result of primary arterial changes. Moreover, Gull and Sutton have overestimated the influence of old age in the causation, and they seem to have overlooked the instances of cardiac hypertrophy in connection with other forms of Bright's disease.

The view is advanced by Weigert that the primary change in renal cirrhosis is atrophy or necrosis of the epithelial cells (therefore not inflammation), and that in accordance with a pathological law this loss of substance is followed by new growth of connective tissue. The primary atrophy of the epithelial cells may be the result of various toxic substances (such as alcohol, lead, and uric acid) or the result of insufficient nutrition from defective circulation (primary arterial changes). In most cases, however, we are ignorant of the primary cause.

CLINICAL HISTORY.—Chronic Bright's disease sometimes follows the acute affection. This statement applies chiefly to the large kidney without waxy degeneration; but as a rule the disease is developed imperceptibly and is subacute from the first. In a large proportion of cases the event which first directs attention to the existence of renal disease is dropsy. Prior to this event the patient for some time may have been sensible of impaired strength, and the appearance may have denoted anæmia; but not infrequently up to the time when dropsy is noticed the patient is not aware of any deterioration of health. The first appearance of dropsy is œdema either around the eyes or in the lower extremities, or in both situations simultaneously. As regards the amount of dropsy, and the rapidity with which it increases and is diffused, cases differ. It may be present and remain in so slight a degree that its existence is ascertained only by close examination, and it may escape the attention of the patient. On the other hand, in certain cases anasarca occurs either rapidly or slowly, the limbs, body, and especially the genitals, becoming enormously swollen, together with more or less effusion into the serous cavities. A convenient place for determining by pressure with the finger a small amount of œdema is over the sternum. The different forms of disease do not equally give rise to general dropsy. It occurs most constantly and is most marked in connection with the large kidney. It is wanting in a certain proportion of cases, and in these cases the most frequent form of disease is the small granular kidney. It is also frequently wanting for a considerable period during the progress of the waxy form of disease. Of 89 out of 102 recorded cases of chronic Bright's disease under my observation, in which facts respecting dropsy were noticed, it existed in 74, and was absent in 15 cases. The dropsy was slight or moderate in 21, and considerable in 36 cases.

in 17 cases the degree and the extent of the dropsy were not noted.¹ Of 430 cases collected from different authors and analyzed by Frerichs, general dropsy existed in 376 and was wanting in 34. As a rule, general dropsy is marked in the cases in which the albumen in the urine is very abundant, and, *per contra*, general dropsy is either slight or wanting in the cases in which the urine contains little or no albumen.

The examination of the urine is of great importance as regards diagnosis in the different forms of chronic Bright's disease. In the large kidney without waxy degeneration the quantity of urine excreted within twenty-four hours is diminished unless the arterial tension be elevated by hypertrophy of the heart, in which case the quantity is normal or even increased. The diminution is rarely as marked as in acute Bright's disease. The specific gravity, as a rule, is high when the quantity of urine is scanty, and low under opposite circumstances. Generally it does not vary much from the normal standard. The urine of this form of kidney is usually of a yellow color and turbid. The amount of albumen is considerable, and in some cases very large. The daily excretion of urea is lessened. There is generally an abundant sediment which contains casts, epithelial cells, red and white blood-corpuscles, and granular material. Urates may be deposited in abundance. All varieties of casts are found, but the most common are hyaline casts, either narrow or broad, and frequently dotted with oil-globules and granular casts which may also contain fatty molecules. To both varieties of casts frequently adhere red corpuscles, pus-cells, and epithelial cells; and casts composed wholly of epithelium may be observed. The pus-cells usually exceed in number the red corpuscles, but there are exceptions to this rule. Cells filled with fatty globules (so-called granular or exudation corpuscles) and free fatty granules are often present.

The urine excreted by kidneys affected with waxy degeneration presents great variations in its characters, these variations being influenced especially by the degree and the extent of the diffuse nephritis which is present and by the amount of waxy deposit. When the parenchymatous changes predominate the urine presents the characters belonging to the preceding form. In consequence of the absence of cardiac hypertrophy the quantity may be greatly diminished, although rarely in the degree belonging to acute Bright's disease. Red blood-corpuscles are absent or few. In no form of Bright's disease is a larger percentage of albumen met with than in these large waxy kidneys with extensive parenchymatous changes. With the typical waxy kidneys—that is, those containing a large amount of waxy deposit and presenting in most parts a pale translucent appearance—the urine usually is abundant, very pale in color, of low specific gravity, clear, and rich in albumen. The specific gravity may fall as low as 1005 or even lower. The quantity of albumen is usually considerable, but it may be slight. The daily excretion of urea is below the normal, but the poor nutrition of the patients ill in a great measure explain this. There is little or no sediment. Casts are not abundant, and they are chiefly hyaline and so-called waxy casts. The term waxy cast is often employed synonymously with hyaline cast. When used in a different sense, it refers to broad homogeneous casts of a yellowish hue and more distinct and refracting than the hyaline casts. These waxy casts are probably similar in structure to the hyaline; and they are not, as the name implies, composed of waxy or amyloid substance. Exceptionally, however, casts are found which give the same reaction with iodine as the waxy material. The so-called waxy casts are not confined to the waxy kidney, but they

¹ Vide "A Clinical Report on an Analysis of One Hundred and Two Cases of Bright's Disease," by Austin Flint, M. D., one of the Attending Physicians of Bellevue Hospital, etc., published in the *Bellerue and Charity Hospital Reports*, 1870, p. 226.

may be found in the urine of any form of chronic diffuse nephritis. It is this abundant, clear, albuminous, light urine which is considered most distinctive of waxy degeneration of the kidney, but, as already mentioned, its characters are greatly modified by the intensity and the extent of coincident inflammation and by the degree of waxy change. Litten and others have reported cases of even extensive waxy degeneration of the kidneys without albuminuria. In some of these cases dropsy was present during life. We have no satisfactory explanation of the absence of albuminuria in these cases.

The small granular kidneys (renal cirrhosis) sometimes secrete urine which in no way differs from the normal. It is particularly to be emphasized that albumen and casts may be absent from this urine. This is one of the reasons why this form of chronic diffuse nephritis so often escapes detection. The quantity of urine excreted by the small granular kidneys usually exceeds the normal. The polyuria may be so great as to lead to the suspicion of diabetes. The specific gravity is low. It averages about 1010, but it may be less. The color is pale greenish-yellow. The urine is clear, there being little or no sediment. The percentage of urea is lessened, as is likewise in most cases the quantity excreted daily. It is not, however, very exceptional to find this quantity equal to that in health. Albumen is usually present in small amount. Its quantity is in striking contrast to that in most other forms of Bright's disease. It may fail altogether, but this is generally only a temporary occurrence. Bartels, however, mentions a case in which albumen was absent throughout the whole course of the disease. Exceptionally, the quantity of albumen is abundant. When a uræmic attack supervenes, the amount of albumen is usually increased. If waxy degeneration be present, there is an increase in the quantity of albumen. Casts may be absent. Careful search will usually reveal a few hyaline casts. Granular casts are much less frequent. Toward the end of life it will usually be found that the quantity of urine is diminished, the amount of albumen is increased, and a sediment containing casts appears. With small kidneys due to secondary atrophy, the urine has qualities similar to those described if hypertrophy of the heart be present.

The characters of the urine belonging to the different varieties of Bright's disease are not sufficiently distinctive to justify a positive diagnosis of the form of kidney in all cases. There is no form of cast which is characteristic of any one variety of the disease. In general, it may be said that hypertrophy of the heart and waxy degeneration tend to increase the quantity of urine, and that low arterial tension and active inflammatory changes diminish the quantity. An abundant sediment containing many casts and blood-corpuscles is indicative of an active inflammatory process, and particularly of that associated with parenchymatous changes. The smaller in quantity the urine, the richer it is in sediment and in albumen as a rule. It is of importance to estimate the amount of urea excreted daily, for which purpose it is of course necessary to determine the percentage of urea in the total quantity of urine passed in twenty-four hours. The specific gravity affords an approximate idea, although far from an accurate estimate, of the percentage of urea. The specific gravity of a single specimen of urine is manifestly of no value in forming an idea as to the daily excretion of urea. It is necessary to take into consideration at the same time the quantity of urine voided in the twenty-four hours. A low specific gravity may be compensated by a large daily excretion of urine.

Pallor of the countenance, due to anæmia, is generally more or less marked. The anæmia is measurably, if not chiefly, owing to the loss of albumen, and it is most marked in cases in which albuminuria and general dropsy are

prominent. It may be an effect of defective nutrition from anorexia or persistent vomiting. In cases of cirrhotic kidney in which albuminuria and dropsy are slight or wanting pallor is not usually a marked symptom. *Edema* and pallor combined give to the face an appearance highly characteristic of Bright's disease.

Symptoms referable to the digestive system are more or less prominent. Indigestion or dyspeptic disorder is common. Flatulence of the stomach is a frequent symptom. Vomiting is a prominent and persistent symptom in certain cases. It is referable to the vicarious elimination of urinary principles by the gastric mucous membrane. It may be preceded or accompanied by other symptoms denoting uræmia, but it is sometimes the chief uræmic manifestation. The uræmic vomiting occurs when the stomach is empty, and often early in the morning. The vomited matter or eructated gas sometimes has an ammoniacal odor. The acts of vomiting often occur suddenly and violently without much previous nausea. These circumstances connected with vomiting should always excite suspicion of renal disease, although no other symptoms pointing to the kidneys be apparent. Uræmic vomiting not associated with general dropsy denotes the small granular kidney. The vomiting is sometimes so persistent as to interfere with alimentation and thus induce alarming prostration.

Diarrhoea is a less frequent symptom. It is, however, a prominent and persistent symptom in some cases, either with or without vomiting, or, like vomiting, it may be a uræmic symptom. It may proceed from uræmic intestinal ulceration. It is especially frequent in cases of the waxy kidney combined with waxy disease of the intestine.

Urea is also eliminated vicariously by the skin. The perspiration emits distinctly the odor of urine in some cases. An intense characteristic odor is given off from the skin by some patients who do not pay any attention to cleanliness. Crystals of urea are sometimes found on the skin. Bartels observed a case in which the full beard of a patient had a frosted appearance from an abundant deposit of these crystals. An occasional symptom is an intense itching of the skin.

Symptoms referable to the respiratory system may be produced by pleural effusion or hydrothorax, by pulmonary oedema, and by oedema of the glottis. Pleuritic effusion and oedema of the lungs sufficient to occasion notable embarrassment of respiration occur, especially when disease of the heart, involving mitral contraction or regurgitation, or both, coexists with the renal disease. Under these circumstances the pleural cavities may become nearly filled with serum. Oedema of the lungs under these circumstances is sometimes the immediate cause of death. The occurrence of pulmonary oedema is sometimes very sudden, and it may prove quickly fatal. Not infrequently, however, the oedema disappears, even when life has been placed in imminent danger. Oedema of the glottis is of rare occurrence (according to the statistics of Frerichs and of Rosenstein, in only 4 of 292 cases). It may occur when general dropsy is moderate or slight or wanting.

Dyspnœa may exist in a marked degree when not referable to any of the conditions just named, but proceeding apparently from a toxic effect upon the nervous centre presiding over respiration. In these cases the moist râles incident to pulmonary oedema and the dry râles of asthma are wanting. Auscultation and percussion give no signs denoting any pulmonary affection. I have met with several cases in which this nervous dyspnœa was the most prominent symptom; and I have known it to exist when no other symptom was present to direct attention to the kidneys as the seat of disease. The patients suffer from a feeling of apprehension of "losing the breath," and are afraid to sleep on this account, an exertion of the will being required

for respiration. Disturbance of the rhythm of respiration characterized by the frequent occurrence of a long interval between the respiratory acts, followed by series of rapid respirations (Cheyne-Stokes respiration), is not infrequent, occurring in connection with uræmic stupor and coma. Enlargement of the heart with predominant dilatation is another cause of dyspnœa. Especially in cases of contracted kidney dyspnœa from this cause may occur before other events have directed attention to the kidneys as the seat of disease.

Symptoms referable to the nervous system are among the most important of those belonging to the clinical history of the disease. Pain in the back is rarely prominent, and is generally wanting. Cephalalgia is a frequent symptom. It may precede as well as accompany other symptoms which point to the existence of renal disease. Neuralgic pains in other parts of the body are common; and attacks of vertigo are not infrequent. Insomnia and disturbed sleep are frequent symptoms. Troubles relating to vision are in certain cases important symptoms. Diplopia or double vision, hemeralopia or night-blindness, myopia, and presbyopia are attributed, and perhaps are fairly attributable, to the disease. Including these forms of disorder, vision is more or less affected in a pretty large proportion of cases; but exclusive of these, either obscurity or loss of sight—that is, amaurosis complete or incomplete—is not of extremely rare occurrence. The amaurosis affects both eyes. When not complete—and it rarely is so—the degree varies in different cases and in different periods of the same case. In chronic as in acute Bright's disease the impairment of vision may depend on an intracranial morbid condition, the ophthalmoscope showing no morbid appearances within the eye. This condition is called uræmic amaurosis. Under these circumstances it is temporary, and is liable to recur from time to time. I have known it to occur repeatedly in the same case as a precursor of uræmic coma and convulsions. More frequently, however, it is connected with changes within the eye, which by means of the ophthalmoscope have been brought under clinical observation. In this so-called *retinitis albuminurica* the optic papilla is swollen, clouded, and indistinctly bounded, the retinal veins are tortuous, and white patches appear in different parts of the retina. The most characteristic appearance, however, is the presence of white dots and streaks in the periphery of the macula lutea. "These fine white dottings and radiating lines give the impression of having been splashed on with a feather." The appearances are so distinctive that a practised ophthalmoscopist is led by them to suspect renal disease. It has happened in several cases which have come under my observation that disease of the kidney was discovered by means of ophthalmoscopic appearances, the patients having first consulted oculists for defect of vision. Amaurosis dependent on neuro-retinitis may diminish, and recovery is possible; but it is almost always persistent, either progressively increasing or remaining stationary after it has reached a certain degree. The development is usually gradual, whereas the so-called uræmic amaurosis occurs suddenly. The patient describes the defect of vision as like that of a mist before the eyes. Deafness, hemiplegia, paraplegia, and paralysis limited to a single member have been observed to follow or accompany uræmic coma and convulsions. Muscular cramps are sometimes a source of suffering, and I have known them to constitute the chief ailment for some time before other symptoms directed attention to the kidneys.

Coma and convulsions are the most important of the symptoms referable to the nervous system. They occur in a pretty large proportion of cases and are often forerunners of a fatal termination. In chronic Bright's disease, as in the acute affection, they proceed from uræmic poisoning; they are therefore among the ulterior effects of interference with the secretory functions of the kidneys. They are consequently most likely to occur when the

cretory structure of the organs is extensively destroyed, and hence especially in connection with the small granular kidney. In acute Bright's disease they always denote great danger, but in chronic Bright's disease the danger is much greater.

Coma occurs in some cases, and death takes place without the occurrence of convulsions. Occasionally coma occurs suddenly, but generally it is developed gradually, the patient having been more or less somnolent, dull, or lethargic for several days before becoming profoundly comatose. The coma is sometimes quiet, and in some cases accompanied by stertor. Marked dilatation of the pupils is sometimes observed. The face is congested, sometimes becoming livid, and death is preceded by tracheal râles. The convulsions are epileptiform in character, varying much in degree and extent in different cases. They occur in paroxysms which may be repeated at short intervals, the patient in the intervals being completely comatose, the convulsions at length ceasing, and the coma continuing until death; or after a paroxysm or a series of paroxysms the patient recovers intelligence, and hours, days, weeks, or months elapse before a recurrence takes place. Convulsions not following coma are generally, but not always, preceded by symptoms referable to the head, such as cephalalgia, vertigo, and sometimes delirium. Contraction or rigidity of certain muscles has been observed to precede convulsions. Of 70 cases among those which I have analyzed, selecting those only the histories of which embrace either death or recovery, coma or convulsions were noted in 26.

The uræmic phenomena, if neither an acute inflammation nor an essential fever exist, are not, as a rule, accompanied by notably increased frequency of the pulse; the action of the heart is sometimes diminished in frequency; and I have known the pulse to fall to 32 per minute. Pyrexia is wanting except in a certain proportion of the cases in which coma and convulsions occur. In some instances, in connection with these events, there is a considerable rise of temperature (105° F.); in other instances the temperature is lowered, and it may fall considerably below the minimum of health. The circumstances which occasion these variations are not as yet ascertained. Further study of the temperature in the different varieties of chronic Bright's disease is a desideratum.¹

Delirium, which has just been mentioned as sometimes preceding convulsions, is occasionally a prominent feature in cases of uræmic poisoning occurring in connection with both acute and chronic Bright's disease. It is characterized in some cases by remarkable hallucinations. The delirium may be quiet or gay or sad, and it is sometimes furious or maniacal. Uræmic poisoning, as manifested by delirium, coma, and convulsions, may occur in cases of Bright's disease with abundant general dropsy, but it often occurs in cases in which dropsy is slight or wanting. Of the 26 cases above referred to in which coma or convulsions occurred, in 11 there was no dropsy. It may follow copious vomiting and purging, but it occurs oftener in cases in which these symptoms are slight or wanting. The symptoms of uræmic poisoning are sometimes the first to direct attention to the kidneys as the seat of disease.

After an attack of uræmic coma and convulsions there is sometimes complete absence of the symptoms of renal disease, inclusive of the morbid characters of the urine, the disease remaining completely latent and another outbreak occurring after an intermission of a greater or less duration.²

¹ Vide Bourneville, *Études cliniques et thermométriques sur les Maladies du Système nerveux*, 1872; also, article by McBride in the *Archives of Medicine*, New York, Feb., 1880; also, Bartels in *Ziemszen's Cyclopædia*, vol. xv.

² For cases illustrating the latency of renal disease, vide *Bellevue and Charity Hospital Reports*, 1870, p. 256.

As regards uræmic phenomena, different cases present a striking difference in the amount of lesions with which their occurrence is connected. Coma, convulsions, and death may take place when the kidneys are not greatly diseased, and, *per contra*, the amount of disease sometimes becomes very great before any uræmic phenomena are manifested. So also there is a great difference in different cases with respect to the relation between the diminution of the excretion of urea and the effects of its accumulation in the blood. The occurrence of uræmic phenomena depends much on the rapidity with which the accumulation of urea in the blood takes place. *Ceteris paribus*, uræmia is quickly induced if the urea accumulate rapidly. On the other hand, if the accumulation take place slowly, the system acquires a tolerance of urea, as of other toxic substances, and hence fatal uræmic effects may be postponed for a long period. Another explanation has reference to the production of urea in the system. This will vary within wide limits according as the ingestion of nitrogenized food is small or abundant, and also according to the amount of muscular exercise. Different cases differ also as regards the vicarious elimination of urinary constituents through the skin and alimentary canal. It is a matter of clinical observation that uræmic manifestations are less frequent with than without dropsy. Bartels finds an explanation of this fact, in a measure, in the amount of urea contained in the dropsical effusions. The elimination of the urea renders the dropsy to a certain extent protective against uræmia.

The complications of the disease form an important part of the clinical history. Several affections included among the symptomatic events might be considered in the light of complications—namely, oedema of the lungs, oedema of the glottis, and amaurosis. Other secondary affections are pericarditis, peritonitis, pleuritis, and cerebral meningitis. Of these, pericarditis and pleuritis occur oftener than inflammations of other serous membranes. They are secondary especially to the small granular kidney.

Hypertrophy of the left ventricle of the heart is developed especially in connection with the small kidney. It may be a secondary affection in cases of the large kidney, but is rarely so in cases of the waxy kidney. If not associated with valvular lesions, hypertrophy of the left ventricle renders the existence of renal disease extremely probable. The hypertrophy may not give rise to any subjective symptoms, and it will therefore be overlooked if the rule be not adopted of always making a physical examination of the chest. With hypertrophy of the heart is associated a hard, resistant pulse and increased intensity of the aortic second sound, indicating high arterial tension. In my analysis, out of 26 fatal cases in which the condition of the heart was noted, in 11 there was more or less enlargement without valvular lesions. Cirrhosis of the liver and fatty liver are not infrequently associated with Bright's disease, but they are to be considered as concomitant, not secondary, affections. This statement is applicable to waxy liver and waxy spleen, which in a very large proportion of cases accompany the waxy form of disease of the kidneys. Waxy disease of the alimentary canal coexists in a certain proportion of cases. Cerebral hemorrhage, although not of frequent occurrence, occurs sufficiently often to show a pathological connection. It is a complication of the small granular kidney oftener than of the other forms of renal disease. Hemorrhagic pachymeningitis is an occasional complication. Epistaxis, the frequent recurrence of which in itself, in a person in middle life, should excite suspicion of renal disease, may be explained by disease of the blood-vessels and hypertrophy of the heart. A relatively greater weakness of the left than of the right ventricle is causative of pulmonary oedema. Pulmonary phthisis is a complication of the waxy kidney sufficiently often to show a pathological connection; but this does not hold true of the other forms

of renal disease. The researches of Fenwick and Wilson Fox show that the appearances after death often denote gastritis. This may be attributed to the presence of decomposed urea in the stomach. Gastritis occurs especially as a complication in cases of the small granular kidney. Epistaxis and hemorrhages in other situations may be here mentioned as of not infrequent occurrence.

Chronic rheumatism is sometimes associated with chronic Bright's disease. It may, however, be doubted whether it occur often enough to establish any pathological connection. Todd and other British writers have observed the frequent association of gout and the small kidney. This form of Bright's disease was called by Todd the *gouty kidney*. Gout in this country is, comparatively speaking, a rare disease, but the small kidney is by no means extremely rare. The union of these diseases is not of frequent occurrence with us.

PATHOLOGICAL CHARACTER.—With the description of the anatomical appearances the grounds for regarding chronic diffuse inflammation of the kidneys as the basis of all forms of chronic Bright's disease have been given.

Albuminuria, dropsy, and uræmia are common to both acute and chronic Bright's disease. Reference has been made to the mode of their production under the pathological characters of the former disease. Although a certain amount of hypertrophy of the heart may occur with acute Bright's disease, especially in the scarlatinal form, this symptom becomes prominent only in cases of chronic Bright's disease. There are many theories and much controversy as to the cause of this hypertrophy. Perhaps the most plausible of these theories is that which was advocated by Bright, which refers this hypertrophy to the accumulation of urinary constituents in the blood, especially urea. In some way, it is believed, these constituents increase the blood-pressure, but whether by irritating the vaso-motor centres, by acting directly upon the vascular walls, or by rendering the blood more difficult of circulation, is uncertain. In a certain number of cases, particularly of the atrophied kidneys, the cardiac hypertrophy may be due to structural changes in the arterial walls.

However produced, the hypertrophy of the heart is an important conservative process. It compensates in a remarkable degree for the disturbance of the renal functions incident to the small granular kidneys. The fact that notwithstanding the destruction of a large amount of renal parenchyma these kidneys secrete a normal or even increased amount of water, and not infrequently a nearly normal quantity of solids, is explained by the high arterial tension in the diseased organs; and this tension could not be maintained without increased force of the heart. The compensation is, however, less complete for the excretion of the solids than for that of the water of the urine. The beneficial effects of this compensatory hypertrophy are made evident when from any cause (dilatation or fatty degeneration) the cardiac muscle becomes insufficient. Then the quantity of urine becomes small, the excretion of solids is still further diminished, and the danger of uræmia is great.

CAUSATION.—In a small proportion of cases chronic Bright's disease follows the acute affection. The causes in these cases are those which give rise to the latter. Exclusive of these cases the causation is often obscure. In a considerable proportion of cases there are no symptoms denoting impaired health prior to the manifestations of the renal disease; that is, prior to either dropsy or uræmic symptoms. This was true in 30 of 53 cases among those which I have analyzed, information on this point being contained in the histories of these 53 cases. In 6 of these 30 cases uræmic coma or convulsions occurred either when the patients were supposed to be in good health or when

these events were preceded by other ailments only for a period not longer than three or four days. In the 23 cases in which ailments preceded the manifestations of renal disease, excluding the cases in which other diseases existed, the patients had complained of general debility more or less marked for a period ranging from a few weeks to several years. It is probable that in many of the cases in which the manifestations of renal disease occurred in persons apparently in good health the urine would have been found for weeks, months, or even years, to furnish proof that the kidneys were not healthy. The disease occurs very rarely in infancy and childhood. The disease is also infrequent in old age. In the vast majority of cases the patients are either young or in middle life. My analysis of 102 recorded cases showed not a single case at less than fourteen or more than seventy years of age. One patient only was seventy years of age. The mean age was thirty-four years. A difference relating to age exists between the different forms of renal disease. The large kidney occurs especially in early life, although it is extremely rare at less than two years of age. On the other hand, the small kidney is seldom developed in early life. It is most liable to occur in the neighborhood of fifty. Men are much oftener affected than women. Of my 102 cases, 67 were males and 35 females. As regards habits of intemperance, of the 102 cases which I have analyzed, in 38 the histories contained information on this point. In nearly all these cases the patients were males. In 18 cases the habits, as regards the use of alcoholic stimulants, were good; in 13 cases the patients were spirit-drinkers and intemperate; 3 patients were moderate drinkers; 4 drank malt liquors freely; and in one case it was simply noted that the patient was a "free liver." So far as these facts go, they certainly do not show any special causative influence pertaining to the use of alcoholic stimulants. It is probable that the abuse of alcoholic beverages contributes to the production of the disease, but it is also probable that their direct agency has been much over-estimated. Clinical observation in this country certainly does not warrant the name *spirit kidney*, as applied to the small kidney by Goodfellow. The disease is much oftener observed in hospitals than in private practice among the better classes of society—a fact going to show that the exposures, hardships, and deprivations incident to the lives of those who seek for hospital relief in illness are involved in the causation. Persons whose occupations involve exposure to cold and wet are more liable to be affected than those who are protected against the vicissitudes of the weather. Cases are more frequent in humid, marshy climates and on the sea-coast than in dry, elevated, and inland situations. Malaria is supposed to be a causative agent, but of 78 cases observed in situations in which intermittent fever was of frequent occurrence, this disease had existed antecedently to the renal affection in only 10. Dickinson shows by statistical data that chronic Bright's disease, especially the small granular kidney, is of more frequent occurrence in temperate than in either cold or tropical countries, and that variableness as regards temperature and humidity favors its production.

Chronic Bright's disease may be developed in the course of various other diseases. It is sometimes developed during the progress of pulmonary tuberculosis, but exclusive of the waxy kidney the proportion of the cases in which after death tubercle in the lungs or elsewhere is found to be associated is perhaps not greater than in fatal cases of other diseases. Of the cases of the waxy kidney, pulmonary tuberculosis exists in a considerable proportion, and it precedes the renal disease sufficiently often to denote a causative influence. The waxy kidney is developed secondarily to syphilis in such a proportion of cases as to show that the latter has a causative agency. Caries and necrosis of bones,

ulcers of the intestine and in other situations, and chronic suppuration in any part, have a relation of causation to this form of renal disease. Todd, Garrod, and other British authors have observed the frequent occurrence of the small kidney in persons affected with gout. That the latter affection is often involved in the causation is doubtless true, but the connection is by no means sufficiently constant to warrant, as a distinctive title of this form of renal disease, the name "gouty kidney." Facts show that the absorption of lead into the system may lead to the development of the small kidney. [It does so, in all probability, in an indirect manner through the medium of the gout to which it gives rise. Garrod found that thirty per cent. of his gouty patients in hospital practice had been exposed to the poisonous action of lead.—H.]

Chronic Bright's disease not infrequently supervenes in protracted cases of diabetes mellitus. In these cases the latter is probably causative. In some of these cases there is a remarkable tolerance of the disease of the kidneys, but in some cases the renal affection has a rapid course, life being speedily destroyed by uræmic coma.

In some instances an hereditary element seems to be involved in the causation of chronic Bright's disease. A number of members of the same family may be affected with the disease.

DIAGNOSIS.—The diagnosis of chronic as of acute Bright's disease is to be based on the evidence afforded by examinations of the urine. It is always to be borne in mind that transient albuminuria is a symptom occurring in the course of many diseases. Albumen in the urine is found in cases of all the essential fevers, inclusive of lobar pneumonia, diphtheria, erysipelas, etc. etc. In these connections it denotes hyperæmia of the kidneys or parenchymatous degeneration. Generally the amount of albumen is small. On the other hand, it is to be borne in mind that albuminuria is not an invariable symptom in cases of chronic Bright's disease, nor is the presence of a few casts a sure sign of Bright's disease. These may be found in other conditions, both with and without albuminuria. In general, the diagnosis is rendered sufficiently easy and positive by persistent albuminuria and casts of the different kinds which have been described, together with dropsy and symptoms pointing to uræmia; but the occasional latency of the disease, exclusive of symptoms referable to the urine, is not to be lost sight of. Not very infrequently albuminuria and casts show disease to exist when dropsy and other diagnostic symptoms are wanting. The disease is always to be suspected in cases of coma or convulsions, of cephalalgia or neuralgia in other situations, of repeated attacks of epistaxis, of cerebral hemorrhage, especially in persons before the middle period of life, of vertigo and other forms of cerebral disorder, of amaurosis and other forms of paralysis, of serous inflammations, of persistent vomiting or purging, and of anæmia and impaired muscular strength, whenever the etiology is not otherwise intelligible. In short, it is a good rule in practice to examine the urine in all cases, whether symptoms point to the kidneys or not, and repeated examinations should be made whenever there are any grounds for a suspicion of the existence of renal disease. To determine the coexistence of Bright's disease or to exclude this disease in all affections is of much importance. Of course the urine is to be examined repeatedly in order to ascertain the persistency of albumen or casts, together with other morbid changes.

When acute diffuse nephritis supervenes upon chronic Bright's disease, it may be difficult to determine the prior existence of the chronic affection, and such cases may lead to the erroneous supposition that the chronic is a sequel of the acute disease.

A difficulty in the way of determining the particular forms of chronic disease represented in individual cases is the fact that the different forms are not infrequently combined. In typical cases of each form, however, the diagnostic points are sufficient for the differential diagnosis, but even then mistakes in diagnosis cannot always be avoided. These points, which have been already presented in the Clinical History and Causation, are as follows:

1. *The Large Kidney without Waxy Degeneration.*—The existence of this form is probable whenever the chronic follows the acute disease. In trusting exclusively to this diagnostic point, however, there would be a liability to error arising from the fact that the acute disease may occur in a patient already affected with either the small or the waxy kidney. Much or considerable general dropsy, assuming that cardiac lesions are not involved in its causation, denotes the large kidney. A scanty secretion of urine, with a large proportion of albumen, abundant sediment, and the specific gravity not low, has the same significance. Hypertrophy of the left ventricle of the heart without valvular lesions may occur in this form of Bright's disease when the affection is of sufficient duration. The amount of urine is then increased. Uræmic phenomena—namely, coma and convulsions, cephalalgia, impaired vision, vomiting, diarrhœa, and inflammation of serous membranes—are of less frequent occurrence than in cases of the small kidney; and when they occur they are preceded by the symptoms which are diagnostic of the large kidney. Anæmia is constant, and often exists to a marked degree. The youth of the patient is a point in favor of the large as contrasted with the small kidney. The absence of phthisis and gout is a point of some weight.

2. *The Small Granular Kidney.*—In this form the disease not infrequently is latent as regards any obvious symptoms prior to uræmic manifestations. The minor manifestations—namely, headache, vomiting, impaired vision, etc.—may be the first to occur, or those of a graver character—namely, coma and convulsions, pulmonary œdema, and pericarditis—may occur without any antecedent events pointing to renal disease. Uræmic phenomena are much more frequent in this than in the other forms. Dropsy is often wanting, and it rarely exists to much extent. The urine is usually increased considerably in quantity (polyuria); its specific gravity is low; albuminuria is often slight, and at times may be wanting. The characters of the pulse and increased intensity of the aortic second sound of the heart, which denote arterial tension and hypertrophy of the left ventricle, are so common in this form, and comparatively so infrequent in the other forms, that they have much weight in the differential diagnosis. The age of the patient has diagnostic weight. In the great majority of cases the age is between forty and sixty. The coexistence of gout or of lead-poisoning has a bearing upon the differential diagnosis.

3. *Waxy Kidney.*—Important diagnostic points relate to causative and coexisting diseases. Antecedent to the renal affection are phthisis, disease of bone, suppurations, ulcers, or syphilis. Enlargement of the liver and spleen from waxy disease is often associated. The urine exceeds the normal quantity. It is pale, clear, and of low specific gravity. Albuminuria is rarely absent, but it is variable as regards its degree, the quantity of albumen being usually less than in cases of the simple large kidney, and more than in cases of the small granular kidney. Anasarca is more frequent and marked than in the small granular kidney, but less so than in the large kidney. Hydro-peritoneum may be out of proportion to the general dropsy, owing to coexisting disease of the liver. Diarrhœa is a frequent symptom, pointing to waxy disease of the intestine. Hypertrophy of the left ventricle does not occur as secondary to the renal affection. Both the minor and the grave manifestations of uræmia are less frequent than in cases of large kidney without waxy

eration, and much less frequent than in cases of the small granular kidney. This form of disease may occur at any age, but it is rare in very early or advanced life. The diagnostic points which have been mentioned apply to the typical waxy kidney. In cases in which parenchymatous changes predominate over the waxy the urine may be scanty, very albuminous, and contain a large number of casts. Dropsy is then usually very marked. In other words, some of the large kidneys with waxy degeneration give the clinical history usually ascribed to large white kidneys without waxy degeneration.

Uræmic coma, with or without convulsions, sometimes occurs suddenly in a patient who is not known to be affected with renal disease. To determine that the coma is due to uræmia in these cases the urine is to be examined with reference to albumen, the presence of casts, the specific gravity, and the quantity as soon as practicable; and the catheter should be resorted to, if necessary, in order to obtain a specimen with as little delay as possible. Apoplexy, congestive or from extravasation of blood, meningitis, epilepsy, narcolepsy, and alcoholism are the affections to be excluded in cases of uræmic coma occurring suddenly or when the previous history cannot be ascertained.

PROGNOSIS.—In a large proportion of cases the different forms of chronic Bright's disease destroy life sooner or later if the patient be not cut off by an intercurrent affection. The duration in fatal cases varies greatly in different cases. It is difficult in many instances to determine the actual duration, because the disease is usually developed imperceptibly and has continued for a greater or less period before its manifestations are observed. From the time when its existence is declared, the fatal termination may take place in a few hours on the one hand, and on the other hand the disease may continue many years. Although recovery does not take place, not infrequently the progress of the disease is stayed or it progresses imperceptibly. The prominent symptoms may disappear, and the patient may enjoy comfortable health for an indefinite period, albumen and casts sometimes ceasing to appear from the urine. The kidneys, like other important organs, such as the heart, liver, lungs, etc., may be damaged to a considerable extent and yet be competent to fulfil their functions sufficiently for the continuance of good health.

Fatal termination is frequently due to accidents or secondary affections, such as pneumonia, pericarditis, œdema of the glottis, cerebral hemorrhage, &c. Coexisting disease of the heart, of the liver, or of other important organs often hastens the fatal termination. The prospects of improvement also depend much on the general condition of the system. As regards the mode of dying, it is by apnoea in some cases, and in some cases purely uræmic. In the former cases uræmic coma, hydrothorax, pulmonary œdema, or œdema of the glottis is the immediate cause of death. In the latter cases long-continued and excessive general dropsy, persistent vomiting, complete loss of appetite and digestion precede death, symptoms of uræmic coma being absent. Of 45 fatal cases among those which I have analysed, in 18 the death was attributable to uræmic coma or convulsions; in 6 the death was due to exhaustion irrespective of complications; and in 21 cases the cause of death related, measurably or entirely, to complications or intercurrent affections.

Examinations of the urine furnish important prognostics. If the urine is found to be loaded with albumen, this, in conjunction with persisting dropsy and marked anæmia, denotes that the disease will probably not be of long duration. Danger from uræmia is to be apprehended in proportion

to the deficiency of urea in the urine. A scanty secretion of urine and a low specific gravity point to imminent danger in that direction. Uræmia may, however, develop when the patient is passing a fair amount of urine.

The prognosis is not the same in the different forms of chronic Bright's disease. It is most unfavorable in cases of the small granular kidney; yet it is certain that with the kidneys considerably damaged from this form life may continue with comfortable health for many years. The form of disease represented by the large kidney without waxy degeneration may exist to a greater or less extent and recovery take place. Bartels cites cases in which there was complete recovery from the waxy kidney. The changes in the small granular kidney do not admit of restoration. Whatever may be the form of disease, it is to be borne in mind that the kidneys may be damaged to an extent equivalent to the loss of the whole of one of the organs, and yet the remaining portion be quite sufficient for life and health.

Of my 102 recorded cases, in 77 the histories extended to either death or a condition which was considered as denoting recovery, and of these 77 cases, in 22 the latter termination was noted. In a few of these cases the affection was acute, and in some, instead of a permanent recovery, there may have been only a temporary suspension of the symptomatic phenomena. Making due allowance for these cases, the result of the analysis affords encouragement to hope for recovery in not an insignificant proportion of cases of chronic Bright's disease; and in many cases the hope may be entertained of an arrest of further progress of the disease.

TREATMENT.—In certain cases of chronic as well as of acute Bright's disease therapeutical indications relate to general dropsy and uræmia. General dropsy, when great or considerable, calls for the same measures as in cases of the acute disease. In general, hydragogue cathartics constitute the most efficient and reliable means of affording prompt relief. If the dropsy be slight or moderate, the saline cathartics suffice—namely, the sulphate of magnesia or soda, especially the so-called bitter waters containing these salts (Friedrichshall, Hunyadi Janos, etc.) or the citrate of magnesia; but if the dropsical effusion be large more active hydragogues are required—namely, elaterium, gamboge, or the bitartrate of potassa with jalap. The acrid or drastic cathartics are to be avoided. The hydragogue may be given in doses sufficient to produce free purging, and repeated after intervals of two or three days, or it may be continued in small doses daily, so as to keep up a moderate draining away of liquid. Elaterium is sometimes well borne in doses sufficient to produce a few watery evacuations daily for a considerable period. When it is important to obtain an efficient hydragogue effect as promptly as possible the elaterium is invaluable. It may be prescribed in doses of from one-sixteenth to one-fourth of a grain hourly until the cathartic operation begins. It should then be at once suspended, in order to avoid vomiting. There is an unnecessary apprehension in the minds of many physicians of dangerous prostration from the use of this drug. I have been led by a pretty large experience to consider it safe when employed in the manner just stated. The sulphate of magnesia in half-ounce doses repeated at intervals of three or four hours is an efficient hydragogue cathartic, and is generally well tolerated by the patient.

Diuretics are much less reliable than hydragogue cathartics. Frequently the kidneys will not respond to them, but in some cases they act efficiently. Experience shows that they may be tried without risk of doing harm. The bitartrate of potassa in doses not large enough to purge, or the acetate of potassa, may be given in conjunction with infusion of digitalis, the infusion of broom, or other vegetable diuretics. I have known the infusion of pot-

sley-root (*petroselinum*) to be remarkably effective as a diuretic remedy. If the state of the stomach and bowels preclude the internal use of diuretics, their external application may be tried after the plan proposed by Christison—namely, an infusion of *digitalis* ℥j, in water ℥xxx, applied to the abdomen by cloths soaked in it or by the spongio-piline. I have known this application to be followed by copious diuresis and disappearance of the general dropsy. A liniment of *digitalis*, iodine, and squill rubbed over the abdomen and limbs will in some instances increase notably the quantity of urine. If continued, however, it soon excites soreness of the skin. As regards *digitalis*, it may be useful in certain cases not only as a diuretic, but by limiting the production of urea. Experimental observations by Mégevaud and Rabuteau, under the direction of Robin of Paris, showed a marked diminution of urea in the urine as an effect of this drug, this effect being greater in proportion to the retardation of the circulation which the drug occasions. The inhalation of the vapor of juniper has proved useful as a diuretic in some cases under my observation when remedies were not tolerated by the stomach. The vapor may be produced by dropping thirty minims of the oil on a sponge dipped in hot water and squeezed. The inhalation may be repeated several times daily. The fluid extract of *convallaria* is useful both in strengthening the heart's action and in increasing the flow of urine.

Sudorifics must be relied upon if hydragogue cathartics be not borne and if the kidneys do not respond to diuretics. The hot-air bath—that is, heated air introduced under the bedclothes—is the most efficient mode of producing diaphoresis. This may be used in alternation with cathartics or diuretics. Patients often express a sense of marked relief after perspiring freely under the use of the hot-air bath, but in some cases it occasions a disagreeable heating of the surface without free perspiration, and if carried too far or repeated too often it produces prostration. Experience in individual cases must be the guide as to its utility and the extent to which it should be carried. The warm bath, perspiration being kept up for some time afterward by covering the patient with an abundance of clothing, may be employed as a substitute for the hot-air bath when the latter cannot be conveniently employed or when its operation is unsatisfactory. *Jaborandi* or its alkaloid, *pilocarpine*, sometimes acts efficiently as a diaphoretic remedy, but it is less reliable than the sudorific measures which act directly upon the skin.

In cases of excessive distension of the integument of the lower limbs and genitals temporary relief may be obtained by making a number of minute punctures of the skin with a pin, the punctures being so superficial as not to draw blood. The amount of water which drains away through these imperceptible punctures is surprising. This method is to be preferred to deep punctures or incisions, which may lead to erysipelas and gangrene. Removal of the dropsical effusion in this way has the advantage over measures which cause its removal by absorption, in that the excrementitious principles contained in the effusion do not re-enter the blood. Uræmic effects have repeatedly been observed to follow the rapid absorption of dropsical effusions.

Hydragogue cathartics, diuretics, and sudorifics are also the means for the elimination of urea in the cases in which symptoms denoting uræmia are present. If uræmic poisoning be manifested by coma or convulsions, diuretics are too uncertain to be depended upon. Active hydragogues and the hot-air bath are indicated. Impending death is to be warded off only by the prompt and efficient action of these measures. We have no knowledge of remedies which will neutralize the toxical properties of urea accumulating in the blood. Elimination, so as to reduce the quantity below the amount requisite to produce poisoning effects, is the only resource. It is a therapeutic

tical object to forestall the development of uræmia sufficient to give rise to poisoning effects in the cases in which an examination of the urine shows a notable deficiency of urea or an examination of the blood-serum shows an excess of this excrementitious principle. A moderate hydragogue action may be maintained for this object, or the hot-air bath may be employed once or twice daily. Under these circumstances diuretics may be adequate if the kidneys respond to them. It might be supposed that diuretics are objectionable on the score of their increasing the excretion of albumen in the urine. Experience shows that they do not produce this effect. Although the quantity of urine is augmented, the amount of albumen is generally not greater than before, and it may even be diminished.

An important caution is not to subject patients to the effects of sudorifics, hydragogue cathartics, and diuretics except when these are indicated by uræmic manifestations or deficient elimination of excrementitious principles. The employment of these measures when these indications for them are not present will tend to disturb the functions of the body and thereby diminish tolerance of the disease. Patients may be injured by active treatment in anticipation of future consequences. The eliminative functions of the kidneys may be adequately performed although albumen and casts be present in the urine in large quantity. On the other hand, eliminative treatment may be urgently indicated when the urine contains little or no albumen and few or no casts.

Certain remedies have been supposed to have a curative effect—namely, the tincture of cantharides, nitric acid, and preparations of mercury. Experience has failed to establish the efficacy of these or other remedies addressed directly to the kidneys. Remedies, however, indicated by morbid conditions associated with the renal disease are often of much utility. Anæmia, which is especially associated in cases of the large kidney, calls for chalybeates and tonics, having reference to improvement of appetite and digestion. Dyspeptic disorders claim appropriate remedies. Antecedent and coexisting affections which may have caused the renal disease or contributed to its progress furnish therapeutical indications. This statement applies particularly to the waxy kidney, but measurably to the other forms. The maxim that to improve to the utmost possible extent the general health of the patient is to promote the restoration from, and the tolerance of, a local lesion which may be irremediable, is important in its application to chronic Bright's disease.

[Nitro-glycerin has been much employed of late in the treatment of Bright's disease, and is a valuable addition to our therapeutic resources. It often increases the secretion of urine when other diuretics fail. It is most effective in cases of contracted kidney, and may be given in doses of $\frac{1}{2}$ minim of a 1 per cent. solution every hour for three or four doses; later in the same dose at longer intervals. It probably exerts its effect by reducing excessive arterial tension.—H.]

Hygienic measures are of the first importance. Alimentation as abundant and nutritious as the powers of digestion will admit of, clothing to secure uniform warmth and activity of the functions of the skin, and such an amount of outdoor life as the strength of the patient will bear, constitute the hygienic management. In all cases, taking into view the correlation of the cutaneous and renal functions, attention to the skin is of special importance. Traveling, and especially long sea-voyages, have been found highly useful. The fact that renal disease is infrequent in tropical and also in cold climates renders it desirable in certain cases for patients to exchange for these climates one which is unfavorable from its variability and humidity. Experience has shown the utility of this measure.¹ In general, warm climates are to be pre-

¹ Vide Dickinson, *op. cit.*

ferred. It is hardly necessary to add that all causes of debility or disorder are as far as possible to be removed. Overtasking the body or mind, exposure to vicissitudes of weather, the use of alcoholic stimulants (save as a means of aiding appetite and digestion, and taken for these objects, if at all, very sparingly), venereal indulgences, and dietetic imprudences are to be interdicted.

Symptoms other than those already referred to in certain cases call for treatment. Cephalalgia and neuralgic pains in different situations call for palliative measures. With regard to the use of opium to relieve pain or procure rest, some writers have inculcated the importance of great circumspection, under the belief that even in moderate doses this drug is liable to produce undue, and even fatal, narcotism if the blood be surcharged with urea. Apprehensions on this score have been greatly exaggerated, if, indeed, there be any foundation for them. I have known opium to be taken habitually in large doses for several months for vomiting and diarrhoea, the urine being loaded with albumen and the dropsy very great, and, so far from its being injurious, life was apparently prolonged by its use. There is reason to believe that opium renders the nervous system more tolerant of the uræmic poison. Opium is indicated by uræmic dyspnoea.

Vomiting and purging, if excessive, claim interference, but it is to be recollected that generally these symptoms denote the vicarious elimination of urea through the alimentary canal. It would be injudicious to attempt to arrest the eliminatory process in this direction, but as excessive vomiting and purging preclude adequate alimentation, palliative measures are to be employed. Relief may be procured indirectly by favoring elimination through the cutaneous surface by means of the hot-air bath. Direct palliation may be obtained by pieces of ice taken into the stomach, by rubefacients or dry cups applied to the abdomen, and by the internal use of hydrocyanic acid, creasote, the oxalate of cerium, and the preparations of bismuth. The latter are often highly useful. The dilute sulphuric or the hydrochloric acid may be given with a view to neutralize the ammonia.

Astringent remedies have been much used with a view to restrain the excretion of albumen in cases in which the urine is highly albuminous. Gallic acid, the acetate of lead, and the astringent preparations of iron have been used for this purpose. I have repeatedly made trial of gallic acid for the end just stated, but with little or no effect.

It has been claimed that restriction of the diet to skim milk effects a cure in cases of the large kidney, and that marked benefit is derived from it in the other forms. These claims in behalf of this treatment have not been substantiated, but there is evidence of its utility in certain cases. It may be tried, but if the symptoms do not within a short period show its utility, it should not be persisted in. Milk, however, may with advantage enter largely into the diet in the different forms of Bright's disease. Buttermilk is sometimes preferred by patients. Owing to the loss of the albumen in the blood from its elimination by the kidney, it is important, if the degree of albuminuria be great or considerable, to make up this loss by a highly albuminous diet.

The treatment of complications, such as serous inflammations, or of affections which may be accidentally associated with chronic Bright's disease, is to be modified by the coexistence of the latter. Active therapeutic measures which, under other circumstances, might be admissible are contraindicated. General or local bloodletting, mercury, and other depressing measures, as a rule, are injudicious. If there be exceptions to this rule, they are of rare occurrence.

In conclusion, the management, as has been seen, does not embrace special

medication, but in addition to remedies for particular symptoms or effects and the treatment of concomitant affections it consists, in a great measure, in the removal of morbid causes and in hygienic regulations. The object is not to effect recovery from damage that has been done, but to prevent further injury of the diseased organs, recollecting that the existence of a certain amount of disease is not incompatible with the continuance of life and comfortable health for an indefinite period. The advantage of an early diagnosis is very great in this disease. The same consideration is applicable here as in cases of pulmonary tuberculosis—namely, inasmuch as the object to be hoped for is an arrest of the progress of the disease, the earlier its existence is ascertained the less will be the amount of damage before the disease is stayed.

CHAPTER II.

ACUTE INTERSTITIAL OR SUPPURATIVE NEPHRITIS.—DISEASES OF THE URINARY PASSAGES.—PERINEPHRITIC ABSCESS.

Acute Interstitial or Suppurative Nephritis.—Pyelo-nephritis: Anatomical Characters; Clinical History; Causation; Diagnosis; Prognosis; Treatment.—Pyelitis.—Pyelonephrosis.—Hydronephrosis.—Renal Colic and Nephro-lithiasis.—Perinephritic Abscess.

Acute Interstitial or Suppurative Nephritis—Pyelo-nephritis.

THE most common form of suppurative nephritis is that in which a number of small abscesses are present in one or both kidneys. This disease is called also acute interstitial nephritis and (when there is coincident inflammation of the renal pelvis) pyelo-nephritis. Large collections of pus in the substance of the kidney, constituting a single abscess or several abscesses, are rare, and are generally due to traumatism or to extension of suppurative inflammation from adjoining parts.

Suppurative nephritis is caused by the presence in the kidney of micro-organisms capable of exciting suppuration. These organisms usually are micrococci, and can generally be demonstrated without difficulty. The bacteria gain access to the kidney either by the blood-vessels or by the urinary passages.

ANATOMICAL CHARACTERS.—When the bacteria are brought by the blood to the kidneys, the abscesses are called pyæmic or metastatic. Such abscesses are embolic in origin. In this form of acute interstitial nephritis there usually are abscesses also in other organs. Both kidneys are involved. Small, yellowish-white elevated spots, often surrounded by a hemorrhagic zone, are generally seen upon the surface of the kidney after removing the capsule. Such purulent foci are present, as a rule, in both cortex and pyramids. There may be present wedge-shaped white infarctions due to larger emboli. Upon microscopical examination are found foci of pus in which the renal tissue has been entirely destroyed. It is not always easy to demonstrate microscopically the presence of bacteria in the fully-formed abscesses. In an earlier stage of

recess colonies of micrococci can be found in the capillaries. Around colonies the tissue may appear normal or it may be necrotic for a certain distance. Around such necrotic spots, containing colonies of micrococci, a mass of pus-cells makes its appearance. Thus, all stages in the formation of abscesses can frequently be demonstrated.

The appearances when the bacteria make their way to the kidney through the urinary passages are somewhat different. In these cases the pelvis of the kidney and the bladder are usually inflamed. The affection is a pyelo-nephritis. The abscesses appear as yellowish-white streaks, and they often extend to the papillæ through the pyramidal and cortical portions. The kidneys are much swollen. Purulent foci are generally evident upon the surface of the kidney after stripping off the capsule. Colonies of micrococci are found in the urinary tubes. Pus-cells accumulate in the interstitial tissue and in the tubules, and lead to a destruction of the renal tissue.

In most cases of acute interstitial nephritis the suppurative inflammation is in a large number of more or less circumscribed foci. In rare instances it is a diffuse suppurative inflammation of the whole kidney.

Large renal abscesses are not common in the form of disease which has been described. Many cases which have been described as renal abscess are really examples of pyonephrosis, an affection which will be considered in the next article. That large collections of pus may, however, in rare instances be formed primarily in the substance of the kidney cannot be doubted.

CLINICAL HISTORY.—The miliary abscesses in the kidneys which occur in pyæmia give rise to no marked local symptoms. The urine undergoes no characteristic modifications. It may, however, contain pus-corpuscles. Miliary renal abscesses are less common than those in the lungs, liver, and spleen, if the pyæmia caused by acute ulcerative endocarditis be excluded. Acute interstitial nephritis supervening upon disease of the urinary passages is of grave import. The symptoms are those of severe constitutional disturbance—namely, repeated chills, irregular fever, delirium, somnolence, etc. These symptoms denote the presence of some toxic agent in the blood. They are attributed by some to uræmia, by some to ammoniæmia, by some to septicæmia or pyæmia. The urine, usually diminished in quantity, is often ammoniacal. It may be albuminous and may contain casts. Alterations in the urine, however, are not diagnostic of this disease. The symptoms distinctly point to a blood disease. The nephritic disease may be suspected when these symptoms follow the causes which give rise to acute interstitial nephritis. This disease is developed in many of the cases in which death takes place within a few days after an operation for stricture in the bladder or for stricture of the urethra. The diagnosis cannot be made with certainty, as similar symptoms and a fatal issue may follow without the kidneys becoming involved. The prognosis is grave—as much so as in cases of pyæmia, with which the condition seems to be identical. Abscesses may be present in other parts of the body, but they are usually confined to the kidneys.

In the consideration of large renal abscesses, usually of traumatic origin, leading to surgery. These cases are clearly distinct from those of acute interstitial nephritis, as just described. These renal abscesses are sometimes due to suppuration in adjacent parts, and they sometimes occur without any apparent causation; that is, idiopathically. They are to be distinguished from pyonephrosis and perinephritic abscesses, and, clinically, this is not always the case. In renal abscess the constitutional symptoms may be either slight or marked. An essential diagnostic point is a recognizable tumor, sometimes pulsating, referable to the kidney.

CAUSATION.—Suppurative nephritis caused by infectious emboli occurs in many cases of pyæmia and in acute ulcerative endocarditis. It is a rare complication of dysentery and of other diseases. Suppurative nephritis has been observed in cases of actino-mycosis.

As already mentioned, when suppurative nephritis is caused by the entrance of the infectious agent from the urinary passages into the uriniferous tubules, there usually is coincident inflammation of the pelvis of the kidney and of the bladder. This pyelo-nephritis occurs in connection with stricture of the urethra, enlarged prostate, gonorrhœa, stone in the bladder, operations on the genito-urinary tract, and cystitis from disease of the spinal cord or from other causes.

Abscess of the kidney from traumatism is likely to be associated with perinephritic abscess.

Finally, renal abscess may occur as an apparently primary or idiopathic disease without evident cause.

DIAGNOSIS.—Miliary abscesses in the kidney due to pyæmia give rise to no diagnostic symptoms. Pyelo-nephritis consecutive to surgical operations on the urinary tract and to cystitis is to be suspected when the symptoms which have been mentioned in the clinical history are present, these symptoms denoting increased gravity of the disease. Suppurative nephritis of traumatic origin may be diagnosed by means of unilateral pain and tenderness, together with rigors, more or less fever, and other symptoms of constitutional disturbance. The diagnostic evidence of a large renal abscess is the presence of a fluctuating tumor referable to the kidney. In making this diagnosis pyonephrosis and perinephritic abscess are to be excluded, which generally is not easy. An exploratory puncture may be employed to reveal the presence of pus.

PROGNOSIS.—The prognosis in suppurative nephritis secondary to pyæmia, to acute ulcerative endocarditis, and to affections of the urinary passages is fatal. Idiopathic abscess of the kidney and abscess secondary to traumatism may discharge in various directions, as into the renal pelvis, into the peritoneal or the pleural cavity, into the stomach or the intestine, or externally. Recovery has taken place in some of the cases in which the abscess opened externally, and also when the opening was into the pelvis of the kidney or into the intestine. A certain number of cases have been cured by appropriate surgical treatment. In all cases, however, the prognosis is grave.

TREATMENT.—The treatment in pyæmic abscesses of the kidney and in suppurative pyelo-nephritis is directed to the general symptoms. In cases of cystitis, or of conditions likely to occasion cystitis, measures to prevent the development of pyelo-nephritis are of great importance. These measures relate to the prevention of the accumulation and of the decomposition of urine in the bladder, to the cleansing of the bladder, and to the treatment of the cystitis. Great care is to be exercised lest infection should occur through the use of unclean catheters. The treatment of traumatic and of large renal abscesses is mainly surgical. The abscess is to be opened, and, if necessary, the diseased kidney to be extirpated, according to established surgical principles.

Pyelitis—Pyonephrosis.

Inflammation of the mucous membrane of the renal pelvis is called pyelitis. In the majority of cases pyelitis is due either to a calculus in the pelvis of the kidney or to some disease of the lower urinary passages, &c.

cularly cystitis. A moderate simple pyelitis is not uncommon as a complication of various infectious diseases or as a result of the elimination of toxic substances by the kidney, but in these cases the affection is not of much clinical importance.

ANATOMICAL CHARACTERS.—The slighter grades of simple pyelitis (often called catarrhal pyelitis) are characterized by hyperæmia of the mucous membrane and the exudation of a little mucus and pus. In more severe cases the formation of pus is greater, and may produce a considerable sediment in the urine. In many of these cases with profuse production of pus there is an obstacle to the passage of the urine, and the pus is retained in the dilated pelvis, causing the condition known as pyonephrosis. In pyonephrosis the kidney may take part in the suppurative process or it may simply undergo atrophy from pressure. In extreme cases a large sac containing pus is formed, the walls of the sac consisting of the atrophied renal tissue and the coats of the renal pelvis. In the so-called diphtheritic pyelitis discolored sloughs and ulcers are present in the mucous membrane in connection with fibrinous exudation. The term diphtheritic is used in this connection in its anatomical sense, and not on account of any relation between this disease and diphtheria. In chronic pyelitis the mucous membrane usually is thickened in places and pigmented, and the cavity of the pelvis contains pus. As has been mentioned in the preceding article, pyelitis is often accompanied with suppurative nephritis, constituting pyelo-nephritis. Chronic pyelitis with obstruction to the flow of urine generally causes a genuine chronic interstitial inflammation of the kidney, with lesions like those in the atrophied kidneys of chronic Bright's disease.

CLINICAL HISTORY.—The symptoms of pyelitis vary according to the variety and the cause of the disease. The simple pyelitis complicating many infectious diseases does not generally give rise to any characteristic symptoms. The leading symptoms of calculous pyelitis are the existence or the history of attacks of renal colic, pain in one of the loins, and the occurrence of mucus, pus, and blood in the urine. Calculous pyelitis more frequently than any other form causes hæmaturia, which may be more or less constant or paroxysmal. As a calculus may be lodged in the renal pelvis without the passage of other calculi along the ureter, there may be no history of attacks of renal colic. The lumbar pain, although not a constant symptom, is of considerable value in diagnosis.

When pyelitis is the result of the extension of inflammation from the lower urinary passages, there is usually more or less pain in the lumbar region. The pain is not generally severe, and it may be slight. There may be some tenderness over the region of the kidney. In severe cases, especially in those complicated with suppurative nephritis and in diphtheritic pyelitis, there is fever, which may be of a pyæmic type, and grave constitutional disturbance. In chronic pyelitis with secondary atrophy of the kidney the urine is often greatly increased in quantity, and the symptoms of the small granular kidney may be developed.

When there is marked pyonephrosis a fluctuating tumor may be appreciated in the region of the kidney. Exploratory puncture with a hypodermic needle will reveal the presence of the pus.

CAUSATION.—It is doubtful whether pyelitis ever occur as a purely idiopathic affection, although in some cases it may not be possible to discover the cause. Pyelitis may be produced by wounds penetrating the pelvis of the kidney, but rarely, if ever, by contusions. One of the most frequent causes

of this affection is the local action of calculi. Such calculi may occupy a large part of the renal pelvis and send offshoots into the calices. Other foreign bodies, such as parasites (*strongylus gigas*, *distoma hæmatobium*, and hydatids) are rare causes. An important cause of pyelitis is obstruction to the flow of urine, leading to the accumulation and decomposition of the urine in the renal pelvis. In these cases some inflammatory irritant is present. The obstruction may be in the ureter, the bladder, or the urethra. Such obstructions are furnished by calculi, tumors, enlarged prostate, stricture of the urethra, phimosis, and paralysis of the bladder in cases of paraplegia. An inflammatory irritant may gain access to the bladder, and thence to the pelvis of the kidney, without any obstruction to the flow of urine. Here belong the cases of pyelitis secondary to gonorrhœa, to specific vaginitis and urethritis in females, and to surgical operations in the genito-urinary tract. In these cases cystitis is nearly always present. Sometimes pyelitis is secondary to disease of the kidney. The pyelitis secondary to smallpox, scarlet fever, and other infectious diseases, and that secondary to the elimination of cantharides and other toxic substances from the kidney, is of comparatively little practical importance. Tuberculous and cancerous pyelitis will be described subsequently.

DIAGNOSIS.—The diagnosis of pyelitis is to be based on characters pertaining to the urine in conjunction with more or less pain and constitutional disturbance, cystitis being excluded.

Pus-cells and (especially in calculous pyelitis) red blood-corpuscles are found in the urine. To determine that these cells are derived from the renal pelvis it is necessary to exclude inflammatory affections of the bladder and of the urethra. This can sometimes be done by the symptoms and by physical exploration. It is not, however, in all cases possible to exclude cystitis. In uncomplicated pyelitis the urine is generally acid, whereas in cystitis it is usually alkaline, but this rule has less diagnostic value than is often assigned to it. On the one hand the urine may undergo ammoniacal decomposition in pyelitis, and on the other hand the acid reaction does not of necessity exclude cystitis. Moreover, an uncomplicated pyelitis is rare. In many cases there is coincident inflammation of the bladder. It is a prevalent view that there are characteristic epithelial cells lining the renal pelvis, and that when these cells appear in the urine the diagnosis of pyelitis is established. It is admitted that these cells are not present in all cases, and that they are found more frequently at the onset than in the later stages of the disease. The cells considered characteristic of pyelitis are described as oval, pyriform, fusiform, and caudate cells. The presence of these cells in the urine is not pathognomonic of pyelitis. It is generally admitted by histologists that no essential differences exist between the epithelial cells of the bladder and those of the pelvis of the kidney. Both belong to the so-called transitional type and are characterized by the variety of forms which they present. The cell-forms which are described as characteristic of pyelitis may also be derived from the bladder.

The occurrence of paroxysms of pain characteristic of the passage of a calculus along the ureter, and the expulsion of calculi or gravel from the bladder, are important diagnostic events. The sudden discharge of pus in more or less abundance with the urine shows that an accumulation in the pelvis of the kidney has escaped through the ureter into the bladder. Sometimes the ureter on the diseased side becomes obstructed by the entrance of a calculus, and in this case the urine which is voided, being excreted only by the healthy kidney, may be clear and normal in appearance.

Pyelitis caused by calculi will be likely to be limited to one kidney, but if

it follow cystitis or retention of urine from an obstruction beyond the ureter, both kidneys will be likely to be affected. Complete or very great obstruction, causing an accumulation of urine within the pelves of both kidneys, leads speedily to uræmia. Complete obstruction, however, limited to one kidney, may exist for an indefinite period without leading to uræmia, the other kidney being sufficient for the excretion of the urine. The accumulation of pus in the pelvis of one kidney may be sufficient to occasion a fluctuating tumor which may be felt through the abdominal walls. This tumor may attain a large size, and in women it may simulate an ovarian cyst. It is to be differentiated from perinephritic abscess.

An accumulation of purulent matter within the pelvis and calices, if the ureter remain permanently obstructed, generally eventuates in perforation and the discharge of the pus in some direction, provided the life of the patient be sufficiently prolonged. The source of the pus is to be determined by the antecedent and coexisting symptoms which point to the seat of the affection. The pus may make its way in an outward direction, giving rise to a subcutaneous purulent collection. It may be discharged into the peritoneal cavity, causing a fatal peritonitis. A case in which these two events occurred has fallen under my observation. Not infrequently the pus has escaped by perforation into the intestine. It has been known to pass into the pleural cavity and into the bronchial tubes.

PROGNOSIS.—The gravity of pyelitis depends much on its causes. If produced by an extension of inflammation in cystitis, and if there be no permanent obstruction to the flow of urine and pus into the bladder, a favorable termination may be looked for. If due to the presence of calculi, and if these make their way into the bladder before destruction of the kidney ensues, recovery will be likely to take place. If from the size of the calculi their escape be impossible, the inflammation will probably continue and the prognosis is unfavorable. Cases have been observed of pyelitis caused by a large calculus in which, after having led to complete destruction of the kidneys, the inflammation has ceased and the calculus has remained encysted by the renal capsule, giving rise to little or no inconvenience, the remaining kidney doing all the work of renal elimination. Permanent obstruction to the flow of urine from the pelvis and calices of both kidneys, dependent on cystitis or retention of urine in the bladder from whatever cause, leads to destruction of the renal parenchyma and death from uræmia. An accumulation of urine and pus in the pelvis and calices of one kidney may prove fatal by perforation into the peritoneal cavity. If the discharge take place either into the intestinal canal or externally, the patient is likely to be worn out by the prolonged drain and constitutional disturbance.

The **TREATMENT** in cases of pyelitis must have reference to the causation. If dependent on retention of urine from stricture of the urethra, enlarged prostate, or paralysis, measures to relieve the bladder are of prime importance. If consecutive to cystitis, the latter claims appropriate treatment. Quietude is to be enjoined, especially in cases in which the affection depends on calculi. Soothing applications to the loins and anodyne remedies are indicated in proportion to the amount of pain. If the affection become chronic, the balsam of copaiba and other balsamic remedies, also boric acid and benzoic acid, are sometimes useful. Liquids should be taken freely in order to dilute the urine. If the accumulation of pus (pyonephrosis) form a tumor which presents itself in an accessible situation, it should be opened after an exploratory puncture. Tonic and supporting measures are required after the opening of the abscess either externally or into the alimentary canal.

When a calculus is lodged in the pelvis of one kidney it may be justifiable to make an incision and extract the calculus or even to extirpate the kidney. Surgical works are to be consulted for the principles guiding the treatment in such cases.

Hydronephrosis.

Hydronephrosis is the name given to dilatation of the pelvis and calices of the kidney by an accumulation of urine in consequence of some obstruction in the urinary passages. This dilatation leads to atrophy of the renal tissue. The obstruction may be seated in the pelvis, ureter, bladder, or urethra, and consequently the dilatation may involve not only the pelvis, but also other parts of the urinary passages. Thus, if the impediment be in the urethra, this canal behind the obstruction, together with the bladder and ureters, will be distended if hydronephrosis be produced.

ANATOMICAL CHARACTERS.—Hydronephrosis, especially if the distension be extreme, in the majority of cases is unilateral. It may, however, be bilateral, and it then constitutes a graver affection. The degree of distension varies extremely. It may be insignificant, or the dilatation may lead to the formation of an enormous sac filling most of the abdominal cavity and containing several gallons of fluid. From the pressure of the liquid in the dilated pelvis and calices the kidney-substance wastes and gradually disappears. At first the papillæ are flattened, and afterward the pyramids are further encroached upon, and finally disappear. The cortical substance also undergoes atrophy. This wasting of the kidney is accompanied usually by increase of its interstitial tissue. It is very rare to find the hydronephrosis and the atrophy of the kidney so extreme that no remnant of the renal parenchyma can be found. Even in large hydronephrotic cysts it is the rule to find a thin border, or at least islands, of renal tissue upon the cyst-wall. A very large hydronephrotic sac sometimes consists of a single cavity. Usually, however, a number of membranous septa project from the wall into the cavity of the sac and give to its external surface a lobulated appearance. These septa partially enclose smaller cavities or sacculi which represent the dilated calices, and which, therefore, communicate by wide mouths with the main cavity or dilated pelvis. These septa may be prominent or may be reduced to narrow ridges on the inner wall of the sac. The walls of a hydronephrotic sac consist, in addition to atrophic kidney-substance, of dense vascular fibrous tissue. The outer surface may be roughened by adhesions to adjoining parts. According to the seat of obstruction one or both ureters may be dilated. A dilated ureter may reach the size and present the appearance of a coil of small intestine. With unilateral hydronephrosis and considerable atrophy of the kidney the other kidney is often hypertrophied.

The liquid contained within a hydronephrotic cyst varies in its composition. It usually has the appearance of watery urine. It is clear in most cases, but it may be discolored and rendered somewhat turbid by admixture with blood, pus, or epithelium. The specific gravity is low, and the reaction often slightly alkaline. The urinary constituents are usually present, but urea and uric acid may be in small amount or even entirely absent. A small quantity of albumen is almost invariably found. In a few cases the contents have consisted of a gelatinous, colloid substance. Paralbumen, the modified form of albumen present in ovarian cysts, has also been discovered in the fluid of hydronephrosis.

CAUSATION.—The causes of hydronephrosis are conveniently divided into

congenital and acquired. Of 52 cases of hydronephrosis collected by Sir William Roberts, 20 were congenital. *Congenital* causes are the following: 1, A supernumerary renal artery crossing and compressing the ureter near its origin; 2, narrowing or obliteration of the orifices or of the lumen of the ureter; 3, a valve-like impediment produced by an oblique insertion of the ureter into the pelvis; 4, the insertion of the ureter into the upper instead of the lower part of the pelvis; 5, certain abnormalities of the bladder or of the urethra, as vesical diverticula, atresia of the urethra, etc. Congenital hydronephrosis is often associated with malformations of other organs, as imperforate anus, hare-lip, etc.

The causes of *acquired* hydronephrosis may be classified as follows: 1. The impaction of substances in the renal pelvis or in the ureter. Calculi impacted in these parts are among the most frequent causes of this affection. Much less frequently the lumen of the ureter is obstructed by coagula of blood or by parasites (*echinococcus*). 2. Disease of the walls of the ureter, causing partial or complete obliteration of its lumen. To this group of causes belong inflammatory thickening, cicatricial stenosis from ulcers, and tumors, especially cancer. 3. Pressure upon the ureter from without. The causes of pressure include pelvic tumors, inflammation of the pelvic connective tissue or of the pelvic peritoneum, prolapse of the uterus, retroflexion of the pregnant or of the non-pregnant uterus, and distension of the rectum. Cancer of the cervix uteri is very frequently complicated by hydronephrosis. It is exceptional for hydronephrosis to be caused by the pressure of an ovarian cyst. The newly-formed fibrous tissue resulting from parametritis and from pelvic peritonitis may compress the ureter. Some of the causes named produce hydronephrosis—not by pressure, but by exerting traction upon the ureter and so causing bends and distortions in its course. 4. Diseases of the bladder which involve one or both of the orifices of the ureters. This class of causes comprises hypertrophy of the coats of the bladder, abscess in the vesical wall, neoplasms, particularly cancer, and large calculi. 5. Affections narrowing the calibre of the urethra. These causes are stricture and the so-called hypertrophy of the prostate. In a few cases hydronephrosis has been attributed to phimosis. Hydronephrosis does not follow these causes until after the bladder has become incapable of overcoming the urethral obstacle. In cases of urethral obstruction, therefore, hydronephrosis is due to a secondary affection of the bladder. 6. In not a few cases no cause of the hydronephrosis has been found. With some of the largest hydronephrotic sacs the autopsy failed to reveal any impediment to the flow of urine. In some of these cases it is believed that a calculus, once impacted in the ureter, has been dissolved or dislodged. In other cases it is probable that some not very obvious cause escaped detection. The largest hydronephrotic cysts are found more frequently with partial than with complete obstruction in the ureter.

CLINICAL HISTORY.—With double congenital hydronephrosis the fœtus is generally not viable. There are cases, however, in which life has been continued in apparent health for many years. A moderate degree of hydronephrosis, whether unilateral or bilateral, is unattended by recognizable symptoms. One kidney may be destroyed by the development of a hydronephrotic sac without any symptoms referable to this condition. In this case the other kidney, which is usually hypertrophied, excretes the normal quantity of urine. If, however, the ureter of the remaining kidney become permanently obstructed, death ensues within a few days with symptoms of *uræmia*. In cases of double hydronephrosis the condition is manifestly grave if the renal tissue be sufficiently impaired to interfere with its functions.

Under these circumstances the urinary constituents are imperfectly eliminated from the body, and death ultimately ensues, usually with the manifestations of uræmia. An important diagnostic sign of hydronephrosis is the discovery of a tumor in the lumbar region. It is only when the hydronephrotic sac is of considerable size that a tumor can be detected. The tumor is fluctuating and presents in some cases a lobulated surface. It has the characteristics of a tumor taking its origin from the kidney, among the most important of which is the existence of the tympanitic resonance of the colon over its anterior surface. This sign, however, may be wanting, the colon being pushed to one side by the tumor. A symptom of almost pathognomonic value is the disappearance of the tumor coincident with the discharge of a large quantity of pale liquid by the bladder. This symptom is not common. It is, of course, present only when the obstacle to the flow of urine is removed or when there is only incomplete obstruction, which latter is more frequent. A hydronephrotic tumor is not painful. It may give rise to symptoms by compression of other parts. Thus obstinate constipation may be due to compression of the colon. The urine presents no abnormal characteristics in most cases of hydronephrosis. As already mentioned, it may be suddenly increased in amount by discharge of the contents of the cyst. If both kidneys be so much involved that their function is interfered with, the urine is usually diminished in quantity. Important symptoms may be referable to the conditions causing hydronephrosis, such as those of renal colic, uterine cancer, etc.

DIAGNOSIS.—If the accumulation of liquid in the renal pelvis be small, the disease cannot be diagnosticated. The recognition of one or more of the various causes of hydronephrosis which have been mentioned is of great importance in the diagnosis. The presence of a tumor and its subsidence or diminution in size, coincident with the discharge of a large quantity of urine, are symptoms which are sometimes available in making the diagnosis. Large hydronephrotic sacs filling the greater part of the abdominal cavity may be mistaken for ascites or for ovarian cysts. Such sacs have repeatedly been mistaken for ovarian cysts, and have been punctured on this supposition. The attempt has even been made to remove hydronephrotic cysts by laparotomy under the belief that an ovarian cyst was present. Some of the characteristic signs of an ovarian cyst have been mentioned on p. 530. It must be admitted that in some cases the diagnosis is very difficult. The presence or absence of urea in liquid withdrawn by an exploratory puncture cannot serve as a diagnostic point. Urea may be present in fluid from an ovarian cyst. It is frequently small in amount, and may be absent in hydronephrosis. The colon is often present over a hydronephrotic cyst, and it is found very exceptionally in front of an ovarian cyst. (The reader is referred to the article on Ascites for the symptoms and physical signs of this condition, p. 526 *et seq.*) Hydronephrosis may be confounded with pyonephrosis. With the latter condition there is more constitutional disturbance with rigors and hectic fever. The presence of pus in the fluid removed by exploratory puncture renders the diagnosis of pyonephrosis positive if other sources of pus can be excluded. The diagnosis also involves the exclusion of hydatid cysts of the kidney, perinephritic abscess, and large renal cysts.

PROGNOSIS.—The prognosis of hydronephrosis depends upon the extent to which the functions of the kidneys are interfered with and the consequent danger of uræmia. Unilateral hydronephrosis is unattended with danger so long as the remaining kidney does its work adequately; but if this kidney become diseased or if its ureter become obstructed, life is endangered. Dou-

Hydroureter is grave in proportion to the liability to uræmia. The liability to rupture of a hydronephrotic sac is so slight that it hardly enters into the prognosis.

TREATMENT.—An important object in the treatment is the removal of the cause of obstruction. This cannot often be accomplished. The measures to be pursued for that object in individual cases are to be determined by the nature and seat of the obstructing cause. In some instances, by means of rubbing and kneading over the sac or along the course of the ureter, an obstruction has been overcome or the urine has been made to pass beyond the obstructed part. These manipulations should not, of course, be so forcible as to cause pain or to incur any risk of rupture. Removal of the liquid by aspiration has proved successful. Using a small aspirating needle or trocar, this measure is attended with little if any danger of the escape of the liquid into the peritoneal cavity. For this reason it is to be preferred to tapping without aspirating. The treatment in other respects is to be governed by the local and general symptoms in each case. Free opening of the sac and drainage and the entire removal of the tumor are surgical procedures which have thus far been attended by favorable results.

Renal Colic and Nephro-lithiasis.

Urinary concretions or calculi are generally formed within the renal cavities. Calculi of small size may pass from the kidneys to the bladder, giving rise to little or no inconvenience, and, having reached the bladder, they are either discharged with the urine, or, remaining in the bladder, they increase in size and may require surgical interference for their removal. In some cases calculi within the renal cavities, increasing in size, become too large to pass along the ureter, and are consequently retained. As has been seen, retention of urine within the pelvis and calices of the kidney, pyelitis, renal abscess, and destruction of the renal parenchyma are sometimes attributable to the presence of calculi or a calculus. A calculus retained in the pelvis of the kidney may continue to increase in size, and, leading to atrophy of the parenchyma, it may acquire a bulk nearly as great as, or perhaps even greater than, that of the healthy organ. Calculi not too large to pass through the ureter, and not small enough to pass with facility, occasion during their passage more or less pain and constitutional disturbance. The amount and duration of the pain caused by the passage of a calculus are in proportion to its size and the roughness of its surfaces. The pain begins when the calculus enters the duct, and ends when it reaches the bladder. The paroxysm is analogous to that occasioned by the passage of a gall-stone from the gall-bladder to the duodenum. The latter is commonly known as hepatic colic, and the paroxysm of pain occasioned by the passage of a renal calculus is called *renal colic*. In rare instances attacks of renal colic are produced by the passage of coagulated fibrin and of an hydatid vesicle through the ureter.

A paroxysm of renal colic is usually developed suddenly. The attack, however, may be preceded by more or less pain or a sense of uneasiness due to irritation or perhaps inflammation caused by the presence of calculi in the pelvis of the kidney. The paroxysm quickly attains its maximum of intensity. The pain in some cases becomes exceedingly intense. It is referred to the situation of the kidney on one side; that is, by the side of the last dorsal and the first lumbar vertebrae. The pain radiates from this point in different directions, but especially along the course of the ureter, extending frequently to the groin and thigh. In the male, pain is generally felt in the testicle, which is often, but not always, drawn upward by the

contraction of the cremaster muscle. Frequently the pain is described as lancinating or tearing. It is sometimes so excessive as to force the patient to groan and cry aloud; he tries a variety of positions to obtain relief, walks about the chamber, and compresses the abdomen with the hands as in intestinal colic. The pain continues without intermission, but there occur exacerbations and remissions. The urine in most cases is notably diminished. The patient experiences a frequent or constant desire to micturate, passing only a few drops at a time. The sensation is well expressed by the term *tenesmus of the bladder*. Not infrequently the urine is bloody. If it contain pus or muco-pus, either pyelitis or cystitis coexists.

With these local symptoms are associated those denoting more or less constitutional disturbance—namely, anorexia, thirst, nausea, and vomiting, coldness of the surface with sweating, and feebleness of the circulation. The countenance is pallid and expressive of anguish. Suddenly, after a duration varying considerably in different cases, the paroxysm ends. The pain abruptly ceases. An abundant discharge of urine takes place. The calculus has reached the bladder, and if care be taken for some time afterward to examine the urine it may be found at the bottom of the vessel. As the passage of a calculus by the urethra, even of one which has caused severe renal colic, may occasion no pain, it is no proof that a calculus is retained in the bladder that its escape with the urine has not been noticed. The general symptoms rapidly disappear, and in one or two days the recovery may be complete. In some cases, however, one or more additional paroxysms follow, other calculi contained within the pelvis of the kidneys entering the ureter in consequence of the dilatation caused by the calculus which has just passed. A person who has experienced one paroxysm is liable to recurrences at periods more or less remote. Not infrequently, however, there is no recurrence of a paroxysm.

The duration of an attack of renal colic varies in different cases, but it is usually short. In the majority of cases it lasts but a few hours, but in some cases it continues for one, two, or three days. Although the suffering is often extreme, it very rarely proves fatal. A persistent impaction of a calculus in the ureter, causing obstruction, is followed by hydronephrosis, and following this pyelitis and pyelo-nephritis may become developed. Ulceration may take place at the point of the obstruction, and fatal peritonitis may be produced by the escape of urine into the peritoneal cavity. These are sources of danger happily of rare occurrence. Simultaneous obstruction of both ureters by calculi has been known to occur, causing anuria and uræmic poisoning.

The diagnostic characters of renal colic are—the suddenness of the attack and termination, the situation of the pain and its extension to the groin, thigh, and testicle, the retraction of the testicle, the diminution of urine, the tenesmus of the bladder, hæmaturia in some cases, and the discovery of the calculus. The fact of antecedent attacks having occurred will assist in the diagnosis. The affections to be excluded are—the form of muscular rheumatism called lumbago, lumbo-abdominal neuralgia, enteralgia, and hepatic colic. In lumbago the pain is less severe, is provoked especially by movements of the body, and is felt on both sides. Lumbo-abdominal neuralgia is characterized by tenderness at certain points. (Vide p. 747.) In enteralgia the seat of the pain is within the abdomen. This statement also applies to hepatic colic. In all these affections the characteristic features of nephritic colic are wanting.

The TREATMENT of an attack of renal colic consists of palliative measures. Complete relief depends on the escape of the calculus into the bladder, and there are no means of aiding directly in effecting its passage. The propelling force is derived from the accumulation of urine behind the calculus and

The peristalsis of the muscular coat of the ureter. The copious ingestion of liquids may, by increasing the urinary secretion, hasten its progress. Rubrications to the loins, the warm bath, morphia given hypodermically, if the suffering be excessive, the inhalation of chloroform, constitute measures for palliation.

The discharge of urinary concretions from the body, either with or without symptoms of nephritic colic, constitutes *lithiasis* or *gravel*. The term "gravel" is properly applied only to concretions formed within the body, not those which form in the urine after its emission. Not infrequently concretions are varying in size from that of a pin's head to a small pea pass through the ureter without giving rise to sufficient pain to constitute an attack of renal colic. The composition of the concretions varies in different cases. In the large majority of cases (five-sixths) they consist of uric acid. The urine in these cases is always acid. The concretions may consist of the earthy phosphates, namely, the phosphate of ammonia and magnesia, the phosphate of lime, and the carbonate of lime. Concretions of carbonate of lime are extremely rare in human urine. Ammonio-magnesian calculi are liable to form in cases of cystitis. These concretions are generally not renal but vesical. The urine in these cases is usually alkaline. In another variety the concretions consist of the oxalate of lime. In frequency these come next to the uric-acid calculi. They are known as mulberry calculi. In cases of renal lithiasis the composition of the calculi which occasion the paroxysms may be ascertained from the knowledge of concretions which have been already passed from an examination of the sediment which the urine deposits. If the urine contains uric-acid crystals or abound in the urates or have an acid reaction, the calculus is probably composed of uric acid; and the urine will be likely to contain the phosphates in more or less abundance when the calculi consist of the earthy salts. Oxalate-of-lime or mulberry calculi will be likely to be preceded or accompanied by oxaluria. Oxaluria is not, as was formerly supposed, attended by any characteristic symptoms. It may happen, however, that the calculi giving rise to renal colic are not of recent formation, and the condition of the urine giving rise to their formation may not exist at the time when the attack of colic occurs. A variety of calculus, so far as to be a curiosity, consists of xanthine. Another rare variety is the fine calculus. The condition of the urine in which the latter occurs is called cystinuria. In this condition the urine contains hexagonal tablets of cystine. This, more than any other form of lithiasis, has been shown to be hereditary. Cystinuria may exist without the formation of calculi. It lasts a long time, and sometimes continues indefinitely.

The TREATMENT of nephro-lithiasis, irrespective of attacks of renal colic, depends on the nature of the concretions or the character of the urine. In cases of uric-acid gravel alkaline remedies are indicated. The liquor potassæ, in half-drachm doses thrice daily, may be given, but either the bicarbonate or the citrate of potassa, a drachm twice daily, is preferable. The chalybeate water and the waters of other alkaline springs are well suited to this variety of gravel. The phosphate of soda and ammonia, introduced by Dr. Jackson of Baltimore, is considered as having the power of keeping uric acid in solution in the urine, given in doses of ten grains thrice daily. The phosphate of soda in doses of from a drachm to six drachms is recommended by Keller. The benzoic acid is another remedy, given in doses of eight or ten grains thrice daily. Lithia in the form of the carbonate and the benzoate introduced by Garrod as a remedy which promised to be especially valuable from its forming with uric acid a highly soluble compound. It may be given in doses of five grains three times daily. All these remedies act as

of gravel. The hygeia water may be especially recommended. The phosphatic and oxalate-of-lime concretions often occur issuing from *nervous asthenia*, and the latter condition claims appropriate treatment. Abstinence from articles of diet containing oxalic acid if the concretions consist of the oxalate of lime. [Piperacently lauded as a solvent of uric-acid calculi. There is no solvent action upon these concretions outside of the body, concerning its power to accomplish this within the organism. It may be given in daily doses of 15 grains.—H.]

As already stated, the sedimentary deposits which occur in emission are not properly called gravel. It is important, to cognizance of these as constituting evidence of disorder and liability to the formation of concretions within the kidney of conditions of the urine known as *lithuria*, *oxaluria*, and *phosphuria* respectively in relation to the different varieties of gravel and appropriate treatment, although concretions within the body place. (For further details respecting these and other disorders of the urine, the reader is referred to works devoted to uric

Perinephritic Abscess.

Inflammation of the connective tissue surrounding the kidney is nephritis. The tissue involved is the lax adipose tissue in which is imbedded (the so-called adipose capsule of the kidney) and retro-peritoneal tissue. It is possible to distinguish an adhesive variety of perinephritis. The former is characterized by the formation of new connective tissue. It accompanies tumors and some cases of the kidney. Adhesive perinephritis has no clinical importance and requires no further consideration in this article. Suppurative perinephritic abscess is not a frequent disease, but it is attended by peculiar symptoms and merits separate consideration. On post-mortem examination collection of pus is found occupying the situation of the adipose tissue around the kidney. There may be a number of abscesses, but as a rule there is but a single abscess cavity.

n, and may open by perforation into the pleural cavity or into the abscess may make its way behind the peritoneum into the pelvis. The peritoneum over the abscess is usually thickened. It is rare for the abscess to open into the peritoneal cavity. More frequently the colon in some course is perforated and the pus is discharged into this viscus. Perinephritic abscess has been known to open also into other parts of the intestine, the bladder, and into the pelvis of the kidney; and it may discharge its contents externally in directions other than those named, as in the gluteal region and in various parts of the abdominal parietes. When allowed to discharge its contents spontaneously, the abscess most frequently opens externally in the lumbar region. The pus in perinephritic abscess often contains necrotic tissue. It may be good and laudable or it may be thin and watery.

The latter is particularly likely to be the case when the abscess is caused by infiltration of urine. In very rare instances the abscess has a purulent character. When the abscess is secondary to calculous pyelitis it may be found in the abscess-cavity if ulceration of the pelvic walls or of the ureter have occurred.

In 130 cases of perinephritis collected by Nieden,¹ 70 per cent. were in females; 26 cases were in children. From an etiological point of view it is important to distinguish between primary and secondary perinephritis. Secondary perinephritis is much more common than the primary form. The causes of primary perinephritis are traumatism (by contusions and wounds in or about the kidney), muscular strain, exposure to cold, and severe acute general diseases. Wounds of the kidney means necessarily followed by suppurative inflammation. Perinephritis has been known to develop in the course of pyæmia, of smallpox, of typhus and of typhoid fever, but this complication is extremely rare. Secondary perinephritis is due to disease of neighboring organs. The most common of this second group of causes are affections of the kidney; above all, suppurative pyelitis and pyelo-nephritis in consequence of the irritation of the kidney. Tuberculous inflammation of the kidney has also been complicated by perinephritic abscess. Tumors of the kidney, the rupture of cysts, and the presence of parasites in the renal pelvis are among the causes of this disease. Perinephritis has been attributed to the extension of inflammation from an inflamed bladder. It has been observed more frequently to follow pelvic cellulitis, especially inflammation of the connective tissue about the uterus. Psoas abscess, which so often accompanies the vertebræ, may give rise to perinephritis, but in most cases the sheath of the psoas is an effectual barrier to this extension of the inflammation. Perinephritis may follow typhilitis and perityphilitis; or, in a suppurative process involving the retroperitoneal tissue. Finally, there are cases of perinephritis for which no cause is discoverable.

Increased by motion, is one of the prominent SYMPTOMS. It is referred to the side of the inflammation, and shoots downward to the lower limb. It is confined to the testicle, but there is no retraction of the testicle if the kidney is not affected. There is tenderness on deep pressure. The patient is obliged to lie to the bed and lies with the limbs flexed. There is more or less of body-heat, with the usual concomitants of fever. Rigors and sweats are likely to occur. After a variable period a tumor is felt in the lumbar region. Fluctuation over the site of the tumor is not readily appreciable. There is a local oedema over the tumor. The urine is unaffected unless the kidney is involved. With reference to the local symptoms and the diagnostic value of the purulent collection to descend below Poupart's ligament, see "Perinephritis," *Deutsches Archiv für klin. Med.*, Bd. 22, p. 451, 1878.

ment, to open into the intestine, the bladder, or the vagina, and in some instances into the pleural cavity and the bronchial tubes, is to be borne in mind.

The DIAGNOSIS is to be based on the presence and situation of the tumor, in conjunction with the local and general symptoms denoting inflammation. The symptoms resemble those of suppurative nephritis and pyelitis. These affections are to be excluded by examinations of the urine. In suppurative nephritis the quantity of urine is notably diminished, whereas in perinephritic abscess there is no interference with the renal secretion. The urine in the latter affection contains neither blood nor casts, and but little if any albumen. In pyelitis, with which suppurative nephritis is often associated, the urine contains pus, and often blood.

As soon as the nature of the affection is ascertained or rendered probable the tumor should be explored, and in this way the presence of pus is demonstrated. There should then be no delay in opening the abscess in order to forestall a spontaneous opening in an unfavorable direction. Bowditch has reported 3 cases in which an external opening was made, all ending in recovery. A considerable hemorrhage followed the opening in 1 of the cases. In 2 of the cases the kidney was felt by the finger at the bottom of the abscess.¹ Gibney has reported 28 cases of perinephritis in children, suppuration more or less extensive occurring in 16. In 14 of these cases the abscess was opened by incision, and in 2 cases the opening was spontaneous. With a single exception, in all of the 16 cases recovery was complete. A little lameness remained in the excepted case. Gibney is of the opinion that in a certain proportion of the cases of reputed recovery from hip-joint-disease without lameness or deformity the affection is in reality a perinephritis.²

THE kidneys are sometimes the seat of affections involving structural changes other than those already considered. Carcinoma and the tuberculous affection occasionally occur in these organs. Hydatids and cysts are additional affections in this category. Some of the structural affections of

¹ *Boston Medical and Surgical Journal*, July 9, 1868.

the kidney are of greater pathological than clinical interest. These will receive only brief consideration.

Renal Cysts—Cystic Degeneration of the Kidneys.

The occurrence of cysts in chronic Bright's disease, especially in the small granular kidneys, has already been mentioned. These cysts are rarely larger than a pea. They frequently contain a colloid substance. They are developed chiefly in the cortical substance. They are attributable to dilatation of Bowman's capsules and of portions of the uriniferous tubes. Similar cysts are often found in senile atrophy of the kidney. Cysts may be formed in otherwise healthy kidneys. These are of pathological rather than of clinical interest.

Sometimes the kidney is converted into a mass of cysts between which little or no renal parenchyma can be discovered. This is the *cystic kidney* or *cystic degeneration of the kidney*. Sometimes only one, but usually both kidneys are affected, although not necessarily in the same degree. Cystic degeneration of the kidney may be a congenital or an acquired condition. Cystic kidneys developed during intra-uterine life may attain an enormous size, so as to prove a serious mechanical obstacle to the birth of the fœtus. The severe grades of this degeneration render the fœtus non-viable, but the lighter grades can be tolerated after birth. In many cases there is some other malformation in the body. Cystic degeneration of the kidney is less frequent in adults than in the fœtus. The causes and the symptoms of this condition are not well understood. An advanced degree of cystic degeneration is sometimes found at autopsies of persons who had presented no symptoms referable to the kidneys during life. There is no doubt, however, that the functions of the kidneys may be so impaired by the cystic formations that death may result therefrom, usually with uræmic symptoms. Sometimes uræmia develops rapidly. In the recorded cases the urine has been rather increased than diminished in quantity. The specific gravity is low. Albuminuria is a frequent but not a constant symptom. The development of a tumor is an important symptom in some cases. Without this symptom the diagnosis is impossible, and with it the existence of cystic degeneration is not easily determined. Hypertrophy of the heart has been known to result from cystic metamorphosis of the kidneys. In most cases in which renal symptoms developed the affection had been considered as Bright's disease prior to the autopsy. No other mode of formation of renal cysts than by dilatation of the tubes and of Bowman's capsules has been proven.

Echinococcus or Hydatids of the Kidney.

Hydatids in the kidney are in all respects similar to those in other organs—for example, the liver (*vide p. 557 et seq.*)—and a description of them need not be here repeated. They occur in the kidney more frequently than in any other organ except the liver and the lungs, but according to Davaine they are twelve times less frequent in the kidney than in the liver. Men are oftener affected than women. The disease is rare in this country. One kidney only is affected as a rule to which there are very few exceptions. They do not, therefore, diminish the excretion of urine sufficiently to occasion uræmia. If they interfere with the excretory functions of the affected kidney, the augmented functional activity of its fellow makes up for the deficiency. So long as an hydatid cyst remains intact within the renal parenchyma, it gives rise to no well-marked symptoms, and it may remain completely latent for an indefinite period. It has been found after death when no renal trouble had

been manifested during life. It may attain a sufficient size to form a tumor perceptible by palpation. The symptoms to which it gives rise depend on inflammation, ulceration, and the discharge of echinococci in different directions.

If hydatid cysts open into the pelvis of the kidney, the echinococci pass through the ureter into the bladder and are discharged with the urine. In their passage along the ureter they may give rise to the same train of symptoms as the passage of a renal calculus; in other words, to renal colic. They may also give rise to more or less trouble in their passage through the urethra. Owing to their elasticity, echinococci of considerable size may pass into the bladder and through the urethra without great difficulty and without much pain. Cases have been reported in which they were discharged in great numbers. Their passage may be accompanied by hæmaturia and pyuria. The latter is due to suppuration of the hydatid cyst or to pyelitis. The opening of the cyst is most frequently into the pelvis of the kidney. Echinococci may form the nuclei of calculi in the pelvis of the kidney or in the bladder.

The hydatid cyst sometimes develops in a direction toward the surface of the kidneys and opens into the circumrenal areolar tissue. Suppuration takes place and an abscess forms in the lumbar region, which when opened or allowed to open spontaneously gives exit to echinococci together with pus in greater or less quantity. Hydatid cysts in the kidneys have been known to open into the stomach, intestinal canal, and even into the lungs, the echinococci in the latter case being expectorated. It is possible that here, as in other situations, the parasites sometimes die, and the cyst contracts and becomes obliterated, or contains a certain amount of calcareous matter, a spontaneous cure in this way taking place. Instances of this, however, are extremely rare, and their occurrence has been denied.

The DIAGNOSIS, prior to the discharge of the contents of the hydatid cyst in some one of the situations named, can be made positive only by a microscopical examination of the liquid contained in the cyst, obtained by means of an exploratory puncture and aspiration. The diagnostic characters pertaining to the liquid are the same as in hydatids of the liver. (Vide p. 561.) The hydatid fremitus is a sign rarely available in cases of renal echinococcosis. Hydatids in the kidney are sometimes not readily differentiated from hydatids in the liver or the spleen. Simon recommends an exploration by means of the hand introduced within the large intestine, in order to determine whether the hydatid tumor be renal or not.¹

The TREATMENT is chiefly surgical. An attempt should first be made to destroy the parasite. For this simple aspiration sometimes suffices. Electrolysis is sometimes effectual. The more effective measure is opening the cyst. Simon's operation is as follows: He thrusts in two canulæ, and allows them to remain until adhesions have formed, and then he connects by incision the two openings made by the canulæ. When the tumor is large enough to cause projection of the abdominal parietes it is time to resort to surgical interference. Simon advises first to make trial of aspiration and electrolysis. These are harmless measures. If at the end of six months they be found not to have succeeded, the cyst should be opened in the manner just described.

Renal Tuberculosis—Renal Phthisis.

Tubercles appear in the kidneys in the following conditions: 1, In acute miliary tuberculosis; 2, as a secondary event in pulmonary phthisis; 3, in primary tuberculosis of the genito-urinary organs. Miliary tubercles are usually present in the kidneys in acute miliary tuberculosis. They give rise

¹ *Die Echinococcycysten der Nieren, Stuttgart, 1877.*

to no symptoms, and therefore do not claim clinical consideration. So, too, the few miliary tubercles or somewhat larger caseous nodules which are frequently found in the kidneys in pulmonary phthisis are without clinical significance.

There may be formed in the kidney large and small cheesy masses, accompanied usually by ulcerative destruction of the affected tissues and by similar caseous deposits in the renal pelvis, the ureter, and other parts of the genito-urinary apparatus. This condition is called renal phthisis, nephro-phthisis, or genito-urinary tuberculosis. Extensive tuberculous infiltration of the kidneys and other parts of the genito-urinary system may be secondary to pulmonary tuberculosis, to tuberculosis of bone, or to tuberculosis in other situations, but it is most frequently a primary disease. Primary genito-urinary tuberculosis is far more common in males than in females. In females primary tuberculosis of the uterus and of the Fallopian tubes is more common than primary tuberculosis of the urinary organs. The primary tuberculous deposit in genito-urinary tuberculosis in males is most frequently in the testicles, epididymis, seminal vesicles, or prostate. From these organs the tuberculosis may extend to the renal pelvis and kidney, involving usually, although not always, the bladder and ureter. Less frequently the tuberculosis extends downward from the kidney to the bladder and genital glands. In rare instances the affection is confined to the kidney and renal pelvis.

In renal phthisis caseous masses usually first involve the pyramids and then extend to the cortex. These cheesy masses generally soften and form cavities, which usually, but not necessarily, communicate with the renal pelvis. The whole organ may be destroyed by this process of softening and of excavation. Sometimes only one, but usually both kidneys, are affected, although often in unequal degree. The diseased kidney is usually enlarged, but it may be shrunken. The mucous membrane of the pelvis and of the ureter is usually thickened from infiltration with fresh and caseous tuberculous material, and it presents ulcerations in some places. As in other situations, inflammatory processes are combined with the tuberculous. The lumen of the ureter, as a rule, in certain places is diminished, and as a consequence the pelvis of the kidney is dilated, so that pyonephrosis often complicates the disease. Tuberculous nodules and ulcers may be present in the bladder. There usually are tuberculous nodules in the testicles or in the prostate.

The tubercle bacilli can generally be demonstrated in the tuberculous deposits. In secondary genito-urinary tuberculosis the bacilli may be carried to one of the genito-urinary organs by the blood. It is probable that the ordinary mode of infection in primary genito-urinary tuberculosis is by the entrance of the bacilli through the urethra.

Acute miliary tuberculosis and pulmonary tuberculosis may be sequences of primary genito-urinary tuberculosis.

The SYMPTOMS of renal phthisis are generally those of a severe pyelitis and cystitis combined. In most cases there is pain in the region of one or of both kidneys. The pain is usually dull, but there may be paroxysms of severe pain. Attacks of renal colic may be caused by the passage of blood or of caseous masses along the ureter. The urine contains pus, and at times blood. The hæmaturia is generally moderate in degree, but it may be severe. The reaction of the urine is acid unless a severe cystitis be developed. Detritus consisting of cheesy particles and of connective-tissue fibres is occasionally but not frequently found in the urine. Of capital importance in the diagnosis, is the discovery of tubercle bacilli in the urine. By careful search these can be found in the majority of cases. The method for detecting them is similar to

that employed in examining the sputum (p. 116). When they are discovered the diagnosis of tuberculosis involving some part of the genito-urinary tract is established, but the exact location of the tuberculosis remains to be determined by symptoms. Inoculation in the anterior chamber of a rabbit's eye with urine from cases of genito-urinary tuberculosis produces tuberculosis in the animal operated upon. This procedure has been recommended for diagnostic purposes. Physical examination of the region of the kidney will sometimes reveal a tumor, but often this examination yields only negative results. It is important to examine the testicles and the prostate gland for tuberculous infiltration. The lungs and other organs are also to be examined for tuberculous lesions. Constitutional symptoms develop sooner or later. These are— hectic fever, chills, night-sweats, progressive emaciation, and loss of strength. There may be diarrhœa with or without tuberculous intestinal ulceration. Waxy degeneration of the organs is an occasional result of renal phthisis. Uræmic symptoms do not usually develop in the course of renal tuberculosis. Bright's disease may, however, occur as an intercurrent affection.

Renal phthisis terminates fatally in the great majority of cases. The duration generally is not longer than one or two years. If the affection be localized in one kidney, recovery may take place.

The TREATMENT is directed to the general condition of the patient and to the palliation of local symptoms. The general health is to be kept up and improved as far as possible. The treatment of the local symptoms is similar to that in other cases of pyelitis and of cystitis. The general indications for treatment are similar to those in cases of pulmonary phthisis.

Carcinoma of the Kidney.

A great variety of tumors form in the kidney, but only cancer and sarcoma are of much clinical importance. Sarcoma of the kidney is infrequent, and when it gives rise to symptoms it cannot usually be distinguished from cancer. Cancer may occur in the kidney as a primary or as a secondary growth. It develops secondarily, either in the form of metastases or as a continuous growth from adjoining parts. Secondary renal cancer, although more frequent than the primary form, rarely attains a large size or gives rise to symptoms drawing attention to the kidneys. It has much less clinical importance than primary cancer, and the latter is the form to be considered in this article. Primary cancer of the kidneys is a rare disease, although less infrequent than was formerly believed. It occurs oftener in the first decade of life than in any succeeding decade, and in this it differs from cancer in other situations. Rohrer has collected 115 cases of primary renal cancer. Over one-third of the cases occurred within the first ten years of life. The next largest number of cases were those between fifty and sixty years. Notwithstanding its infrequency, cancer of the kidney is the cancer oftenest met with in childhood. Of the cases of renal cancer in children, by far the largest number fall within the first five years of life.¹ In very rare instances it has been observed as a congenital affection. In the majority of cases primary cancer of the kidney is unilateral. It may, however, develop as

¹ Rohrer, *Das primäre Nierencarcinom*, Inaug. Diss., Zurich, 1874. Of 107 cases in which the age of the patient was stated, 37 were less than ten years, 4 were between ten and twenty, 5 between twenty and thirty, 10 between thirty and forty, 10 between forty and fifty, 17 between fifty and sixty, 10 between sixty and seventy, 3 between seventy and eighty, and 11 were described simply as adults. Of 29 cases of cancer in children collected by Hirschsprung (1868), 15 were of the kidney; 82 per cent. of all renal cancers in childhood fall within the first four years of life (Rohrer).

a primary affection in both kidneys.¹ Males are somewhat more frequently affected than females.

Renal cancer, in the great majority of cases, belongs to the soft or medullary variety. Cancer in this situation may, however, present all grades of transition between the medullary and the scirrhus forms. Colloid renal cancer has also been described. The new growth may appear either as a diffuse infiltration of the kidney or in a nodular form. There may be remnants of intact renal tissue or the entire parenchyma may be destroyed. The size of the tumor is in many cases enormous, and it is a remarkable fact that relatively, and almost absolutely, the largest tumors are met with in children. According to Sir William Roberts, the average weight in children is 8½ pounds and in adults 9½ pounds. The maximum weight was 31 pounds, and this was observed in a child. In the most frequent form of renal cancer the consistence is soft. Not infrequently cavities form containing soft, pulpy, degenerated cancerous material. From the fluctuating feel afforded by these softened masses renal cancer has often been punctured during life under the supposition that a cyst or an abscess was present. The color is not uniform. In most cases a section of the tumor presents a whitish or yellowish appearance mottled with red and brown portions. The red portions are due to dilated blood-vessels and to hemorrhages. When their number is large the red patches give a hemorrhagic aspect to the tumor, whence it derives the name fungus hæmatodes. The brown portions result from pigmentary changes in blood-extravasations. Sometimes the tumor is confined within the capsule, and at other times it invades surrounding parts. In some cases the appearance is as if the tumor took its origin in the connective tissue or the lymphatic glands about the kidney, and secondarily invaded this organ. Those who maintain the epithelial origin of cancer are unwilling to admit that it ever develops primarily in the perinephritic tissue. The tumor usually contracts adhesions to surrounding parts, but sometimes a cancerous kidney is movable. In nearly all cases the colon lies in front of the tumor. Secondary cancerous growths are found in other organs in rather less than half the cases of cancer of the kidney. It is a peculiarity of primary renal cancer, especially in children, that it gives rise to metastases less readily than cancer in other situations.² The secondary deposits are met with most frequently in the retro-peritoneal glands, the lungs, and the liver. The frequency with which the renal vein is involved in the new growth explains the common occurrence of secondary cancerous deposits in the lungs, as by this implication of the veins cancerous material may gain access to the blood-current. Metastases are rare in the lower urinary passages, but cancer of the kidney frequently grows continuously into the renal pelvis, and it may invade the ureter. It is not rare to meet with calculi in the pelvis of a cancerous kidney. It is exceptional for renal carcinoma to cause ulceration of the superjacent integument. The intestine, especially the overlying colon, may be perforated by the cancerous growth. Intestinal fistulæ opening externally have been caused by this disease. The vertebræ in some cases are involved in the malignant growth. Pressure upon the inferior vena cava may cause œdema of the lower extremities. Ascites is rare. Displacements and distortions of the abdominal organs are often the result of pressure from cancerous tumors of the kidney. The diaphragm may be pushed upward and the lungs compressed. If the disease be uni-

¹ Of 114 cases, the cancer was 52 times on the right side, 50 times on the left, and 12 times bilateral. In children the left kidney was oftener affected than the right (2½ : 2). In adults, the right oftener than the left (5 : 4). Bilateral cancer was of equal frequency in children and in adults (Rohrer).

² According to Kühn, secondary growths are found in 28 per cent. of the cases in children, and in 44 per cent. in adults (*loc. cit.*).

lateral the kidney unaffected by cancer is generally hyperæmic. Amyloid degeneration of the kidney, as well as of other parts, may be caused by renal cancer.

Upon microscopical examination the tumor presents the characteristic arrangement of cells in alveoli with intervening stroma. The microscopical appearances as regards the size of the alveoli, the shape of the cancer-cells, the amount and character of the stroma, and the degree of vascularity vary in different cases. The designation of the tumor as medullary or as scirrhus depends upon these variations. In the soft renal cancers, which is the most frequent form, the alveoli are separated by a small amount of stroma and are usually large. It is a peculiarity of soft cancer of the kidney that the alveoli may be separated from each other in some places by nothing but blood-vessels, the appearance being that blood-vessels actually penetrate the alveoli. The stroma of these cancers in its scanty amount of fibrillated connective tissue resembles the normal interstitial tissue of the kidney. The stroma is not in all places as thin as has been described, and it may be abundant. In some cases the cancer-cells resemble the epithelium of the convoluted tubes, being very granular and indistinctly separated from each other. They are, however, always irregular in shape. Cylindrical-celled epithelioma of the kidney has been described by Wagner. Waldeyer, Klebs, Pereverseff, and others have described with much detail the development of cancerous alveoli from the uriniferous tubes, and of cancer-cells from the epithelium of these tubes, the tubes becoming dilated and irregular in shape, and giving off processes; and within these dilated branching tubes the epithelial cells proliferate. In the immediate neighborhood of the cancerous growth the interstitial tissue of the kidney is often increased in amount, and the tubes are in some places compressed and in others dilated. Cancer seems to take its origin more frequently from the cortical than from the medullary tubes.

In a clinical point of view, as already stated, secondary cancer of the kidneys has little interest. It is generally latent as regards diagnostic symptoms. Both kidneys are affected, as the rule. The disease does not advance sufficiently to form appreciable tumors, and there may be no symptoms denoting renal disturbance. Primary cancer, on the other hand, is generally unilateral, and in a large proportion of cases it gives rise to symptoms which direct attention to the kidney. Lumbar pain on the affected side, extending down the ureter to the thigh, may be a more or less prominent symptom, but it is not so except in a certain proportion of cases; and this symptom for a long time may be wanting. There are loss of appetite, progressive emaciation, and other symptoms which belong to the cancerous cachexia and denote an inroad upon the constitution, but they may be long deferred. The diagnosis hinges upon the discovery of a renal tumor.

The tumor is felt between the ribs and the pelvis latero-anteriorly. It varies greatly in size and form in different cases. It may be as large as the closed hand or a child's head, and in young subjects it sometimes attains enormous dimensions, as in the case cited by Roberts, in which the weight of the tumor was 31 pounds. In the pictorial representation of that case the enormously enlarged abdomen contrasts strikingly with the attenuated chest and limbs. The tumor may be smooth or lobulated. The aortic impulses may cause it to pulsate, resembling in this respect an aneurismal tumor. It may be hard and resisting to the touch or it may give a sense of fluctuation. It is sometimes hard to the touch in some and soft in other parts. The tumor sometimes retains the shape of the kidney, although much enlarged, but oftener there is so much distortion that the shape is of no value in the

diagnosis. The cancerous disease may extend to the neighboring lymphatic glands, and these may form a mass which may exceed in size the enlarged kidney.

The first point with reference to the **DIAGNOSIS** is to determine that the tumor is renal. It is to be discriminated from enlargement of the liver and spleen, from an ovarian and from a fecal tumor. It is shown not to be connected with the liver or the spleen if the fingers can be pressed between the lower margin of these organs and the tumor. The evidence afforded by percussion must not be too confidently relied upon. The renal tumor is usually behind the intestine, and therefore a tympanitic resonance is often obtained by percussing over it; but it is common to find this resonance over the liver and the spleen, owing to its being conducted from the colon and stomach upward to a greater or less height. Hence the resonance over the liver and over the spleen may be tympanitic, although no part of the intestine is situated over these organs. On the other hand, the portion of intestine situated over a renal tumor may not at all times contain gas, and there may then be flatness on percussion. Too much reliance on a tympanitic resonance over an abdominal tumor as a differential point is likely to lead to error in the diagnosis. A cancerous kidney usually becomes closely adherent to adjacent parts, and it is not, like the liver and spleen, lowered by the descent of the diaphragm in inspiration. An ovarian tumor differs in being found at first in the iliac fossa, and as it increases in size it extends upward, whereas an enlarged kidney is at first felt in the hypochondrium, and as it enlarges it descends. For further diagnostic evidence of ovarian tumors the reader is referred to works on gynecology. Fecal tumors have their characteristics which have been considered (p. 442).

A renal cancer is to be discriminated from other affections of the kidney—namely, hydronephrosis, pyonephrosis, renal abscess, hydatid disease, and cystic degeneration. Relying upon palpable characters of the tumor this is by no means easy. With reference to this differentiation the antecedent and concomitant symptoms are to be considered, and, as bearing on both the seat and the character of the tumor, hæmaturia is pre-eminently a diagnostic symptom.

Hæmaturia and the existence of a tumor referable to the kidney render the diagnosis of renal cancer almost positive. The analysis, however, of 59 cases by Sir William Roberts gave 28 in which hæmaturia did not occur, and of the larger collection of cases by Rohrer this symptom was present in only 34 per cent. The absence of hæmaturia therefore by no means excludes cancer. Hæmaturia, too, without tumor is not evidence of renal cancer. It is the conjunction of the hæmaturia and the tumor which establishes the diagnosis, and a positive diagnosis is not possible unless these two events be conjoined.¹

The hæmaturia may occur for the first time early or late in the progress of the disease. It often recurs more or less frequently after irregular intervals. The hemorrhage is sometimes profuse, and sometimes it is small. Clots formed in the calices or the pelvis of the kidney in passing through the ureter may give rise to all the symptoms which attend renal colic. The coagula in some instances become moulded in the ureter, and appear in the urine in the form of casts resembling lumbricoid worms. Many of these were passed in a case which came under my observation. The coagula may obstruct the

¹ With reference to these two diagnostic events—namely, tumor and hæmaturia—Rohrer divides his 115 cases into four classes, as follows: 1, in 36 cases there was neither tumor nor hæmaturia, and the disease was therefore unsuspected; 2, in 12 cases there was hæmaturia without tumor; 3, in 25 cases there were both tumor and hæmaturia; 4, in 42 cases there was tumor without hæmaturia.

ureter and give rise to hydronephrosis. The blood sometimes coagulates in the bladder, and the coagula are with more or less difficulty expelled through the urethra.

The mistake is often made of supposing that the urine may contain cells distinctive of cancer. It is perhaps true that cells from the tumor may be contained in the urine, but these cells have no characters by which they can be distinguished as cancer-cells. The normal epithelial cells lining the urinary bladder present such a great variety of forms that they are often taken as the physiological type or paradigm of cancerous cells. There is no instance of the diagnosis having been based upon the recognition, in the urine, of masses of cancerous tissue of sufficient size to enable an alveolar structure to be determined. If blood or pus be contained in the urine, there is of course a certain amount of albuminuria; but if these elements be absent renal cancer may exist without any trace of albumen in the urine. The disease may, however, be attended by changes in the kidney which give rise to considerable albuminuria.

The TERMINATION in cases of renal cancer is inevitably in death, sooner or later. The duration of the disease in children is shorter than in adults. Sir William Roberts found the average duration in children to be about seven months, the extremes being ten weeks and over a year. In adults the average duration was two and a half years, and the extremes five months and seven years. Rohrer from his statistics reaches similar results. It is to be observed that in the cases embraced in these statistical analyses the latent period of the disease when there were no symptoms present cannot be taken into account, and there is reason to believe that this latent period may be of long duration. Wharry mentions a case which proved to be one of renal cancer in which a tumor, gradually increasing in size, had been ascertained fourteen years before death.¹ Dunlop has reported two cases, the duration having been ascertained to have been in one between ten and twelve years and in the other sixteen years.² Rohrer cites a case which lasted seventeen years. These are, of course, exceptional cases, but it is a noteworthy fact that cancer in this situation is tolerated in some instances for a very long period, and a great length of time may elapse without much constitutional disturbance. On the other hand, in some cases, especially in children, the tumor grows with astonishing rapidity.

It is a peculiar feature of primary cancer seated in the kidney that the tendency is much less here than in other situations to extend to neighboring parts or to give rise to metastatic cancerous disease in situations more or less remote. Heredity seems not to be involved in the causation of the disease in this situation. Respecting the causation nothing is known.

The indications for TREATMENT have reference in some cases to lumbar pain, to the occurrence of renal colic, to urethral obstruction from clots, to the removal of coagula from the bladder, to hæmaturia when the hemorrhage is profuse, and to other effects, symptoms, or complications which are liable to occur during the progress of the disease. Aside from meeting these indications, the object of treatment is to render the system tolerant of the disease as completely and as long as possible. The measures for this object are the same as in other diseases in the management of which all that is to be hoped for is retardation of their progress and of their inroads upon the constitution. These measures embrace tonic remedies, palliatives, nutritious diet, and favorable hygienic influences, moral and physical, in the place of those which tend to impair the ability to endure an incurable disease. The only hope of reest-

¹ *The Lancet*, Feb. 10, 1877.

² *Ibid.*, April 21, 1877.

ery is to be sought in extirpation of the tumor. This operation has been performed a number of times, but thus far not with favorable results.

Movable Kidney.

One of the kidneys is sometimes loosened so as to form a movable tumor which may be felt through the abdominal walls. This condition is called movable kidney, floating kidney, wandering kidney, or ectopia renis. The degree of mobility varies much in different cases. The kidney is normally held in position by the layer of peritoneum which is attached to the anterior surface of its adipose capsule. In movable kidney the adipose tissue in which the normal kidney is imbedded partly or wholly disappears. The overlying peritoneum becomes lax and may form a partial or even complete investment of the kidney. In extreme cases the mobility of the organ is restrained only by its vessels and the ureter. Unusual length of the renal vessels is thought to be a predisposing cause of displacement of the kidney. In nearly all cases the intestine is interposed between a movable kidney and the abdominal walls. In very exceptional cases the organ has been found in front of the intestine. A displaced kidney may become fixed in its abnormal position by the formation of adhesions.

It is difficult to form an estimate of the frequency of this abnormality of the kidneys, as the condition doubtless often exists without being recognized. It is probable that abnormal mobility of these organs is not very uncommon. It is far more frequent in women than in men. Of 290 cases collected by Newman, 252 were in women and 38 in men.¹ The right kidney is movable oftener than the left. Both organs may be affected. Of 91 cases brought together by Ebstein, the right kidney was affected 65 times, the left 14 times, and both kidneys 12 times.² The affection may be congenital or acquired. It is usually acquired. In most of the cases the abnormality developed between the twentieth and the forty-fifth year, or, in other words, during the child-bearing period in women. The affection may, however, appear at any age. Mobility of the kidney is attributable to relaxation of the abdominal walls from pregnancies, to the use of corsets and tight girdles about the waist, to violence, to increased weight of the organ from disease, to the pressure of tumors growing in the neighborhood of the kidney, and to the traction of hernias. The disappearance of the fat from the adipose capsule of the kidney, as happens in wasting diseases, has also been assigned as a cause, but its efficacy is doubtful. Unusual laxity of the abdominal walls from causes other than pregnancy may be an element in the causation. In congenital floating kidney there is usually some abnormality in the development of the peritoneum covering this organ or in the length, origin, or distribution of the renal vessels.

Movable kidney may exist without causing any noticeable SYMPTOMS. In several cases it has been discovered accidentally by the physician while making a physical examination of the abdomen. Usually, however, the condition gives rise to more or less uneasiness. The patient often experiences a sense of weight and dragging pain, especially when walking or standing. There may be severe neuralgic pain radiating from the affected side. If the tumor be first discovered by the patient, it becomes often a source of great mental anxiety. In some cases the movable kidney gives rise to the paroxysmal development of symptoms of considerable severity to which the name "symp-

¹ *Glasgow Medical Journal*, Aug., 1883.

² Of 65 cases collected by Roberts, in 42 the right alone was movable, in 9 the left alone, and in 14 both kidneys.

toms of incarceration" was applied by Dietl. These symptoms are chilliness, nausea, vomiting, prostration, intense pain, and anxiety. The affected kidney and surrounding tissues are swollen and sensitive to pressure. These symptoms usually subside within a few days under the influence of rest and opiates. They are relieved if the kidney be replaced. The explanation of the symptoms of incarceration is not satisfactorily established. The symptoms have been ascribed to twisting of the ureter and to retention of the urine in the pelvis of the organ from the temporary obstruction thereby occasioned. In this way it is claimed that acute hydronephrosis and pyelitis may develop. Hydronephrosis may coexist with movable kidney, but this explanation does not seem to be applicable to all cases. The symptoms have more frequently been attributed to inflammation of the peritoneum and connective tissue surrounding the kidney. Another possible explanation is that the symptoms are due to partial strangulation of the kidney from compression or from twisting of its blood-vessels. It is claimed that a movable right kidney pressing on the duodenum may be a cause of dilatation of the stomach. Constipation may be a result of compression of some part of the intestine, most frequently of the colon, by a movable kidney. Edema of the lower extremities has been described as a result of compression of the inferior vena cava by a displaced kidney. According to Roberts, epigastric pulsation is in some cases a prominent phenomenon in connection with movable kidney. Various symptoms resembling hysteria have been frequently observed in women suffering from this disorder.

The occurrence of movable kidney is to be recollected in determining the nature of obscure tumors within the abdomen. The recognition of this variety of tumor is to be based on the following diagnostic points: It is situated in the hypochondriac region. It has the size and the shape of the normal kidney, and this may be determinable by palpation, which is most advantageously employed by placing one hand over the lumbar region and the other in front on the abdominal walls, and then making counter-pressure from one hand to the other. It is generally movable, and in some cases the organ can be restored to its proper situation. Over the normal site of the organ on the affected side a depression is sometimes observed, with a tympanitic resonance on percussion derived from the portion of the intestine which is situated in the place which the kidney should have occupied. These two latter diagnostic points are available in so few cases that they are of more theoretical than practical interest. Other tumors are to be excluded by the absence of their diagnostic characters.

The inconvenience, and sometimes suffering, attending this anomaly may often be obviated, in a measure at least, by mechanical compression of the abdomen by means of a bandage or belt or abdominal supporter. In attacks of pain the organ should if possible be replaced; rest and recumbency are to be enjoined; emollient applications should be made over the abdomen; and if these measures do not afford relief opiates are indicated. It very rarely happens that the symptoms are so severe as to justify extirpation of a movable kidney, although this operation has been repeatedly performed. An operation for fixation of the kidney by means of sutures has been devised (nephrorrhaphy), but this also is open to many objections. [The indications for operation in cases of movable kidney are thus formulated by M. H. Richardson: "If the symptoms are unendurable, then nephrorrhaphy can be done with little danger to life and with a very good chance of permanent recovery, or, at least, enough lasting benefit to justify the operation. Finally, if fixation has not followed, nephrectomy can be resorted to as a remedy for unbearable pain and distress."¹—H.]

Renal Hæmaturia.

Hæmaturia, or bloody urine, occurs in various diseases, as well as after wounds and other injuries of different parts of the urinary apparatus. The blood may come from the kidney, the pelvis of the kidney, the ureter, the bladder, or the urethra. When it takes place from the bladder or the urethra, it comes within the province of surgery; but the means of determining whether the hemorrhage be either cystic or urethral are of importance to the physician. Urethral hemorrhage is easily discriminated. The blood escapes without any effort of micturition or it immediately precedes the first escape of urine. Moreover, the seat of the disease or injury may be ascertained by surgical exploration. Vesical hemorrhage is discriminated by attention to the following points: The last part of the urine discharged is often more bloody than the first part; there usually are blood-clots in the urine, and these may prove an obstacle to the free escape of the urine; there can frequently be found some cause of vesical hemorrhage, such as a calculus, a tumor, or some wound or injury of the bladder; and ammoniacal decomposition of the urine and other symptoms of cystitis are often present.

Hemorrhage from the ureter generally involves the presence of a calculus. Hemorrhage from the pelvis of the kidney is most frequently due either to calculus or to tuberculous pyelitis, and occasionally to infectious diseases with a hemorrhagic tendency. Sometimes coagulated blood is moulded in its passage through the ureter so as to form casts of this tube, compared in their appearance to leeches.

When the bleeding is from the kidney the blood is thoroughly mixed with the urine, which often presents a smoky or sooty appearance. Blood derived from renal hemorrhage is very rarely coagulated. Of great importance in the detection of renal hemorrhage is the recognition of changes in the urine indicative of disease of the kidney, especially casts and a much larger proportion of albumen than can be explained by the quantity of blood present. The presence of blood-casts in the urinary sediment is proof that the hemorrhage is renal. The reaction of the urine is generally acid. It is to be borne in mind that blood-corpuscles may not be discoverable in urine which has become ammoniacal, as under these circumstances they may be speedily destroyed. In urine of low specific gravity the blood-corpuscles appear very pale, or only the so-called shadows of blood-corpuscles may be present. If, owing to the absence of blood-corpuscles, there be doubt as to the presence of blood-coloring matter in the urine, chemical tests¹ or the spectro-scope may be employed. Bloody urine is always more or less albuminous.

Bloody urine should not be confounded with any of the following conditions: the high-colored, saturated urine of fevers, the urine of jaundice, the dark urine from carbolic-acid poisoning, and urine stained by ingestion of rhubarb, senna, logwood, madder, beet-root, the prickly pear, and fuchsin.

The causes of renal hemorrhage are injuries to the kidney, as from wounds or from a fall or a blow; the absorption of various toxic substances, such as cantharides, turpentine, or oil of mustard; congestion of the kidney due to these or other causes; acute, less frequently chronic, Bright's disease; rarely embolism, thrombosis, or aneurism of the renal blood-vessels; abscess, echinococcus, tuberculosis, and cancer (rarely other tumors) of the kidney; occa-

¹ Teichmann's blood-test is convenient. Some of the urinary sediment or a portion of the dried urine on a slide is treated with glacial acetic acid after the addition of a few minute crystals of common salt. The specimen is covered with a cover-glass and heated until it begins to boil. After cooling (more glacial acetic acid can be added if necessary) the characteristic brownish rhombic hemin crystals appear if blood be present.

sionally acute infectious diseases; and the hemorrhagic diathesis, including purpura and scurvy. Sometimes hæmaturia, apparently of renal origin, occurs without any apparent cause. The influence of malaria and of parasites in the production of hæmaturia will be considered in the following articles.

In cases of renal hæmaturia, if the hemorrhage be considerable, the application of cold over the kidneys by means of compresses wet in cold water or the ice-bag is indicated. Internal hæmostatics which may be prescribed are tannic or gallic acid, ergot, the muriate and other astringent preparations of iron, alum, and acetate of lead. Hypodermic injections of ergotin may be employed. Aside from the treatment having reference to the hemorrhage, indications are to be derived from the diseases or morbid conditions with which it is connected as a symptom.

Endemic Hæmaturia.

This name is applied to a form of hæmaturia occurring in Brazil, Egypt, the Cape of Good Hope, and some other tropical countries. The hæmaturia is caused by the distoma hæmatobium, a parasite which is common in these countries, and which was discovered by Bilharz in 1851. This parasite, which is one of the suetorial worms or trematodes, is about half an inch in length, and is found especially in the portal and other abdominal veins. The parasite is thought to be ingested with the drinking-water. It produces a multitude of eggs, which are found in the liver, the intestine, the bladder, ureter, renal pelvis, kidney, and other organs. The lodgment of these ova produces symptoms referable especially to the liver, the intestine, and the urinary organs. The mucous and submucous coats of the bladder, and of the ureter and renal pelvis are thickened, inflamed, and ulcerated. The local effects of the parasite and its ova upon the urinary organs are manifested in hæmaturia, combined generally with symptoms of cystitis and of pyelitis. There frequently is diarrhoea, and there may be pyrexia with symptoms of typhoid fever or septicæmia. The ova often form the nucleus of a renal or a vesical calculus.

The diagnosis is based upon finding the eggs in the urine. The eggs are from $\frac{1}{180}$ to $\frac{1}{160}$ of an inch in length, and are either sharply pointed or furnished with a projecting spine near one end.

The disease is a severe one and may terminate fatally. Recovery, if it take place, is slow, generally extending over several years.

No remedy has been discovered which will destroy the parasite. The indications are to remove the patient from the endemic influence, to support the strength by tonics and good hygiene, and to treat the cystitis. For the latter purpose the bladder should be cleansed, and such drugs as boric acid, benzoic acid, bicarbonate of potash, and infusion of buchu may be employed.

According to observations in China and in India, hæmaturia may be caused by the *filaria sanguinis hominis*.

The *strongylus gigas* is a long, cylindrical, red worm found sometimes in the pelvis of the dog's and of the horse's kidney, but is so extremely rare in human beings that it does not require consideration.

Hæmoglobinuria—Hæmatinuria.

If from any cause the red blood-corpuscles be dissolved in the blood, the hæmoglobin which is thus set free is excreted by the kidney. The condition of blood thus produced is called hæmoglobinæmia, and that of the urine hæmoglobinuria. The urine in hæmoglobinuria contains, therefore, dissolved blood-coloring matter, but usually no red blood-corpuscles. The urine has a

lish-brown color, which in extreme cases is compared to the color of ter.

Hæmoglobinæmia and the consequent hæmoglobinuria may be produced a variety of causes. A large number of substances when taken into the od cause a dissolution of the red blood-corpuscles. Such substances are rogallic acid, naphthol, arseniuretted hydrogen, glycerin, hydrochloric acid, phuric acid, chlorate of potash, and the biliary salts. The ingestion of tain poisonous fungi has this effect, as well as the transfusion of the blood one species of animal into the blood-vessels of another species. Hæmoglobinuria has been observed in the course of various infectious diseases, such scarlet fever, typhoid fever, and malaria. It is also produced by extensive perficial burns, and in one form of paroxysmal hæmoglobinuria exposure to ld is an important cause.

In all cases of hæmoglobinuria which have terminated fatally nephritis a been found. This nephritis is to be regarded as secondary. There are merulo-nephritis, degeneration and necrosis of the epithelial cells of the bes, small-celled infiltration, and especially characteristic casts in the tubes mposed of reddish-brown pigment-granules.

Hæmoglobinuria is distinguished from genuine hæmaturia by microscopical amination, which shows the absence of red blood-corpuscles. The presence blood-coloring matter is made evident by spectroscopic or chemical exam- ation, as mentioned in the article on Hæmaturia. The urinary sediment ually contains formless, granular (less frequently crystalline) reddish-brown gment, and casts of which the most characteristic are those containing or mposed of similar pigment. The urine is always albuminous. Of course re must be taken not to mistake for hæmoglobinuria urine in which the od-corpuscles have been dissolved in consequence of ammoniacal decom- sition.

Experiments have shown that fragments of red blood-corpuscles are not ly excreted by the kidney, but are also taken up by the spleen, the liver, d the marrow of the bones. The spleen becomes thereby swollen, and the er excretes an increased amount of bile, which may have an abnormally ck consistence. The jaundice which is a frequent attendant of hæmo- binæmia is probably to be regarded as hæmatogenous, although the nges in the liver which have been mentioned might be adduced in favor its hepatogenous origin.

There is a form of hæmoglobinuria which deserves consideration as an inde- dent disease. This is the so-called paroxysmal hæmoglobinuria. Some these cases are of malarial origin and others are not. On account of its ortionance malarial hæmoglobinuria will receive separate consideration.

Paroxysmal Hæmoglobinuria.

Exclusive of its causation by malaria in certain regions, this affection is common. It may occur in persons otherwise apparently healthy. As the ne implies, the disease appears in paroxysms. A typical paroxysm is ered in by pain in the back, the limbs, and the head, sometimes by nausea l vomiting and a sensation of coldness in the extremities. Frequent yawn- has been noted as a premonitory symptom in several cases. There is ally a distinct chill, followed by rise of temperature and sweating. Dur- this attack, and generally for a few hours afterward, the urine acquires a k reddish-brown, sometimes almost black, color, is generally of acid reac- , and is of rather low specific gravity. While the spectroscope reveals absorption-bands of hæmoglobin and of meth-hæmoglobin, the micro- pe shows the absence of red blood-corpuscles. There is generally a choco-

late-colored sediment containing pigment-granules and hyaline, epithelial, and pigment casts. There is at the same time albuminuria. Severe colicky pain in the region of the liver is sometimes experienced during the attack. A more or less distinct icteric hue of the skin is present. Urticaria in some cases, and exceptionally purpuric patches, have been noted. After the paroxysm the urine gradually becomes clearer, and in from twelve to twenty-four hours it becomes normal. Meanwhile, the other symptoms diminish and disappear, and on the day following that of the paroxysm, except the weakness due to the latter, the usual health of the patient is restored.

With a light paroxysm there is only chilliness, followed by little or no fever, and the symptoms may not be sufficient to interrupt the usual occupation of the patient. Rarely the hæmoglobinuria appears without marked premonitory symptoms.

The paroxysms may occur with some regularity, but more frequently they recur irregularly at variable intervals. Two or more daily sometimes occur, or the intervals may be days, weeks, or months. In proportion as the paroxysms are frequent and severe patients present a pale, cachectic aspect.

Examination of the blood withdrawn during the paroxysm by wet cups has shown a reddish color of the serum, indicating solution of the hæmoglobin. The red blood-corpuscles have been found sometimes altered in shape and size, and the so-called shadows of the corpuscles have been detected in the blood. The number of red blood-corpuscles is diminished. There is less tendency than normal in the red corpuscles to form rouleaux.

In a large number of cases the causation of the paroxysm has been attributed directly to exposure to cold, but of the *modus operandi* of this cause we possess no definite knowledge. In persons subject to the disease attacks have been repeatedly produced experimentally by plunging the feet or hands into cold water. It is not improbable that the red blood-corpuscles in these individuals possess some peculiarity in composition which renders them abnormally susceptible to the action of cold.¹ All cases of paroxysmal hæmoglobinuria, however, do not seem to possess this peculiar susceptibility to cold. Some cases are referred to muscular exercise. The disease is more common in men than in women. Most of the paroxysms occur in winter. A large proportion of the patients have had syphilis. That malaria has an important influence in the causation of periodical hæmoglobinuria in this country will be made evident in the following article.

Exclusive of malarial cases, paroxysmal hæmoglobinuria does not involve danger to life. Paroxysms may recur for an indefinite period, but recovery may be expected to take place sooner or later.

The TREATMENT during the paroxysm consists in placing the patient in bed, applying heat to the surface, and giving hot drinks internally, with the addition of some form of alcoholic stimulant. After a paroxysm measures to maintain warmth of the surface are of prime importance. A rough, changeable climate may be exchanged with advantage for one which is mild and uniform, and woollen underclothing should be constantly worn. Only in a few cases, in which a syphilitic history has existed, has mercurial treatment been found effective. Even in non-malarial cases quinine is often beneficial. Chalybeates and other tonics, with good alimentation and the moderate use of wine, are to be prescribed according to the indications in individual cases.

¹ This view is supported by the experiment of Ehrlich and of Boas, who, in a case of paroxysmal hæmoglobinuria, after applying an elastic ligature around the root of one of the fingers, plunged this finger into ice-water for a quarter of an hour. In blood withdrawn then from this finger they observed the changes in the serum and red blood-corpuscles above noted, while blood taken from other parts of the body did not present these changes.

Malarial Hæmaturia—Malarial Hæmoglobinuria.

Both hæmaturia and hæmoglobinuria may be caused by malarial poisoning. In the Northern and Middle States of this country only the milder forms of malarial hæmaturia are observed, and these are not common, whereas in parts of the Southern and South-western States and in tropical countries malignant malarial hæmoglobinuria is not uncommon.

In the *milder* cases the affection may be either hæmaturia or hæmoglobinuria. The diagnosis is based upon the history of malaria. The attacks of hæmaturia may occur with the regularity of malarial paroxysms, but more frequently they are variable in the time of their appearance. In some instances the hæmaturia becomes continuous, although fluctuating in intensity. The ordinary symptoms of intermittent fever may or may not be present at the time of the hæmaturia. The paroxysms may resemble those described in the preceding article, and they may likewise be caused by exposure to cold.

Malignant malarial hæmoglobinuria is one of the manifestations of pernicious malarial fever, and is a disease of great gravity. During the last twenty-five years a large number of cases have been observed in parts of the South and South-west of this country. The disease may be preceded by one or more paroxysms of intermittent fever, or the hæmoglobinuria may be developed suddenly. There is always a history of exposure to malarial influences. The urine is of a dark reddish-brown, sometimes almost black, color. It contains few or no intact red blood-corpuscles, but an abundance of hæmoglobin and meth-hæmoglobin, as is shown by the production of hæmin crystals or by spectroscopic examination. The sediment contains hyaline and epithelial casts, granular matter, and granules of blood-pigment, both free and in casts. The urine is albuminous and generally acid. At first it is usually excessive in amount, and later it is diminished. In addition to the hæmoglobinuria, there are other symptoms of gravity. After a few hours the patient becomes jaundiced. Usually at the onset of the attack there are nausea and vomiting, and often black vomit makes its appearance. There may be bleeding from the nose, from the bowels, from the uterus, from blistered surfaces, etc. Pain in the back and in the epigastric region is often complained of. The temperature is elevated, sometimes as high as 106°; the pulse is rapid, small, and feeble; and there is great prostration. There may be delirium, and frequently the patient passes into a state of somnolence and coma. The mind may, however, remain unaffected. Death may occur during the first attack, or the symptoms may be relieved, and then recur after one or two days, attended in all cases with great danger to life.

Malignant malarial hæmoglobinuria seems to be more common in males than in females. It is said that negroes are exempt from this form of the disease.

The PROGNOSIS is grave, but under appropriate treatment recovery may take place.

The TREATMENT of the malignant form consists in the administration of quinine in large doses and hypodermically. Of great importance is the administration of stimulants to maintain the vital forces, which are often at a low ebb. Morphine may be employed to relieve the gastric symptoms. Physicians in the South consider stimulants and restoratives of equal importance with quinine in the treatment of this affection.

The milder forms of malarial hæmaturia are often relieved or cured by quinine. The ordinary astringent remedies may be employed in conjunction with quinine. All severe muscular exertion should be avoided. For cases which are rebellious to treatment—and such cases are not very rare—Tyson recom-

mends the use of chalybeate and alum springs.¹ Iron and appropriate hygienic treatment are to be used to counteract the anæmia attending or following malarial hæmaturia.

Chyluria.

This disease is characterized by the passage of urine which resembles milk. The urine has sometimes a rose or pink tinge, due to the presence of a little blood, and the disease is sometimes associated distinctly with hæmaturia. In many instances the urine has the opaque white appearance of milk, without any admixture with blood. After its passage the urine generally forms a jelly-like coagulum which disintegrates in a few hours. The microscope shows the presence of fatty matter in the form of very minute granules. The fatty matter is dissolved by ether, and the urine which remains assumes a normal appearance. The urine contains albumen, usually in large amount. The abnormal chemical constituents of the urine, therefore, in chyluria are fat, albumen, and fibrin. To these blood is frequently added.

Chyluria prevails in certain tropical and subtropical countries. It is observed in China, the East and West Indies, South America, Africa, Australia, and some tropical islands. In the cases which have fallen under observation in temperate climates the disease, as a rule, has been contracted in a hot climate. Chyluria, however, has sometimes appeared in persons in this country and Canada, as well as in England and Germany, who have never visited tropical regions.²

The milky urine in most cases appears without any premonition or apparent exciting cause. All of the urine may be chylous, or it may part of the time be normal. Chyluria usually occurs intermittingly, the intervals in different cases varying from days to months or years. There is no regularity as regards either the duration of the attacks or their recurrence. In the intervals between the attacks there is no evidence of urinary disease.

In severe cases there are lumbar pains and symptoms denoting exhaustion. Dysuria from coagula in the bladder sometimes occurs. Milder cases are not only exempt from grave symptoms, but there may be nothing which points to any disease, aside from the passage, after irregular intervals, of milky urine.

Tropical chyluria is caused by the presence of the parasite called *filaria sanguinis hominis*, first accurately described by Timothy Lewis in 1872. The adult or parent worms are cylindrical, thin, smooth nematode worms three or four inches in length. The sexes are distinct. The female gives birth to an enormous number of living embryos without sexual distinction. In the disease under consideration the parent worms are lodged somewhere in the body, probably in the lymphatics. The embryos make excursions into the blood and lymphatic vessels, where they are found, sometimes in enormous numbers.³ These embryos are from $\frac{1}{16}$ to $\frac{1}{8}$ of an inch long, and about as broad as a red blood-corpuscle. They are elongated, generally enclosed in a membranous sheath, and endowed with the property of a rapid coiling and twisting motion. In a drop of blood they can often be detected with a low power of the microscope by the motion which their lashing imparts to the

¹ James Tyson, article "Malarial Hæmaturia and Hæmoglobinuria," in *Pepper's System of Practical Medicine, by American Authors*, Philadelphia, 1886, vol. iv. p. 111.

² Dr. Guiteras has found the *filaria sanguinis hominis* in two persons in Charleston, South Carolina. In one case the patient had always lived in Charleston or its neighborhood, and in the other case the patient had always lived in Charleston with the exception of five years in Augusta, Ga. One was a case of chyluria, the other one of chylæcele (John Guiteras, *The Medical News*, Apr. 10, 1886).

³ Stephen Mackenzie estimated that there were from 36,000,000 to 40,000,000 embryos *filariæ* in the blood of a patient whom he observed.

red blood-corpuscles. In chyluria these embryonic filariæ are found in the urine and also in the blood. They have the singular habit of disappearing from the blood during the daytime, and appearing in large numbers at night, the maximum number being usually found about midnight. What becomes of them in the daytime is not known. By reversing the patient's habits—that is, by making him sleep during the day and eat and move about during the night—the migrations of the parasites become diurnal instead of nocturnal.

In what way chyluria is produced in general, and what the relations of the filariæ are to this disease, are problems which have not been satisfactorily solved. The common theory is that chyluria is caused by some abnormal communication between the lymph-vessels and the urinary passages. It is suspected that the filarial worms are often lodged in the thoracic duct or abdominal lymphatics, and thus cause a damming back of lymph and consequent distension of the lymphatics.¹ Some think that the blood contains at times in chyluria an excess of chyle.

Chyluria is not the only affection which may be caused by the *filaria sanguinis hominis*. This parasite may be the cause also of hæmaturia, chylous hydrocele, chylous ascites, elephantiasis, milk scrotum, and nævus-like dilations of the lymphatics in various situations, particularly upon the external surface of the body, from which a chylo-serous fluid may escape. Abscesses are sometimes produced in which the parent worms have been found. These various affections may be combined with chyluria.

According to Manson of China, the embryonic filariæ are sucked up with the blood from patients affected with the filaria disease by mosquitos, in which the parasite undergoes further development, and, being discharged into water, is prepared to again enter the human body, where it forms the mature organism. Filariae have been found very frequently in the blood of healthy individuals in China.

The cause of the non-parasitic form of chyluria which sometimes develops in temperate climates is not known.

The PROGNOSIS is generally favorable. So long as the parent worms remain alive in the human body complete recovery from chyluria is not to be expected. The embryos are probably not endowed with long vitality. It may be expected that sooner or later the parent worms will die, and then recovery takes place. As already mentioned, these worms have been discharged from abscesses. They seem to suffer in their vigor by febrile diseases; at least, it has been repeatedly noticed that the embryos disappear from the blood during attacks of fever.

The rational indication for TREATMENT is of course the destruction of the parasite in filarial chyluria, but no drugs are known which will accomplish this. Gallic acid, from one to two drachms given daily, is the remedy which thus far has proved most useful. Iodide of potassium in large doses has been beneficial in a few cases. Special virtue has been claimed for the decoction of mangrove-bark (*Rhizophora racemosa*) and the picro-nitrate of potash, but without satisfactory evidence. Rest, tonic treatment, and change of climate meet manifest indications in many cases.

Diabetes Insipidus.

The term "diabetes" signifies simply increased flow of urine, or diuresis.

¹ In Mackenzie's case an enormous dilatation of the lower part of the thoracic duct and of the renal and some other abdominal lymphatic vessels was found after death, which occurred from pyæmia, the parent worms having died some time before and not being found at the autopsy. In the few other reported autopsies no changes have been found in the urinary organs or lymphatics to explain the chyluria.

The term is applied to two affections which differ essentially each from the other. In one of these affections notable diuresis exists, a given quantity of the urine containing a small proportion of solid constituents; that is, the specific gravity is low, being sometimes but little above that of spring-water. The morbid abundance of urine in this affection is due to an excessive elimination of water by the kidneys. Considered as a urinary affection, it is called diabetes insipidus. The other affection to which the term diabetes is applied is characterized by the presence of sugar in the urine. This affection will be considered in the next article.

A morbid excess of water in the urine, expressed by the terms hydruria and polyuria, is a symptom occurring in various pathological connections. It is a frequent symptom in cases of the small granular kidney, and is not infrequent in cases of the waxy kidney. Polyuria has been observed also as a symptom of hydronephrosis with wasting of the kidneys and in cases of enlarged prostate and some other surgical affections of the urinary organs. Polyuria occurs also, in some cases, as a symptom of cerebral diseases and of lesions caused by injuries of the skull. It is a symptom in cases of hysteria, asthma, and other nervous affections. In all these instances the polyuria is not properly to be considered as constituting an individual disease. Polyuria and hydruria, therefore, are terms not synonymous with diabetes insipidus. The latter term, if properly applied, denotes a disease characterized by an excess of water in the urine when not symptomatic of the foregoing diseases.

In well-marked cases of diabetes insipidus the quantity of urine greatly exceeds that of health. It may amount to fifteen and even twenty quarts per diem. The specific gravity varies between 1003 and 1007. There is no essential change in the composition of the urine except the excess of water. There is thirst, which leads the patient to ingest fluids in an amount proportionate to their loss by the kidneys. When deprived of other liquids patients have been known to drink their own urine. The need of drinking often and the frequent acts of micturition occasion much annoyance and interfere with sleep. The disease may not otherwise interfere with health. Patients of either sex, affected with the disease, have been able to perform active labor, have had children, and their lives have apparently not been shortened by it. It is not incompatible with good appetite, digestion, and nutrition. It has been tolerated for fifty years.

The PROGNOSIS is favorable as regards the duration of life and the preservation of general health if the disease be uncomplicated; but it is unfavorable as regards recovery from the disease. As remarked by Senator, "Recovery is rare, but death is still more rare."

The ETIOLOGY is obscure. The disease has followed injuries of the head, and an hereditary influence is involved in some cases.¹ In the majority of instances the disease cannot be traced to any adequate cause. It occurs not infrequently in infancy. In a proportion of about one-half, when the disease is developed, patients are less than twenty years of age, and in about the same proportion the age is between thirty and fifty. It is extremely rare after the age of fifty. The number of males affected with the disease is considerably larger than of females. There have been a few instances recorded in which diabetes mellitus has passed into diabetes insipidus, the sugar disappearing from the urine.

The PATHOLOGY is unsettled. The discovery by Bernard that a puncture

¹ Weil has reported the history of a family of 91 members, extending through four generations. Of these, 23 had polyuria, and in 13 it could not be determined whether this existed or not. This affection existed throughout life without impairment of the general health (*Virchow's Archiv*, Bd. 95, p. 70).

the floor of the fourth ventricle of the brain will produce polyuria without any disease. Cases have been observed in which after death lesions were found to involve this part. There is not, however, sufficient ground for assuming that diabetes insipidus depends on anatomical changes here or elsewhere in the brain. The absence of all symptoms of cerebral disease, exclusive of polyuria, in cases the duration of which extends over many years, militates against this assumption. That the disease is neuropathic is rendered probable by the occurrence of polyuria as a symptom in various nervous affections. The production of polyuria in animals by division of the splanchnic nerve favors this view. A reasonable hypothesis attributes the polyuria to a dilatation of the renal capillaries from influences exerted through the vaso-motor system. This result may be produced either by a paralytic effect through the splanchnic nerves, or by an active dilatation of the capillaries by excitation of vaso-dilator nerves. (Vide p. 813.) The presence of inositol in the urine has been shown to be an effect, not a cause, of the polyuria. This principle appears in the urine if a large quantity of fluids be ingested by healthy persons.

The polyuria in cases of diabetes insipidus may be suspended during the continuance of an inflammatory or febrile disease. Excluding cases of polyuria as symptomatic of cerebral or of renal lesions, diabetes insipidus is an extremely rare disease. The basis of the DIAGNOSIS is a persistent polyuria which is independent of these lesions. The disease is to be distinguished from polydipsia. In the latter disease the excess of water in the urine is an effect of the excess of liquid ingested. If the quantity of urine exceed the quantity of drink, and if polyuria continue notwithstanding a restriction of the latter, the differential diagnosis is established. From diabetes mellitus the discrimination is easy. The low specific gravity of the urine is distinctive, but the exclusion of that disease is rendered positive by the negative result of testing the urine for the presence of sugar.

It is injudicious to attempt to limit the excess of the water in the urine by diminishing the amount of ingested liquid. The disease is not thereby cured, and not only is there suffering from thirst, but, inasmuch as the polyuria continues, serious evils may arise from a morbid reduction of water in the food. Theoretically, it is an object of TREATMENT to diminish the size of the renal capillaries. In a case reported by DaCosta recovery within a short period was apparently effected by the fluid extract of ergot in drachm doses, increased to two drachms and given three times daily. This remedy was recommended, on the basis of experience, many years ago by Prof. Gross. Ergot or ergotin has been found useful by others. Other remedies which are recommended are gallic acid, dilute nitric acid, and valerian.

The patient's strength is to be maintained as far as possible by tonic remedies, good alimentation, and favorable hygienic influences.

The disease is not in itself fatal, but it may occasion more or less exhaustion, and thus increase the liability to death from associated or intercurrent actions.

Diabetes Mellitus.

An increased flow of urine or diuresis is generally a notable feature of the affection now to be considered. The distinctive feature, however, is the presence of grape-sugar or glucose in the urine; and hence the significance of the term mellitus. *Glycosuria* and *melituria* are other names applied to the affection characterized by saccharine urine. The affection is far from being of frequent occurrence, yet it is not so rare but that cases come under the obser-

vation of every physician. From the number of cases which have come under my observation in recent years I have been led to think that the disease is less rare than formerly in this part of the world. One reason of its apparent infrequency is that it is liable to be overlooked in cases which end fatally with some intercurrent disease.

Sugar in the urine, like albuminuria, may occur as a symptom in various pathological connections. It follows anæsthesia produced by the inhalation of chloroform or ether, an epileptic or an hysteric paroxysm, some violent emotion, etc. The sugar under these circumstances is usually not abundant, and the urine contains it for a brief period only. As the distinctive feature of an individual affection the sugar which the urine contains is in greater or less abundance, and it continues more or less persistently. Even when the affection exists the saccharine urine is in fact merely a symptom. It does not constitute the affection. It is incidental to or an effect of the real disease. The sugar exists in the urine because it pre-exists in the blood and is excreted by the kidneys; but with our present knowledge the true seat and nature of the disease are not established, and therefore, provisionally, it is named as if it were a disease of the urinary system, and is included for the sake of convenience among the diseases affecting this system.

An abnormal accumulation of sugar in the blood constitutes the morbid condition called glycohæmia. Glycohæmia stands in an immediate causative relation to the presence of glucose in the urine, and glycosuria is an effect of the glycohæmia. The latter stands in a nearer relation than the former to the pathology of diabetes mellitus. The pathology of glycohæmia is the pathology of the diabetic disease.

ANATOMICAL APPEARANCES.—Although the pathological anatomy of diabetes mellitus is not known, certain anatomical changes have been found with sufficient frequency to deserve mention in this connection. That any of these changes are concerned in the production of diabetes mellitus has not been proven.

[Dickinson¹ believes diabetes to be always dependent upon changes in the central nervous system, the most important of which are dilatation of the arteries and perivascular spaces, minute hemorrhages, and disintegration of nerve-elements. Such changes, however, are not constant in diabetes, and have been found in other diseases.—H.] Frerichs also found dilatation of the vessels, capillary hemorrhages, and minute myelitic foci frequently present in the medulla oblongata after death from saccharine diabetes.

The liver may be large, small, or of normal size, hyperæmic, anæmic, or of normal vascularity, and the hepatic cells fatty, atrophic, or normal. In other words, there is no anatomical basis for the current theory which refers diabetes mellitus to abnormalities in the circulation or in the functions of the liver. The amount of glycogen in the liver of diabetics seems to be diminished during life.

Attention has been directed in recent years especially to alterations in the pancreas in cases of diabetes. In many cases atrophy of the pancreas has been observed. The atrophy of the gland-structure may be combined with increase of the interstitial connective and adipose tissue. Whether, as has been surmised, the celiac plexus be involved in the pancreatic disease is not known. Glycosuria is occasionally present in cases of cancer and of calculous disease of the pancreas. It is claimed that diabetes mellitus associated with pancreatic disease runs a particularly rapid and severe course, and is accompanied often with fatty diarrhœa.

[Extirpation of the pancreas in the dog is invariably followed by diabetes

¹ *Med. Times and Gazette*, March 9, 1870, and *Treatise on Diabetes*, 1875.

ellitus, the animal developing also polydipsia and polyphagia and becoming greatly emaciated. To produce diabetes experimentally the entire pancreas must be removed. It is said that if a portion amounting to no more than one-tenth of the gland be left behind, it will suffice to carry on its function so far as the suppression of diabetes is concerned. In explanation of these facts the theory has been advanced that the pancreas elaborates a glycolytic ferment—*i. e.* a ferment which destroys glucose. If so, it is manifest that this ferment does not pass into the intestine through the pancreatic duct, for diabetes is not produced by ligaturing this duct. The supposititious ferment is formed in the gland and absorbed by the blood-vessels and lymphatics.¹—[H.] The kidneys of diabetic patients are often large and hyperæmic, probably in consequence of their increased functional activity. Glycogenic degeneration of the epithelial cells lining the looped tubules of Henle is a constant change in diabetes mellitus (Ehrlich). These tubes occupy the boundary-line of the pyramids. The affected cells are swollen and hyaline in appearance. The presence of glycogen is proven by the reaction with iodine. This change is probably secondary to diabetes. Chronic diffuse nephritis is not a rare complication of diabetes.

A hyaline degeneration of the walls of small arteries in various parts of the body has been often seen in diabetic cases.

An excessive amount of fatty matter in the blood, constituting lipæmia, is common in diabetes.

The complications of diabetes will be mentioned in connection with the clinical History.

CLINICAL HISTORY.—Notable increase of the urine, or polyuria, is usually the symptom which first awakens suspicion of the existence of the disease. It is not only the acts of micturition more frequent, but the quantity of urine voided in a given time is much greater than in health. The urine is deficient in color in proportion to the amount of sugar which it contains. The appearance is generally clear as well as pale. It has frequently a sweetish odor like that of whey. The presence of sugar is perceptible to the taste. Flies and bees are attracted to it if emitted on the ground. The density exceeds that of healthy urine in proportion to the amount of sugar. The specific gravity varies between 1025 and 1074, the latter being an extreme of increased density. A specific gravity below 1020 is exceptional. The reaction is in most cases feebly acid. The water of the urine is more or less increased; and hence the increased quantity of urine. The increase in the quantity of urine is generally very great, and sometimes enormous. It may amount to fifty pints or even more in the twenty-four hours. The frequent calls to micturate are a source of great discomfort, and especially during the night they constitute a serious evil by interfering with sleep. The action of sugar on the urethra may occasion a sense of heat and stinging pains. Inflammation and excoriation of the prepuce and glans are sometimes produced, and may lead to phimosis. I was led to the discovery of diabetes by examination of the urine in a case in which the patient complained only of an itching sensation in the middle of the penis, there being no increase of urine, no thirst, and no symptom of any disease except that just mentioned. The urine was found to be loaded with sugar. In women eczema of the vulva is a frequent effect, giving rise to distressing pruritus. It has been stated that more liquid is contained in the urine in some cases than is expected. This may be true for a limited period, but examinations extend-

¹ Vide Nommes, "Étude sur le Pancréas et sur le Diabète Pancréatique," *Thèse de Paris*, 1889.

ing over several days show that, large as is the quantity of urine, it falls short of the amount of liquid contained in food and drink.

Cases differ in respect of the quantity of urine and the amount of sugar. Generally, at the beginning of the disease the quantity of urine and the amount of sugar are not large, but the increase of both is progressive as the disease advances. Exceptionally, the quantity of the urine is not increased, although abounding in sugar. This has been true of several cases which have come under my observation, the patients not being under treatment, and for this reason the disease is liable to be overlooked. The quantity of both urine and sugar also varies at different periods of the day, being generally largest within a certain period after meals. The proportion of sugar in the urine varies between $\frac{1}{2}$ and 10 per cent., in extreme cases being 15 per cent. Usually from 2 to 4 per cent. is found. The quantity of sugar contained in the urine during twenty-four hours has been known to amount to fifty ounces. The quantity of sugar and of urine may be diminished by inter-current febrile diseases and toward a fatal termination of the disease. Inosite has been found in the urine in some cases with grape-sugar, or after this had disappeared.

The daily excretion of urea in diabetes is generally markedly increased. Uric acid, although a frequent sediment in diabetic urine, is not excreted in abnormal amount. In many but not in all cases of diabetes there is a notable excess in the excretion of ammonia by the urine. This is associated with the presence of oxybutyric acid, a substance which by oxidation gives rise to diacetic acid. Acetone has been frequently found in diabetic urine, but whether it be preformed or originate from some other substance in the urine is uncertain. Many refer the formation of acetone to the presence of diacetic acid, which is probably the substance which imparts to the urine a burgundy-red color upon the addition of ferric chloride (Gerhardt's reaction). Albuminuria, although not rare, is to be regarded as a complication.

The urine when preserved for several days undergoes the alcoholic fermentation. It remains acid and is devoid of the ammoniacal odor which is emitted by decomposed healthy urine. It is rendered turbid by the development of the *Torula cerevisiæ*, or yeast-fungus. This alcoholic fermentation imparts to the urine irritating properties which cause inflammation and irritation of the skin with which it comes in contact.

Emaciation is usually marked after the disease has existed for some time. Cases differ as regards the rapidity of the emaciation. In general, it is in proportion to the abundance of sugar in the urine and the duration of the disease, but it is affected in a greater measure by the condition of the digestive organs. It is evident that certain alimentary principles which in health contribute to the growth and repair of the body are lost to nutrition in this disease. The development of other affections, especially pulmonary tuberculosis, increases the emaciation. The occurrence of diabetes is not infrequently preceded by *embonpoint* more or less excessive.

Increase of the appetite is usually a prominent symptom. The patient ingests much more food than in health. The abnormal appetite may amount to bulimia or polyphagia. This, conjoined with progressive decrease of weight, should excite suspicion of the disease. Exceptionally, the appetite is not increased, but, on the contrary, it may be more or less impaired. Not infrequently, in the course of the disease the appetite fluctuates, being sometimes greater and sometimes less than in health. It fails as the disease approaches a fatal termination.

Thirst is one of the first symptoms, occurring as soon as the quantity of urine is increased. It is urgent in proportion to the degree of diuresis. The quantity of liquid ingested is sometimes enormous. The necessity of drink

during the night contributes, with the calls to urinate, to prevent sleep. Dryness of the mouth is a source of considerable inconvenience. The tongue is sometimes moist and coated, and sometimes dry and reddened. The gums are generally affected. They are softened, and either pale or reddened, bleeding readily on pressure. The teeth may become loosened and carious. The saliva is usually acid.

Digestion, until the disease is far advanced or until serious complications occur, generally appears to be well performed. Dyspeptic ailments, however, are not uncommon. If vomiting occur, the vomited matter is found to contain sugar. Sugar is also contained in the feces. Constipation is the rule, but in some cases diarrhoea alternates with constipation. The dejections show a deficiency of bile.

The respiratory function is not disordered, save by the pulmonary affections with which the disease is liable to become complicated, especially pulmonary tuberculosis. The respirations are somewhat fewer than normal if there be no pulmonary complication. It is stated that the amount of carbonic acid in the expired air is less than in health. The breath has a mawkish, sweetish odor which is quite characteristic. It has been compared to the odor of hay and of apples. I have recognized a patient whom I had examined at a clinic months before, and whose features I had entirely forgotten, as soon as he came sufficiently near for the odor of his breath to be perceptible. In repeated instances I have been led to suspect the disease by this peculiar odor. The condition of the gums and teeth renders the breath in some cases fetid.

The circulation often offers no symptoms of importance. The pulse, if at all affected, is oftener retarded than accelerated, exclusive, of course, of the effect of complications. I have observed capillary congestion of the surface in a notable degree. Symptoms denoting cardiac weakness are sometimes present, causing shortness of breath and tendency to syncope. Failure of heart-power may occur suddenly and terminate fatally. The temperature of the body is lowered, the thermometer in the axilla showing a temperature of 96° or 95° F. in some cases in which the disease is uncomplicated. The skin usually is dry and rough. It is rare for perspiration to occur except when pulmonary tuberculosis becomes developed. Furfuraceous desquamation of the epidermis is not uncommon. Itching of the skin is a symptom which sometimes occasions much annoyance. Diabetics are subject to carbuncles, boils, and various eruptions—namely, psoriasis, lichen, eczema, and impetigo. Spontaneous gangrene of the lower limbs is an occasional event. I have known of several instances in which this occurred. The gangrene resembles gangræna senilis. Ulcerations of the lower limbs without gangrene have been observed. Wounds and surgical operations often take an unfavorable course in diabetic patients. In protracted cases œdema of the legs frequently occurs. Bright's disease is an occasional complication of diabetes.

Muscular feebleness is more or less marked and progressive. Aside from the effect of complications, the patient is enfeebled in proportion to the excessive excretion of the urine, the amount of sugar which it contains, and the duration of the disease. Troubles of vision are not very infrequent. Amblyopia, or feebleness of vision, sometimes occurs early, and may eventuate as the disease advances in confirmed amaurosis, either complete or incomplete. Troubles of accommodation are not rare. In the majority of cases in which the vision is affected the defect is slight or moderate. Complete amaurosis is extremely rare. In the cases in which amaurosis, complete or incomplete, exists, the ophthalmoscope shows atrophy of the optic discs. Retinitis is a ground for suspecting that albuminuria coexists. The

diabetic condition also favors the development of soft cataract. In some cases recovery from defect of vision occurring in diabetes takes place after the sugar has disappeared from the urine. Diminution, and at length extinction, of venereal desire belong to the clinical history of the disease. This effect frequently occurs early in the history of the disease, before the general powers of the system are much reduced. It may be the first symptom noticed by the patient. It is not, however, a constant symptom. In women the menstrual discharge gradually diminishes and is at length suppressed.

Certain symptoms referable to the nervous system are of great importance in the history of diabetes. The mental condition frequently undergoes a marked change; the patients become irritable, sad, and hypochondriacal; and the intellectual faculties are enfeebled. Neuralgia, affecting most frequently the sciatic nerve and often occurring on both sides of the body, is an obstinate symptom in some cases of diabetes. Occipital and trigeminal neuralgiae have also been repeatedly observed. Absence of the knee-phenomenon is not an infrequent symptom in diabetes.

By far the most important of the nervous symptoms of diabetes are those which have been embraced under the name diabetic coma. The coma may follow physical over-exertion, mental excitement, or some slight bodily ailment, such as pharyngitis, gastritis, or bronchitis, or it may appear without any apparent exciting cause. The advent of coma may be sudden, but more frequently it is preceded by premonitory symptoms, of which the most important are headache, nausea, and vomiting, a sensation of anxiety and of oppression, restlessness, and noisy delirium, sometimes attended with fits of screaming. With or without this premonitory period of excitement and delirium the patient sinks into a state of somnolence deepening into coma. The coma is usually accompanied with a peculiar dyspnoea, without evidence of disease of the lungs or air-passages, the respirations being strong, deep, and often noisy. The number of respirations is either normal or more frequently moderately increased. The pulse usually is small and frequent. The temperature usually is subnormal. A peculiarity of diabetic coma is the marked ethereal odor of the breath, compared to the odor of fruit or of chloroform. The urine in the great majority of cases presents Gerhardt's reaction. The duration of the coma is generally between one and three days, but it may be shorter or longer. The termination is generally, but not necessarily, fatal. Coma may occur without the characteristic dyspnoea.

The most plausible explanation of diabetic coma refers this symptom to the presence of some toxic substance in the blood, but we are ignorant as to the nature of this substance. The fruity odor of the breath and the changes in the urine have led to the supposition that acetone or some kindred substance is the toxic agent; but it has not been possible to confirm this supposition. It is not probable that the coma is due to fatty embolism, as has been suggested.

Coma may occur in diabetes from uræmia, sudden failure of heart-power, and cerebral hemorrhage, but these cases are not identical with the so-called diabetic coma.

The course of diabetes is generally slow. Its development is imperceptible, and when discovered it had probably, in most cases, existed for a considerable period. It is therefore difficult to fix the date of its origin; but, dating from the time when its existence is known, in most cases it continues for many months, and not infrequently for many years, before ending fatally. Its duration is indefinite and variable. Exceptionally, it runs rapidly to a fatal issue. Generally in these cases the patient is cut off by some intercurrent affection. The existence of diabetes notably impairs

the tolerance of other diseases. Griesinger found the mean duration in 225 cases to be between two and three years. Cases have been described under the name *diabetes acutus* in which the disease has appeared only a few days or weeks before death.

CAUSATION.—In the vast majority of cases of diabetes the age is between thirty and fifty years. The disease occurs in infancy, youth, and advanced life, but instances are rare. Facts go to show that predisposition is an important factor in the causation, and that this predisposition may be inherited. Of 36 cases recorded, with reference to this point, by A. Flint, Jr., in 10 two or more cases occurred in members of the same family. In one instance a father, an uncle, two sisters, two brothers, and a son of one of the sisters were affected with the disease.¹ As regards pathogenetic influences pertaining to climate, season, diet, temperament, habits of life, etc., we have only conjectures without any precise information. Men are oftener affected than women. Of the 225 cases analyzed by Griesinger, in 172 the patients were men, and in 53 women.

In a considerable—not a large—number of instances the disease follows some injury of the head or spine or a concussion of the whole body. In some of these instances the glycosuria may have been only a transient symptom, and in other instances there may be room for doubt as to any causative connection, considering that in a large majority of cases no such causation is evident. A constant connection has not been established between the disease and cerebral lesions affecting the floor of the fourth ventricle, which the experiments of Bernard on animals showed to stand in a causative relation to glycosuria. Autopsical examinations in cases of diabetes mellitus have failed to discover lesions in this situation, and lesions have been found here when diabetes had not existed. No pathological connection of the disease with any anatomical changes in the liver has been ascertained. Syphilis and gout have been assigned a share in the causation, but with what propriety is uncertain.

The disease in some cases has been attributed to violent mental emotions. [Prof. Cantani of Naples, whose experience of diabetes was based on the study of more than one thousand cases, believed the principal cause of this disease to be the abuse of farinaceous and saccharine substances. In support of this view he adduces the following facts: In Naples, where the diet of the people is largely farinaceous, diabetes is so prevalent that a physician in large practice may have twenty or thirty cases of the disease under observation at the same time. On the other hand, in Genoa, where the amount of meat consumed by the inhabitants is large, it is difficult to obtain a case of diabetes for clinical purposes.

According to Cantani, diabetes begins with non-combustion of a fraction of the ingested carbohydrates, and therefore there appears in the urine—which, as a rule, is not increased in quantity at this early stage—only the non-assimilated sugar. By degrees less and less sugar is consumed, until at last there comes a stage when the amount of sugar excreted corresponds exactly with that ingested. It is therefore, according to Cantani, no real privation to eliminate carbohydrates from the diet of a diabetic, at least in late stages of the disease, for they serve no nutritive purpose. They are excreted practically unchanged, and are the chief cause of the polyuria and its evil consequences.

The other principal theory of the etiology of diabetes is that of Ebstein. This observer, having determined by a series of ingenious experiments that

¹ *Journal of the American Medical Association*, April 17, 1886. The "son of one of the sisters" developed diabetes since the note appeared in the *Journal*.

carbon dioxide retards the conversion of glycogen into sugar outside of the body, employs this fact to explain the non-combustion of sugar in the diabetic. He believes diabetes to have its source in a general alteration of the protoplasm of the body, as a result of which it produces less than the normal amount of CO_2 . In consequence an excessive quantity of glycogen is converted into sugar, giving rise to the glycæmia and glycosuria of diabetes.—H.]

DIAGNOSIS.—It is to be borne in mind that the fact of sugar existing in the urine is not alone sufficient evidence of the existence of the disease under consideration. Sugar, generally in small quantity and for a transient period, is not infrequently found in the urine in the course of various maladies. In aged persons the urine sometimes temporarily contains a considerable amount of sugar. A number of instances have fallen under my observation. I have known much needless uneasiness to be occasioned by announcing to a patient the discovery of a trace of sugar after an analysis of the urine.

If diabetes exist, saccharine urine is more or less persistent, the amount of sugar is unusually large, and generally the quantity of urine is notably increased. These points relating to the urine render the diagnosis sufficiently easy and positive. The diagnosis is confirmed by other symptoms belonging to the clinical history of the disease. If the quantity of urine be considerably increased, and on testing with the urinometer the specific gravity be found high, sugar is probably present. Sugar, however, is sometimes present in urine of low specific gravity. In cases of polyuria in which only the water of the urine is increased, as in diabetes insipidus, the specific gravity is extremely low, sometimes but little above that of spring-water. The fragrant odor of diabetic urine is characteristic, and it froths readily on agitation, the air-bubbles remaining for some time, but the practitioner should not be satisfied without demonstrative proof of the presence of sugar. Of the several methods of testing urine for sugar, one readily available is the fermentation test. A common test-tube or phial containing a little ordinary yeast is to be filled with urine, inverted and placed in a saucer containing the urine, care being taken to prevent the entrance of air. Kept at a temperature of 70°F. fermentation ensues, and the gas formed rises in the tube and displaces the urine. The gas is shown to be carbonic acid from its failure to support combustion. Christison states that a cubic inch of the carbonic acid formed in the fermentation test represents a grain of sugar. Of the various other methods of testing for sugar, the employment of Fehling's solution is the most convenient, and it is sufficiently reliable. I have found this test as prepared by Squibb in two separate solutions, to remain unchanged for a year kept in glass-stoppered bottles, although used almost daily. Böttger's test with the subnitrate of bismuth is readily applied. The polarization test is probably the most accurate, but it is not necessary to resort to this for clinical purposes. If it be desired to ascertain the actual amount of sugar excreted in a given period, the volumetric method of analysis by Fehling's test or Roberts's differential density method may be employed.¹ Examinations of urine are to be repeated, in the first place, to settle the persistence of the saccharine condition, and in the second place with reference to improvement or otherwise. [A convenient instrument for the estimation of the quantity of sugar in the urine has been recently devised by Dr. Charles W. Purdy of Chicago.—H.]

PROGNOSIS.—As regards prognosis, a distinction is to be made between cases in which the sugar disappears from the urine when the diet is free

¹ Vide Roberts, *Urinary and Renal Diseases*, Philadelphia, 1879.

from carbohydrates, and cases in which sugar persists during a strictly albuminous diet. The former class of cases is in general more amenable to treatment and offers a better prognosis than the latter. The milder cases may, however, become severe, and they may terminate fatally by some of the many complications to which diabetic patients are subject.

An early diagnosis diminishes the gravity of the prognosis. This fact enforces the importance of examining the urine for sugar in all cases in which there are any grounds for suspecting its presence; and it is to be recollected that sugar is sometimes persistently present when the quantity of urine is not much, nor even at all, increased, and when the specific gravity is not notably above the normal standard. Examination of the urine for sugar should not be omitted whenever failure of strength or emaciation occurs without apparent cause, and especially if the appetite be increased rather than diminished. Unusual thirst, dryness of the mouth or fauces, acidity of the saliva, impairment of vision, obstinate neuralgia, diminution or extinction of venereal desire, dryness and itching of the skin, irritation or inflammation of the prepuce or glans penis, and pruritus vulvæ, should suggest the possibility of the existence of this disease. A certain amount of increase in the quantity of urine may not attract the attention of the patient, or the patient may not deem it a symptom of importance, and it is therefore necessary for the physician to direct inquiries to this point.

The age and the weight of the body have a bearing on the prognosis. The prognosis is in general unfavorable in proportion to the youth of the patient, and as regards this disease corpulence is a distinct advantage.

The existence or development of complications is of great influence in the prognosis. The majority of fatal cases of diabetes terminate either in phthisis or in diabetic coma. According to some statistics, the most frequent cause of death is coma. The phthisis is a genuine pulmonary tuberculosis. Other not infrequent complications which may prove fatal are—pneumonia, nephritis, carbuncles, gangrene, and cerebral hemorrhage. The existence of diabetes lessens the ability to cope with affections which under other circumstances might not prove serious. Not a few cases terminate in debility and marasmus.¹

In respect of prognosis much depends on the ability and willingness of the patient to efficiently carry out the dietetic treatment.

Undoubtedly, the majority of cases of diabetes mellitus terminate fatally sooner or later. My experience, which has been considerable, has led me, however, to modify somewhat the views respecting prognosis which were expressed in the early editions of this work. The disease seems to me less formidable than heretofore, provided proper treatment be adopted and persisted in. Moreover, I have met with a number of cases which illustrate the tolerance of the disease by those who have not been aware of its existence and by those who refuse to submit to rigid dietetic restrictions. In the great majority of cases the diabetic condition may be notably ameliorated, but there is always more or less danger of a relapse even in cases in which the sugar has been made to disappear and the patient has regained his usual health.

TREATMENT.—The essential treatment of diabetes mellitus is dietetic. The object is the exclusion, as far as possible, of sugar and starch from the diet.

¹ Of 250 fatal cases observed and analyzed by Frerichs, the following were the causes of death: Exhaustion, 18; phthisis, 34; pneumonia, 7; nephritis, 8; carbuncles, 6; cerebral hemorrhage, 10; cerebral softening, 2; cerebro-spinal meningitis, 3; other complications (cancer, etc.), 9; and in all the remaining cases (153) coma diabeticum (Frerichs, *Ueber den Diabetes*, Berlin, 1884). Most statistics have shown a larger proportion of phthisical cases; for instance, 43 per cent. in Griesinger's analysis.

In proportion as this object is effected the glycohaemia and glycosuria diminish. Not infrequently all evidence of the disease disappears under strict dietetic treatment, and the patient is apparently in perfect health. Difficulties in the way of success under this treatment arise from the inability to carry it out rigidly. Patients sometimes have not sufficient strength of will to adopt and persevere in the dietetic restrictions. In some cases this difficulty does not exist, but the system will not tolerate the restrictions, and the vital functions give way under the continuance of the treatment. Complications or associated diseases sometimes render its adoption impracticable.

In not a few instances the physician is responsible for want of success with dietetic treatment, his instructions not being given with sufficient precision. It will not be sufficient to say, in general terms, that saccharine and starchy articles of diet are to be avoided. Most patients have not sufficient knowledge of alimentary principles to discriminate correctly the food which is allowable. I have known instances, for example, of diabetic patients eating freely of rye and corn-meal bread under the belief that only wheat bread was interdicted. It is essential that a written or printed list be furnished to patients of all the articles which may enter into the diet and of all those which are to be excluded. Such a list is essential in order to meet another requisite for success. The dietetic treatment must be made to satisfy not only the needs of nutrition, but the desires of the patient. This can be done only by varying the articles of diet from day by day, by making combinations to suit the appetite, and by the preparation of food in ways to be acceptable to the taste. Hence the diet-list should be as comprehensive as possible.

Bread occasions more difficulty than any other article of food. The force of the phrase "staff of life," as applied to bread, is appreciated when the attempt is made to exclude it persistently from the diet. Diabetic patients of good resolution will begin the dietetic treatment with the conviction that they can do very well without bread, but after a time the desire for it becomes too imperative to be resisted without great discomfort. The fact, then, is to be accepted that some form of bread must enter into the diet. Different substitutes for bread which have been devised do not satisfy the want of it. Flour consisting only of bran, prepared after Camplin's method, is generally tolerated but for a short time. Patients soon have a repugnance for it, and, as it is innutritious, there is then no advantage in persisting in its use. This is measurably true, also, of flour consisting of pure gluten, and of the almond-flour recommended by Pavy. Either a certain quantity of ordinary bread must be allowed, or a bread must be used containing a diminished proportion of starch without its entire exclusion. A bread made by Messrs. H. V. Hecker & Co. of New York contains a very small proportion of starch. This bread is light and agreeable, but it requires great care in its preparation. Analyses made by Prof. C. A. Doremus gave between 1 and 2½ per cent. of starch, whereas in ordinary bread the proportion is about 55 per cent. In a number of cases in which I have advised its use patients have found it to be a satisfactory form of bread.

The bill of fare for diabetics is very extensive. All varieties of shellfish are allowable. Soups of various kinds may be prepared without flour, rice, vermicelli, or any other article which contains starch. Fish of every description may be eaten, either fresh, salted, or preserved in oil. Of meats, poultry, and game, there is but a single exception—namely, the livers may contain enough sugar to warrant their exclusion. Salads may be made of lettuce, celery, cucumber, romaine, watercress, Brussels sprouts, chicory, dandelion, young onions, coldslaw, and olives. Of vegetables, other than those just named, the list embraces spinach, cabbage, cauliflower, string beans, pickles, beet-tops, sorrel, radishes, mushrooms, asparagus, truffles, artichokes, oyster-plant or

salsify, and tomatoes. Eggs, caviar, cheese of all kinds, butter, cream in moderation, unsweetened jellies, filberts, pecan-nuts, almonds, butternuts and walnuts, Brazil-nuts, and cocoanuts are included. Of drinks, coffee, tea, and cocoa without sugar, whiskey, brandy, gin, claret, Burgundy, and dry sherry are permissible. Glycerin may be used in lieu of sugar in coffee and tea. A patient under my care ate with relish custards made with glycerin instead of sugar. It is stated that mannite, inosite, levulose, and inulin are forms of sugar which may be taken without rendering the urine saccharine. This statement needs further confirmation based on experimental observation. The interdicted kinds of food are—sugar, syrups of all kinds, and honey, wheat and rye flour and corn-meal, arrowroot, sago, tapioca, oatmeal, barley, potatoes, beets, parsnips, carrots, rhubarb, peas and beans, chestnuts, sweet fruits of any kind, chocolate, cider, most malt liquors, champagne and other sparkling wines, all the sweet wines, sweetened spirits, and liqueurs. The admissible articles of diet have been conveniently arranged by Austin Flint, Jr., in the form of a bill of fare.¹

The very bitter ales may be taken moderately. Turnips are considered by some as allowable. Celery is interdicted by some, but probably without reason. There have been doubts as to tomatoes, but they are probably correctly placed in the list of allowable articles. The quantity of ingested fluids should be moderately restricted.

For the sake of emphasis it may be repeated that success will depend on the pains taken to vary, combine, and prepare the allowable kinds of food, so as to render the diet satisfactory as regards the patient's taste, appetite, and digestion. To do this will require much and constant attention on the part of those who have charge of the dietary of diabetic patients. It is difficult to carry out the dietetic treatment properly in hospitals. Patients can rarely have it properly carried out in hotels and boarding-houses. Poverty is sometimes a serious obstacle in the treatment of this disease.

Under the dietetic treatment, faithfully carried out, the sugar in the urine is speedily diminished. In a considerable proportion of cases it disappears; the quantity of urine decreases and often becomes normal in this regard; the thirst disappears, and there may be no evidence of ill health. Patients have repeatedly declared, even when the urine still contained some sugar, that were it not for the knowledge of this fact they would not suspect the existence of any malady. Not infrequently there is a consciousness of better health than for a long time before the diabetic disease was discovered.

The return to the articles which are not in the list of those allowable is to be made after a time gradually and tentatively, watching the effect upon the urine. Probably in most instances an unrestricted diet will cause a return of the saccharine urine if the cases of transient diabetes, to which reference has been made, be excepted. Under these circumstances patients cannot be considered as cured; but, on the other hand, the restricted diet, with proper pains, may be well tolerated indefinitely, the general health remaining excellent. Although, therefore, the disease be not cured (quoting the language of Senator), it may be made entirely harmless.

Reference may be here made to the skimmed-milk treatment proposed by Donkin. His method consists in confining the patient strictly to skimmed milk, from six to eight pints being taken daily, the treatment to be continued for ten or twelve weeks, after this period other articles of diet being gradually added and at length substituted. That this plan of treatment has proved temporarily useful in some instances must be admitted; in most

¹ A. Flint, Jr., "On the Treatment of Diabetes Mellitus," *Journal of the Am. Med. Association*, July 12, 1884.

instances, however, it has been not only nugatory, but hurtful and even destructive.

As regards the employment of drugs, if there be no special symptomatic indications to be met by remedies, before any medication is employed it should be ascertained how much may be effected by diet alone.

The alkalies, first employed for theoretical reasons, have been found to be useful in some cases. Trousseau's method was to give a drachm daily of the bicarbonate of soda, and to increase the doses gradually to three or even four drachms. In order to avoid the evils incident to super-alkalinity of the blood he advised that the remedy be given only during ten consecutive days in each month. I have seen the good effect, apparently, of this treatment when there was not much restriction in diet. The benefit which patients derive from treatment at Carlsbad and Vichy cannot depend greatly on the alkaline springs, for the same benefit is not derived from the water when taken at home. The credit belongs, in a great measure, to accessory circumstances in these watering-places and to the treatment in other respects. A cure is not to be expected from the use of alkalies, and it is seldom advisable when patients can carry out and tolerate strict dietetic treatment.

Opium causes diminution of the sugar in the urine. Pavy, who advocates the opium treatment, advises, in preference to other preparations, codeia, giving it in doses gradually increased from a quarter of a grain to two grains three times daily. The treatment relieves, but it does not effect a cure, and it is open to objection on the score of a liability to the formation of the opium habit. Opium, however, is indicated in some cases for the relief of muscular pains, from which diabetics not infrequently suffer, and which prevent sleep.

Other remedies among the great number which have been recommended are—the carbonate of ammonia, lactic acid, cod-liver oil, the iodide and the bromide of potassium, iodoform, ergot, arsenic, arsenite of bromine, carbolic acid, salicylic acid, salicin, strychnia, jambol, and sulphide of calcium. Each of these in certain cases is more or less useful, but no one of them is entitled to be considered as a curative remedy. The late Dr. Frick of Baltimore studied the relative effects of different remedies in a case under his observation for nine months, and the diminution of the sugar in the urine was most marked under the use of strychnia. Dickinson remarks that "strychnia is, of all remedies, the most constantly useful." Some cases are notably benefited by salicylic acid or salicylate of sodium. [Favorable reports concerning the treatment of diabetes with jambul or jambol have been recently made by several writers, while with others the results have been negative. Possibly the discrepant results are due to the fact that in India different plants are included under the term jambul. The powdered seeds may be used in daily doses of 150 to 320 grains. It is highly significant that the drug is recommended to be always given in connection with a carefully regulated diet.—H.]

There may be indications for remedies without reference to any curative effect. Tonics are indicated if the appetite or the digestion be impaired. Anæmia, as in other pathological connections, calls for iron. The nervous system may be tranquillized and sleep induced by the bromides or other hypnotic remedies. Various symptoms may require palliative treatment.

An important part of the treatment of diabetes pertains to hygienic observances. The body should be protected against atmospherical changes and the functions of the skin should be well maintained. The warm bath or sponging the body, if the immediate effect be agreeable, is to be recommended. The hydropathic pack has been found serviceable. A change from a climate which is cold and variable to one uniform and warm is often highly advantageous.

long sea-voyage in a warm latitude has proved signally beneficial. Exercise in the open air is to be advised, not exceeding so far the limits of comfort as to induce over-fatigue or exhaustion. Gymnastic exercises may sometimes be resorted to with profit. [By means of muscular exercise sugar may be made to disappear from the urine in the early stages of the disease in mild cases, even though the use of carbohydrates be continued in moderation; and in the severer forms the affection may by the same means be diverted into a more benign course.—H.] Last, but not least in importance, mental relaxation and recreation are to be enumerated in the list of regiminal measures.

An efficient treatment in cases of diabetic coma has not been found. Camphor, ether, and other stimulating restoratives may be tried.

Involuntary Seminal Emissions—Spermatorrhœa—Impotence.

Involuntary seminal emissions, spermatorrhœa, and impotence frequently depend on abnormal conditions which belong to surgery, but not infrequently they fall properly within the sphere of the practice of medicine. By involuntary seminal emissions is meant the ejaculation of semen and the venereal orgasm without any voluntary effort, either natural or unnatural. Involuntary emissions occurring during sleep are common, taking place in connection with erotic dreams. Occurring after intervals of several days in persons of continent habits, they are physiological rather than pathological. They denote simply a certain amount of functional activity of the generative organs. They do not imply a morbid condition nor do they lead to any morbid effects. They occur especially when habitual sexual intercourse is interrupted from any cause. Under these circumstances they are manifestations of health rather than of disease. The physician is warranted in giving such assurances to patients, who are often rendered needlessly apprehensive and unhappy by popular works or lectures the object of which is to excite fears for a mercenary purpose.

Occurring more frequently, the emissions denote a morbid erethism and weakness of the organs of generation. They occur sometimes nightly, and sometimes even repeatedly during the same night. They then call for remedial measures, although even under these circumstances their morbid effects have been much exaggerated. Occurring in persons debilitated from any cause, they may take place without erection and with little or no venereal excitement, the patient sometimes becoming aware of their occurrence only by the seminal stains. They occur sometimes during the day when the venereal desire is excited. These are called diurnal in distinction from nocturnal emissions. A patient stated to me that they had occurred in his case from excitement caused by shampooing the head in a barber-shop. Persons who have been addicted to venereal excesses or to unnatural abuse of the sexual function are especially subject to this morbid frequency of involuntary emissions. The mind in such cases, particularly if the affection be attributable to unnatural abuse, may become greatly depressed; the patient is apprehensive of impotence or fancies that he is already impotent; his attention is absorbed with the affection; he suffers from a sense of pollution and degradation; he believes that his constitution is ruined and that there is danger of insanity. Patients in the condition just sketched form an unfortunate class with which every practitioner is more or less familiar. They go from one physician to another, and upon patients of this class quacks prey largely. The affection sometimes exists in a still greater degree. The emissions are

diurnal as well as nocturnal. They are produced by anything which provokes the sexual passion, and may take place with little or no excitement of the external organs.

Spermatorrhœa means, strictly, the discharge of semen without the occurrence of the orgasm. It is an affection superadded to morbid seminal emissions, the seminal secretion passing into the urethra, and sometimes into the bladder, without the consciousness of the patient. In cases of spermatorrhœa the semen is expelled in the acts of micturition and defecation. Cases of true spermatorrhœa are far less frequent than has been supposed. Persons have been regarded as having this affection whenever a mucilaginous fluid bearing some resemblance to semen is discharged from the urethra. The microscope affords the only trustworthy mode of determining that the liquid is seminal. Were this mode of examination generally employed, cases of spermatorrhœa would be found to be extremely rare. In examining the sediment of the morning urine it is to be borne in mind that spermatozoa will be likely to be found if sexual intercourse or a seminal emission have taken place during the night. The presence of the spermatozoa under these circumstances is not evidence of spermatorrhœa. Veritable spermatorrhœa doubtless occurs, but probably only in persons who are affected with a morbid frequency of seminal emissions. Mucopurulent matter escaping from the urethra or observed in the urine in cases of cystitis may give rise in the mind of the patient to the apprehension of spermatorrhœa. A transparent viscid liquid escaping in small quantity from the urethra, especially after prolonged erection, not infrequently occasions much uneasiness in the minds of persons whose attention is directed to the sexual organs with reference to spermatorrhœa, and of those who have gonorrhœa. This is treated as a gleet discharge by empirics. The discharge is a secretion from the prostate gland and is of no practical importance. It is sometimes of importance in a medico-legal view to determine whether stains on linen be caused by dried semen. The physical characters of suspected stains are not to be relied upon, nor is chemical analysis reliable. If, however, water be slowly added to the stains and portions be examined by the microscope, spermatozoa will be recognizable when the stains are seminal.

Involuntary seminal emissions and spermatorrhœa are frequently associated with symptoms denoting various kinds of functional disorder, especially disturbance of the nervous system. These symptoms have been considered as direct morbid effects of seminal losses. More or less general debility is undoubtedly a result of an abnormal discharge of semen, but the latter is often incidental to disorder of the system otherwise produced; and the disturbance of the nervous system so frequently associated with seminal losses is measurably due to the mental depression and apprehensions which they frequently occasion.

In the TREATMENT of seminal emissions the distinction which has been made between their physiological and pathological character is to be kept in view. Occurring infrequently in a person of full health, in addition to assurances of their innocuousness it will generally suffice to advise moderation in the use of wine or spirits and stimulating articles of food, saline laxatives occasionally, cold ablution of the genital organs at night, avoidance of undue warmth from the bed or bedclothes and of distension of the bladder, and that the mind be diverted as much as possible from provocatives of sexual desire. If these measures do not suffice, certain remedies which appear to exert an aphrodisiac influence may be prescribed. Remedies which may be given for this purpose are camphor, lupulin or the tincture of hops, conium, belladonna, and the bromide of potassium. The remedy last named has seemed

to me to be distinctly efficacious. Marriage is always remedial in these cases.

Cases in which the emissions depend upon a morbid erethism and weakness of the generative organs, and cases of spermatorrhœa, are of more importance and the treatment is more difficult. The anaphrodisiac remedies are indicated, but in these cases much benefit is derived from tonic remedies and an invigorating regimen. Quinia, small doses of strychnia or nux vomica, and the preparations of iron are useful. Sea-bathing or the sponge-bath and out-of-door life or gymnastic exercises are useful regiminal measures. The diet should be nutritious, but not stimulating, and alcoholic stimulants are to be taken very moderately or interdicted. Everything calculated to provoke sexual desire should, as far as practicable, be avoided. Healthful mental occupation and chaste associations do very much toward effecting a cure. It is obvious that to carry out the moral part of the treatment requires on the part of the patient a determination and perseverance which are often wanting. Taking into view all the circumstances in individual cases, it is sometimes judicious to encourage or recommend marriage.

Attention is to be directed to the condition of the urethra in cases of seminal emissions and spermatorrhœa. They often follow gonorrhœa, and are sometimes dependent more or less on urethral stricture. According to Lallemand, seminal losses often depend on an abnormal sensibility at or near the prostatic portion of the urethra, and the treatment in these cases requires the use of the bougie and cauterizing applications. The opinion of Lallemand is held by distinguished surgeons at the present time. For information on this point the reader is referred to surgical works.

Impotence means inability to perform the act of coition. The term does not mean want of the power of procreation, and the latter may be wanting when there is no incapacity for sexual intercourse. Exclusive of malformations and other abnormal conditions of a surgical nature, impotence, in the first place, may involve absence of sexual desire. Different persons in health differ widely as regards the venereal propensity; in some persons the sexual desire is intense and importunate, in others it is feeble, and sometimes it is altogether wanting. The propensity may, on the one hand, be increased by indulgence and by fostering in various ways ideas connected with it; and on the other hand it may be diminished and extinguished by an opposite course. In the marital relation frigidity, as regards this propensity, may depend on personal antipathy, and hence is a not infrequent source of domestic unhappiness. Absence of sexual desire may arise from general debility, and is incident to various diseases. If the disease with which it is connected be not serious nor permanent, a return of sexual desire may be expected on recovery of the accustomed health. Intense mental preoccupation, the depressing emotions, and exaltation of the higher sentiments tend to repress sexual desire.

As the loss of virility is generally dreaded, physicians are often consulted when a notable change as regards the venereal propensity is experienced. The circumstances which have led to the change in individual cases are to be investigated, and the conclusion with respect to the probability of impotence, together with the treatment, is to be based on these circumstances. In a large proportion of cases the deficiency or absence of sexual desire is due to temporary causes. Premature decline or extinction may result, on the one hand, from early and excessive indulgence or abuse of the generative function, and on the other hand from prolonged continence. Under certain circumstances aphrodisiac remedies are desired. The remedies so called are of doubtful efficacy. Phosphorus, cantharides, and nux vomica have been

considered as special stimulants acting on the organs of generation. They should be given circumspectly. It is sometimes useful to secure the moral influence of the administration of remedies supposed to have this effect.

Impotence may exist without loss of sexual desire. Temporary incapacity proceeds from timidity or deficient self-confidence. The physician is not infrequently consulted by persons about to enter upon marriage who are apprehensive of being incompetent to accomplish coition. Assurances of capability, if it be evident that the apprehensions are imaginary, may be all that these cases require. Persons who have practised masturbation in boyhood, and they who are subject to involuntary emissions during sleep, are not infrequently led to believe that they are impotent by pernicious publications or lectures designed to alarm sensitive minds; and apprehension on the score of ability to accomplish the act of coition creates incapacity. A failure to accomplish the act is likely to be followed by the conviction that impotence exists, and, practically, it does exist so long as this conviction continues. In such cases all that is requisite is that the act of coition should be undertaken without any anxiety as to success. It is useful in such cases to interdict sexual intercourse for a certain time, in order to prevent tentative efforts, which, if unsuccessful, fasten the conviction of impotence more and more upon the mind. If a certain period of abstinence be enforced, it will be likely to happen that the patient is impelled by his desires to demonstrate his capacity before the period expires. It is sometimes the case, however, that coition is permanently prevented by fancied incapacity. I have known an instance in which this was the probable explanation of the absence of sexual intercourse during the whole of a married life lasting over fifteen years, and in another instance five years had elapsed without any accomplishment of the act of coition. In both instances seminal emissions occurred not infrequently. A remedy prescribed with an assurance of a cure doubtless sometimes proves curative by a moral effect. In certain cases impotence, with sexual desire, is a result of the erethism and weakness of the generative organs associated with seminal emissions and spermatorrhœa. The ejaculation and orgasm take place at the beginning of, or prior to, the act of coition. This kind of impotence is sometimes, temporarily, a result of prolonged continence. The measures of treatment in such cases are those indicated by seminal emissions and spermatorrhœa. Persistence in the employment of these measures, together with a proper degree of reserve as regards the frequency of the attempts to consummate sexual intercourse, will generally prove successful.

Excessive indulgence in venery, when it does not lead to involuntary seminal emissions, spermatorrhœa, or impotence, is a not infrequent cause of ill health. Dyspeptic ailments, attacks of vertigo, functional disorder of the heart, melancholia, and hypochondriasis are among the morbid effects of this cause. It is the duty of the physician to inquire into the habits of patients in this regard. The evils of excessive indulgence, aside from moral consequences, are greater when it is illicit than when it is marital; and moreover, the former is far more likely to be excessive. The limits of a healthful indulgence doubtless vary according to constitutional vigor, but it may be considered as excessive if the acts of coition are repeated several times a week.

The unnatural abuse of the sexual function, or masturbation, as a cause of involuntary seminal emissions, spermatorrhœa, and sometimes of impotence, has been already referred to. The effects on mind as well as body are pernicious. It is plainly the duty of the physician not only to endeavor to discover and arrest this practice in individual cases, but to enjoin upon parents, teachers,

and associates the importance of watchfulness in this respect over those for whose welfare they are to a greater or less extent responsible. There is also another duty of the physician connected with this important topic. Many sensitive persons who have been addicted to self-abuse in early life suffer greatly from the belief that their mental and physical powers have been irreparably injured. The evils, great as they sometimes are, are much exaggerated by popular works and lectures designed to excite fears for a mercenary end. The physician may often do much good by removing undue apprehensions connected with the errors of youth.

SECTION SEVENTH.

FEVERS AND OTHER GENERAL DISEASES.

CHAPTER I.

CLASSIFICATION AND PATHOLOGY OF FEVER.—FEBRICULA —CONTINUED FEVERS.

Classification of Fevers.—The General Pathology of Fever.—Febricula.—Typhoid Fever: Anatomical Characters and Clinical History.

Classification of Fevers.

THIS concluding section will be devoted to fevers and other general diseases.

Fevers are distinguished as *essential* and *symptomatic*. A symptomatic fever is one which is secondary to some local affection, such as an acute inflammation. The term essential distinguishes a fever which is not secondary or symptomatic, but is primary or idiopathic. Local affections may exist in essential fevers, but they cannot be considered the cause of the fever. The essential fevers are febrile infectious diseases. The essential fevers are those which are to be considered in this section.

According to the usual symptomatic classification of fevers we distinguish—

1. *Febricula*, a form of fever characterized by its short duration and mildness.

2. *Continued fevers*, which are distinguished by the unbroken continuity of the febrile phenomena, such as typhoid and typhus fevers. Relapsing fevers and erysipelatous fever may be included in this class.

3. *Periodical fevers*, which are distinguished by the occurrence of distinct paroxysms or notable exacerbations as regards the febrile phenomena, such as intermittent fever, remittent fever, typho-malarial fever, yellow fever, and dengue.

4. *Eruptive or exanthematous fevers*, in which an eruption on the surface of the body is a prominent feature, as in smallpox, scarlet fever, measles, roseola, and typhus.

Fevers are also often classified on an etiological basis into miasmatic, contagious, and miasmatic-contagious fevers. The malarial fevers are the type of the *miasmatic* forms. Probably pneumonia, and perhaps acute articular rheumatism, are also to be included in this category. *Contagious* fevers are smallpox, chicken-pox, scarlet fever, measles, r  theln, typhus fever, and relapsing fever. As *miasmatic-contagious* fevers are reckoned typhoid fever, yellow fever, and dengue. Epidemic dysentery and Asiatic cholera are also to be regarded as miasmatic contagious diseases.

The foregoing list of fevers does not comprehend all that exist. It com-

prehends, however, those which from their prevalence and established identity it is desirable to consider in this work. Some of the diseases which for convenience have been considered in preceding sections of this work, such as epidemic dysentery, Asiatic cholera, cerebro-spinal meningitis, trichinosis, and pneumonia, might with propriety have been included in the present section.

There are certain terms in common use which in their application to fevers require a few words of explanation. Fevers characterized by great prostration have been called *adynamic*, *asthenic*, or *low*. Fevers have been said to be *ataxic* when symptoms referable to the nervous system, such as delirium, etc., are prominent. Fevers of unusually long duration have been called *slow*; and when the febrile phenomena—especially the temperature—are intense, the fever is said to be *high*. The *initial stage* of a fever extends from the beginning of the disease until the full development of the fever. The period of full development, or acme, of the fever is sometimes called the *fastigium*. The fastigium is followed by the *stage of defervescence*, or decline of the fever. When the decline is rapid, occupying only a few hours or a day or two, the fever is said to terminate by *crisis*. When the decline is protracted the termination is by *lysis*. These different stages of fevers, to which may be added the *period of convalescence*, are of very unequal duration in the different forms of fevers.

General Pathology of Fever.

It is deemed desirable to introduce this subject in this connection, although properly it belongs to the department of General Pathology. The general causes and the theory of fever are among the most difficult and least understood subjects in general pathology.¹

It has been proven experimentally that various substances when injected into the blood or the tissues of an animal are capable of exciting fever. It has not been found possible to determine any general characters which distinguish these pyrogenic substances. It is of especial interest that various ferments, particularly fibrin ferment, and many of the so-called ptomaines or cadaveric alkaloids, possess pyrogenic properties. This has given rise to the supposition that the fever which is secondary to local inflammations, to necrotic foci, and to injuries is often due to the absorption of fermentative substances which are produced by the local disease. Micro-organisms are among the most important of fever-exciting agents, and are probably involved in the causation of all the essential fevers. It has been proven by experiment that injuries of various parts of the central nervous system, especially puncture of certain circumscribed regions of the brain, are followed within a few hours by marked elevation of temperature. There is reason, therefore, to believe that fever may be in some cases a purely nervous affection produced without the introduction of any pyrogenic substance into the blood.

In what way is the abnormal elevation of temperature produced in fever? It seems to be established, on the one hand, that an excessive amount of heat is produced in fever within the body, and, on the other hand, that in proportion to this excessive production less heat is given off from the body than in health. It is well known that animal heat is the result of chemical processes, especially processes of oxidation, which are constantly going on within the body. Now, it is found that in fever, in proportion to the amount of nourishment taken, there is an abnormally large quantity of urea excreted by the urine, and particularly that more oxygen is absorbed and more carbonic acid given off by the respiration than in health. These changes have been observed to be present before there is any elevation of temperature, so that

¹ An important monograph on this subject is that of H. C. Wood—*Fever: A Study in Morbid and Normal Physiology*, Washington, Smithsonian Institution, 1880.

they cannot be considered, at least not entirely, as secondary to the fever. They also indicate an increase in the oxidizing processes within the body, and therefore an increase in the amount of heat produced.

It has furthermore been rendered probable that the amount of heat given off from the body in fever is diminished relatively to the amount produced. When a fever is ushered in by a chill or by chilly sensations, the arterioles of the skin are contracted, the surface is cold, and there is an absolute diminution in the radiation of heat from the body. There is at this time the most rapid development of pyrexia. When the surface of the body is abnormally hot, as it is during the greater part of most fevers, it is evident that more heat must be given off by radiation than at the normal temperature of the skin; but there seems to be no doubt that, in proportion to the amount of heat produced in the body, there is less heat given off in fever than would be the case during a corresponding increased production of heat in health, as by severe muscular exercise. In other words, the equilibrium which normally exists between the amount of heat produced and that given off is disturbed in fever. Perspiration, which is an important factor in the regulation of the bodily temperature, is usually, although not always, diminished during the height of a fever.

We have no positive knowledge as to how fever-producing agents act in causing pyrexia. Since experiments have shown that injury of certain parts of the brain is followed by rapid elevation of temperature, which cannot be identified with ordinary traumatic fever, the theory has gained wide acceptance that the pyrogenic agents act primarily upon certain nervous centres. Whether these centres be special heat-centres, as has been surmised, or vaso-motor or other centres, is uncertain.

Our knowledge of the effects of the elevation of temperature upon the various organs and functions of the body is imperfect. Fever is accompanied with increased frequency of pulse and of respiration, and it has been shown experimentally that these effects follow elevation of the temperature of the blood. It has not, however, been proven, nor is it indeed probable, that all of the circulatory and respiratory disturbances of fever are directly referable to the elevation of temperature. The injurious effects of the special agents which cause the fever must also be taken into consideration. There has doubtless been a tendency to exaggerate the immediate effects of the pyrexia as such, and to disregard the action of the special agents of infection. Parenchymatous degeneration of muscular tissue, particularly of the heart, and degeneration of glandular cells, are common, but by no means constant, in fevers, even in severe forms, and are referable probably more to the infection than to the elevation of temperature. Nor is it justifiable to refer disturbances of the nervous, digestive, and renal functions in fever exclusively to the elevation of temperature. We possess no satisfactory explanation of the diminution of the chlorides in the urine in fever. The blood-pressure is generally diminished in fever. It has been shown that many fevers are accompanied by a destruction of red blood-corpuscles. The increased quantity of coloring matter in the urine also points to this. That fever of long duration should cause a loss of weight of the body is not strange when one considers the increased consumption of tissue and the small amount of nutriment ingested.

Facts warrant the conclusion that each of the essential fevers has its own special cause; in other words, that each requires a particular causative agent capable of producing that fever and none other. It is most consistent with our present knowledge, if it be not logically certain, that this causative agent is a living organism. The unlimited reproduction of the special cause within the body in the infectious fevers is a fact of which the causation by living organisms alone affords a rational explanation. In relapsing fever and in

id fever it is probable that the causative organisms have been diagnosed.

Febricula—Ephemeral Fever—Simple Fever.

The term *febricula*, a diminutive of *febris*, is perhaps the best name to give a mild, short fever which is everywhere of not infrequent occurrence. If very short, lasting only a single day, it is appropriately called an *ephemeral* fever. When not ephemeral the fever may continue for a period varying between three and eight, even ten, days. It has been known by a variety of names. It is frequently called *simple continued* or *simple fever*.

This fever has no known anatomical characters. The opportunity of post-mortem examination is seldom offered, for the disease rarely if ever of itself proves fatally, at least in cold or temperate climates. No lesions belonging to it have ever been found in cases in which, owing to complications, death has taken place.

The invasion in cases of febricula is generally abrupt, but in a certain portion of cases lassitude, loss of appetite, and general malaise exist for one or three days before the fever is developed. Irregular chilly sensations accompany the attack, but there is seldom a well-pronounced chill. The pulse movement is more or less intense; and not infrequently the acceleration of the pulse and heat of the surface are greater than at the beginning of typhus or typhoid fever. Pain in the head is a prominent symptom, the pain being generally frontal. There is more or less pain in the loins and back. Anorexia is usually complete. Constipation is the rule, and the intestinal symptoms which belong to typhoid fever are wanting. The urine is scanty and high-colored; the intelligence remains unaffected; and the hebetude which characterizes typhus and typhoid fever is not observed. There is no characteristic eruption; herpetic vesicles about the mouth sometimes occur; and bluish spots (*tâches bleuâtres*), from three to eight lines in diameter, not elevated and not disappearing on pressure, have been observed. They occur occasionally in typhoid fever.

The febrile career ends suddenly after one, two, three, or more days, the duration of the fever being ten days. Frequently with the cessation of fever there is a copious perspiration. Epistaxis and, occasionally, hemorrhage from the nose and rectum have been observed at the end of the fever. The convalescence is usually rapid, and there are no sequels. The thermometer indicates a sudden rise of temperature of four or five degrees, and as rapid a fall, the heat passing in one or two days to the normal standard.

This kind of fever is supposed to occur irrespective of any special cause; and, as a rule, ordinary causes are supposed to produce it. It is observed to follow exertion, dietetic excesses, and exposure to the sun's rays. This view of the causation is, however, conjectural. It is probable that certain cases which from their short duration are considered as cases of febricula are in cases of typhoid or typhus fever, the disease ending without going through its usual career; in other words, cases of ephemeral fever may be cases of abortive typhoid or typhus fever.

The diagnosis of febricula is of importance with reference to the success of measures employed to arrest or abridge the duration of typhoid and typhus fever. In cases in which measures employed for these ends appear to prove successful, the question is, Was the disease typhoid or typhus fever, or was it febricula? The following are considered as diagnostic points: 1, the rapid development of the fever; 2, the attack succeeding obvious and primary causes. To these is to be added absence of diagnostic traits belonging to the clinical history of either typhoid or typhus fever. Cases, however,

occur in which it is difficult or impossible to decide during the progress of the fever whether it be typhoid or typhus or a febricula, and after the fever ends whether it have been a febricula or an abortive or arrested typhoid or typhus fever.

Febricula in cold and temperate climates is rarely, if ever, fatal, except from an accidental complication of a serious nature. It is said to prove fatal not infrequently in tropical countries.

As regards the TREATMENT of febricula in cold and temperate climates, hygienic and palliative measures only are called for. A saline laxative, refrigerants, and anodynes are the remedies indicated.

Typhoid Fever.

The name *typhoid* signifies *typhus-like*. The pertinency of this name, as applied to the fever to be now considered, consists in the resemblance of the disease to typhus fever. It might, therefore, seem most appropriate to consider first typhus fever; but typhoid fever prevails very extensively in this country, and has been known with us as *common continued fever*, whereas typhus is comparatively rare, and the latter is perhaps never an indigenous disease. For this reason, reversing the order which the name suggests, I shall consider first typhoid fever with reference to its anatomical characters, clinical history, causation, diagnosis, and prognosis; afterward, typhus under the several aspects just named; and last, the treatment of typhoid and typhus fever.

The name *typhoid* is open to objection. It is customary to apply this name to a condition or state incident to many diseases, and hence has arisen confusion. Of other names which have been proposed, no one has been generally adopted, and probably the disease will continue to be called typhoid fever. This name was introduced by Louis, whose clinical researches were of great value, not merely with reference to our knowledge of this disease, but as inaugurating the true method of the study of the clinical history of all diseases—namely, by means of the analysis of carefully recorded cases. The correspondence of the results of the researches of Louis as regards typhoid fever with the results of similar researches by others in different countries furnishes the best possible proof of the value of the method of study, and at the same time shows the remarkable uniformity of the disease at different times and places. By German writers the disease is called *abdominal typhus* or *ileo-typhus*. Prof. Geo. B. Wood suggested as an appropriate name *enteric fever*. Both these names relate to the intestinal lesions which are characteristic of the disease, and they are objectionable because they convey the impression that the fever is the result of these lesions. Murchison proposed as the name *pythogenic fever*—a name which implies that the disease is produced by putrescent matter. It is an objection to this name that the source of the special cause, implied in the name, has not been established.

ANATOMICAL CHARACTERS.—The characteristic lesions of typhoid fever are seated in the lymphatic structures of the intestine—namely, Peyer's patches and the solitary follicles. Corresponding to the intestinal changes are alterations in the mesenteric glands. There are also important changes in other organs of the body, but most of the latter changes are common to many infectious diseases.

Four stages of the morbid process in the *intestine* may be distinguished: 1, the stage of congestion and simple inflammation of the mucous membrane; 2, the stage of medullary infiltration of the lymphatic structures; 3, the stage of retrograde metamorphosis and ulceration; 4, the stage of repair. These

stages correspond approximately to certain periods of the clinical history. In the *first* week of the disease are developed congestion and inflammation of the mucous membrane of the small intestine, together with swelling of a certain number of solitary follicles and agminated glands. In the *second* week the general congestion of the mucous membrane diminishes, and the swelling and infiltration of the solitary follicles and Peyer's patches increase. During this week necrotic changes in the swollen follicles and patches take place. The casting off of the necrotic tissue results in the formation of the typhoid ulcers. In the *third* week the process of ulceration is completed. After this follows the period of repair of the ulcers, which occupies a variable time. It is to be noted that different stages of the lesions are usually found in the same case. The changes are most advanced in the small intestine near the ileo-cæcal valve.

At the onset of the disease the mucous membrane of the lower part of the small intestine is hyperæmic, swollen, softened, and coated with mucus. At the same time Peyer's patches and the solitary follicles of the lower half of the ileum begin to enlarge. As their enlargement increases the hyperæmia diminishes, except in the immediate neighborhood of the swollen follicles and patches; these remain surrounded by a zone of congestion. The morbid process is most intense in the ileum near the ileo-cæcal valve. In some cases the solitary follicles of the large intestine are swollen, and they may ulcerate. This involvement of the large intestine is more common in some epidemics than in others. The follicles of the jejunum may likewise become swollen, but ulceration in this situation is rare. According to Hoffmann,¹ the disease rarely extends higher than nine and a half feet above the valve. Usually, both Peyer's patches and the solitary follicles are involved. Sometimes the changes are more marked in one of these structures than in the other. In the stage of *medullary infiltration* the solitary follicles and Peyer's patches are swollen, and project, one, two, three, or even four, lines above the plane of the adjacent mucous membrane. The enlarged solitary follicles preserve their round shape and may attain the size of a pea. The swollen Peyerian plaques are elliptical or long-oval in shape. Swellings many inches in length and in breadth may be produced, especially near the valve, by the confluence of several enlarged patches. Usually the patches are indurated to the touch. Their surface is sometimes smooth, and sometimes it presents an irregular, granular aspect. The edges are generally abrupt, and sometimes they are constricted near the base, so that the patch has somewhat of a mushroom shape. Upon section the infiltrated follicles and plaques have a grayish-red or a whitish color. The appearance on section frequently resembles that of the white matter of the brain or spinal cord, and hence the name *medullary infiltration* which is applied to this condition. The peritoneum corresponding to the affected patches is usually congested. The swelling of Peyer's patches and of the solitary follicles is due to an increase in the number of lymphoid cells normally present in these structures. In addition to the ordinary lymphoid cells there are also found larger cells with a greater amount of granular protoplasm. Some of these large cells contain several nuclei. The new cells are generally considered to be the offspring of the pre-existing lymph-cells of the follicles, and the whole process is regarded as a hyperplasia of the lymphatic structures. The cellular infiltration is not confined to the limits of the solitary follicles or of Peyer's patches, but extends for a certain distance into the surrounding mucous membrane. It also extends in depth for a variable distance. Sometimes chains of lymphoid cells can be traced from the follicles through the muscular coat to the subserous tissue.

¹ *Untersuchungen über die Path. anatom. Veränderungen der Organe beim Abdominaltyphus*, Leipzig, 1869.

The medullary infiltration may terminate in *resolution* or in *ulceration*. In the process of resolution the swelling of the follicles gradually diminishes, and many of the new cells undergo fatty degeneration and are absorbed. As a rule, this retrograde metamorphosis by degeneration and absorption occurs in some of the swollen follicles and plaques, while in others ulceration takes place. Sometimes the individual follicles of a Peyerian patch soften and discharge their contents. In these patches the intervening tissue forms a projecting network around the sunken follicles. This appearance characterizes the so-called reticulated patches. A reticulated aspect of the patches may be due also to simple degeneration and absorption of the infiltrated material in the follicles. The most characteristic termination of the process, however, is in the formation of a slough, and by the separation of the slough the production of the typical typhoid ulcer. The slough may occupy a whole Peyer's patch or only portions of a patch. It has usually a yellowish color from imbibition with bile. It may present a hemorrhagic appearance. The rapidity with which the sloughing process takes place varies in different cases. The process usually reaches its acme in the second week, but cases have been described in which the ulcers were fully formed on the seventh or eighth day of the disease. It must be remembered that it is by no means easy to determine in all cases the day on which the disease begins. It may be stated here that there is no constant relation between the extent of the intestinal lesions and the severity of the disease as denoted by the abdominal and other symptoms. The sloughing and ulceration take place earliest in the glands nearest the ileo-caecal valve, and usually different degrees of progress are presented in the series above this point. The necrosis or sloughing of the infiltrated glands is sometimes ascribed to arrest of the circulation from the pressure upon the small blood-vessels exerted by the excessive production of new cells; but it is equally probable that it is due to the presence of the typhoid bacilli. The necrosis does not usually extend beyond the boundaries of the affected Peyerian patches. Sometimes the slough separates *en masse*, but more frequently it is thrown off in fragments, leaving at first small, irregular losses of substance. After the sloughing is completed ulcers take the place of the affected solitary follicles and Peyer's patches. These ulcers have certain distinctive features. Those resulting from necrosis of the solitary follicles are round, while those which take their origin from Peyer's patches preserve the oval or elliptical shape of these patches, the long axis of the ulcer being parallel to the direction of the intestine. The bottom of the ulcer is usually smooth, and often presents to view the transverse muscular fibres of the intestine. The edges are undermined and more or less swollen and congested. The ulcer may extend in depth and reach the deeper layers of the muscular coat, or its floor may consist only of the serous membrane. *Cicatrizization* is the last step in the series of processes. Granulation-tissue springs from the floor of the ulcers. The undermined edges become united with the bottom of the ulcer. The resulting cicatrix is whitish, or more frequently pigmented, slightly depressed, and covered by epithelium. The villi and glands of the mucous membrane, according to most writers, are not regenerated. It is a remarkable fact that the cicatrices of typhoid ulcers have very little tendency to cause stenosis of the intestinal lumen. The process of cicatrization usually begins in the third week of the disease and continues during convalescence. The time occupied in the completion of this process varies in different cases. It is sometimes unusually slow—a fact which accounts for the persistence of the abdominal symptoms in certain cases for some time after the career of the fever is ended.

Perforation of the intestine is liable to occur in one or more of the ulcers. According to Hoffmann, perforation occurs in about 1 per cent. of the cases of

typhoid fever, and in about 8 per cent. of the deaths from this disease. It is most frequent between the third and the fifth week of the disease. It is rarely caused by the primary sloughing, but is due to secondary ulceration after the separation of the slough. The perforation may be due to rupture of the thin floor of an ulcer by distension of the intestine with gas, by the contact of feces, or by the presence of round worms. The opening in the peritoneal coat may be of considerable size or it may be no larger than a pin's point. With intestinal perforation are associated appearances denoting acute diffuse peritonitis, the latter being occasioned by the escape of the gaseous and other contents of the intestine into the peritoneal sac. In rare instances the peritonitis is circumscribed around the seat of perforation by means of adhesions. Death may occur before sufficient time has elapsed for the production of inflammatory exudation. Profuse hemorrhage may occur from the primary sloughing or from the secondary ulceration.

More or less enlargement of the *mesenteric glands* is always associated with the intestinal lesions. The mesenteric glands which are in immediate relation to the affected Peyerian and solitary glands are especially enlarged. Their volume is often much increased, and not infrequently they attain to the size of a pigeon's egg. The enlargement is due to congestion and to the production of new cells resembling those normally present in the glands. The same large, granular, sometimes multinuclear, cells found in the infiltrated follicles of the intestine are met with in the swollen mesenteric glands. The morbid process, in fact, in these glands is of the same nature as that in the lymphatic structures of the intestine. Only in exceptional cases does the morbid growth which gives rise to the enlargement produce sloughing. This process of necrosis is, however, an occasional source of peritonitis developed in the course of the disease. Usually the glands diminish in size as the process of ulceration is going on in the intestine. The new cells undergo fatty degeneration. The resulting molecular mass in part is absorbed, and in part remains as a dry detritus which may become infiltrated with the salts of lime.

The *spleen* is enlarged, dark red in color, and softened. It is often two or three times the normal size, and may be larger. In very exceptional cases no swelling of the spleen is found. The enlargement is due to congestion and to hyperplasia of the cellular elements. Large cells containing one or more red blood-corpuscles or fragments of corpuscles are found in the splenic pulp and veins. Hemorrhagic infarctions are occasionally met with in the spleen. Instances of rupture of the capsule of the spleen with escape of blood into the peritoneal cavity have occurred. The result is a fatal peritonitis or sudden death.

Typhoid fever, like other infectious diseases, is attended by *parenchymatous degenerations*. The parts most affected are the cardiac muscle, the liver, the kidneys, and the glands of the stomach. The voluntary muscles also undergo the change. The degeneration is probably due to infectious blood-changes. Hyaline or pseudo-waxy degeneration occurs in voluntary muscles. This change affects only certain muscular fibres, not the whole muscle uniformly. It is observed most frequently in the recti abdominis, in the adductors of the thigh, and in the diaphragm. It may also occur in the cardiac muscle. The affected portions of muscle are pale and have a grayish waxy lustre. The muscular fibres are transformed into a homogeneous friable mass without trace of the normal transverse striation. This change may lead to rupture of the muscular fibres with hemorrhage. This metamorphosis is not confined to typhoid fever, but it may occur in other diseases, and may be produced in animals by injuries to the muscles. Regeneration of muscular fibres destroyed by parenchymatous or by hyaline metamorphosis takes place during convalescence.

Changes in the *lungs* are present in nearly all cases of typhoid fever. Congestion and inflammation of the bronchial mucous membrane form an almost constant element in the disease. Hypostatic congestion and the condition called splenization of the lungs are found in a large proportion of cases. Pulmonary oedema is not uncommon. Pneumonia, usually in the lobular, but sometimes in the lobar, form, is a frequent complication. The lobular pneumonia is due often to aspiration of sputum and of foreign particles. Hemorrhagic infarctions may be caused by emboli derived from thrombi formed in the right cavities in the heart.

Ulcerations in the *larynx* are found in many cases. These occur most frequently on the edges of the epiglottis and on the posterior wall of the larynx just above the vocal cords. Writers are not agreed as to whether some of these ulcers be specifically typhoid or not. These ulcers may extend in depth and cause perichondritis. Oedema of the glottis is a rare complication of typhoid fever. Various forms of angina, catarrhal, follicular, croupous, and ulcerative, occur. The follicles at the base of the tongue are often swollen. Aphthous inflammation of the mouth and pharynx is not very infrequent in typhoid fever.

The *liver* is usually somewhat swollen, pale, and softened. The hepatic cells are in a condition of parenchymatous degeneration. Accumulations of lymphoid cells in the interlobular tissue about the branches of the portal vein are described by Wagner under the name of typhoid lymphomata. The bile is usually pale yellow and thin. The *kidneys* may present lymphomata similar to those in the liver. Parenchymatous degeneration of the renal epithelium is the rule. A genuine acute nephritis may occur, but it is rare. Hoffmann describes as a frequent occurrence proliferation and parenchymatous degeneration of the cells in the acini of the *salivary glands* and *pancreas*. Abscess of the parotid gland may occur in typhoid as well as in typhus fever.

No changes have been discovered in the *central nervous system* to explain the mental disturbance which characterizes this disease. There may be some increase of the cerebro-spinal fluid. Lymphoid cells are sometimes found around the ganglion-cells of the brain, but these wandering cells may be present in various other conditions.

The *blood* in typhoid fever, as in other infectious diseases, is poor in fibrin, and contains a relatively or absolutely larger number of white blood-corpuscles than normal. [The red blood-corpuscles are also relatively increased in number. The writer counted the corpuscles in five cases of typhoid fever during the height of the disease, the result being an average of 5,176,000 per cubic millimetre. In two of the same series of cases an examination of the blood during convalescence showed a marked diminution in the number of the red corpuscles, in one amounting to 804,000 per cubic millimetre, in the other to 1,306,000. These facts are only explicable on the theory of an abnormal loss of water during the febrile period and its absorption during convalescence.—H.]

No disease is accompanied by so great a number and variety of *complications* as typhoid fever. Some have already been mentioned. Other possible complications or sequelæ are—peritonitis without perforation, pleuritis, pericarditis, endocarditis, meningitis, cerebral hemorrhage, otitis media or externa, cystitis, epididymitis, orchitis, embolism of arteries of the lower extremities with gangrene, embolism of the pulmonary artery, thrombosis of the femoral vein with phlegmasia alba dolens, thrombosis of other veins, thrombosis of the heart, arteritis, necrosis of bone, periostitis, noma, gangrene of various parts of the body, bed-sores, septicæmia from bed-sores and other sources, pyæmia with abscesses in the lungs, spleen, and other parts, erysipelas,

uncles, retro-pharyngeal abscess, dysentery (during convalescence), abscess of the liver, suppurative nephritis, croupous or diphtheritic inflammation of the larynx and pharynx, hemorrhagic diathesis, icterus gravis, ulcer of the cornea, peripheral degenerative neuritis, neuro-retinitis, inflammation of the mucous membrane of the gall-bladder, and pyæmic or rheumatic polyarthritis.

A micro-organism peculiar to typhoid fever was discovered by Eberth in 1880, and was further investigated, and for the first time isolated in pure culture, by Gaffky, whose researches were published in 1884. Its pathogenic properties were demonstrated experimentally by Fraenkel and Simmonds in 1885.¹

The organism is a short, thick bacillus with rounded ends. The average length is about one-third of the diameter of a red blood-corpuscle and three times the breadth of the bacillus. The individual bacilli vary considerably in size. According to Gaffky the bacillus forms endogenous spores, even within the body.² Each spore occupies one end of a bacillus. The bacillus can be cultivated upon nutrient gelatin, agar-agar, potato, blood-serum, and various other media. It grows readily at ordinary temperatures, but even more rapidly at the temperature of the human body. It does not form spores at temperature much below 70° F. In nutrient gelatin it forms at first bluish-white, later whitish, opaque colonies upon the surface. It does not liquefy gelatin. It is aerobic, but grows to some extent in the depths of the solid culture media. The most characteristic growth is upon the surface of sterilized, steamed potato, on which it grows rapidly, but in such a way as to leave the surface of the potato almost unchanged, so that to the naked eye no growth is apparent, or at the most a delicate pellicle may be discovered. However, scrapings from the surface of the potato be examined microscopically, there is found a luxuriant growth of the bacilli. Examined in a drop of liquid, the living bacilli are found to be endowed with the property of active movement.

The morphological characters of the typhoid bacillus are not sufficiently marked to distinguish it from other similar organisms. For this distinction is necessary, as with other forms of bacteria, to take into consideration all the properties of the organism, particularly its peculiar growth on potato. When all of these properties are considered, it is found that the typhoid bacillus is a species distinct from any other known species of bacteria.

The typhoid bacillus is constantly present in the early stages of typhoid fever in the affected solitary follicles and Peyer's patches, in the swollen mesenteric glands, and in the spleen. It has also been found in the liver, kidneys, and the lungs. It has been found only exceptionally in the blood, although it is often found microscopically in the interior of small blood-vessels in the liver. The bacillus is usually absent after the fourth week of the disease, and is often not found during the fourth week. It may, however, be present at a much later period. Upon microscopical examination

the bacilli are found in irregular clumps which stain deeply with various aniline dyes. The examination is usually made in sections of the spleen or of the mesenteric glands, as other organisms are usually mixed with the typhoid bacillus upon the surface of the intestinal lesions. Often prolonged search is required to discover the colonies, and sometimes the microscopical examination is negative. Gaffky found the colonies in 27 out of 28 cases, and in the

¹Eberth, *Virchow's Archiv*, 1880, Bd. 81; Gaffky, *Mittheil. aus d. Kaiserl. Gesundheitsamt*, Berlin, 1884; Fraenkel u. Simmonds, *Die aetiologische Bedeutung d. Typhusbacillus*, Hamburg u. Leipzig, 1886.

²Other observers have failed to detect spores. Vacuoles in the ends and sides of the bacilli are common.

exceptional case death occurred at the end of the fourth week. Other observers have been less fortunate in their microscopical examinations; but even in the cases with negative microscopical result the bacillus can be obtained by pure culture from the spleen unless the examination be made at too late a stage of the disease.¹ The culture method is a much more delicate method of demonstrating the presence of the typhoid bacilli than the microscopical examination. It is needless to say that the typhoid bacillus has not been found in any disease other than typhoid fever, although many diseases have been examined with that object in view. We may conclude, therefore, that a specific micro-organism is constantly present in the typical lesions of typhoid fever.

Gaffky failed to obtain positive results by the inoculation of cultures of the typhoid bacillus in inferior animals, but the experiments of Fraenkel and Simmonds have shown that this bacillus possesses pathogenic properties. The majority of the mice inoculated died, and the majority of the rabbits inoculated within the peritoneal cavity or by injection into the blood died. Many of those which did not die were manifestly ill. In the organs of the dead animals were found the characteristic bacilli. The important lesions consisted in swelling of various lymphatic glands, including the solitary follicles and Peyer's patches, and of the spleen. It is not claimed that the disease produced is identical with typhoid fever as it occurs in man. It is not known that the inferior animals are susceptible to typhoid fever.

The constant presence in the characteristic lesions of typhoid fever of a pathogenic organism which does not occur in any other disease or in health hardly admits of any other interpretation than that this organism is the special cause of the disease. The idea that this organism is secondary to typhoid fever, being present simply because the disease produces favorable conditions for its growth, is met with insuperable difficulties.

The typhoid bacillus has been repeatedly demonstrated by means of cultures in the stools of patients affected with typhoid fever. This demonstration, however, does not always succeed.

The discovery of the typhoid bacillus makes it possible to determine in many cases whether the various and frequent complications of typhoid fever be the direct effect of the typhoid poison or not. The question here raised has been answered in only a few instances. It has been found that the abscesses and the severe inflammations of the throat have been caused by the secondary invasions of other organisms. A secondary invasion of micrococci is not uncommon in typhoid fever.

We are ignorant as to the manner in which the typhoid bacilli produce the manifestations of the disease. The fact that the bacilli are found in small number or not at all in the blood, taken in connection with the severe constitutional and nervous symptoms, suggests the possibility that they produce some toxic substance which is absorbed by the blood. (The etiological relations of the typhoid bacillus will be further considered under Causation.)

CLINICAL HISTORY.—Typhoid fever, as a rule, is developed gradually

¹ The greater certainty with which the presence of typhoid bacilli can be demonstrated in the spleen and other organs by means of cultures than by the microscope is probably owing to the circumstance that isolated typhoid bacilli or their spores cannot be discovered microscopically, or at least are readily overlooked. Reher and Fraenkel and Simmonds find that from the isolated organisms the characteristic colonies may develop in the spleen after death, so that they advise, for microscopical purposes, preserving the spleen for twenty-four hours after death, wrapped in a cloth wet with an antiseptic solution, before hardening in alcohol. For one familiar with the modern methods of cultivation on solid transparent media it is very easy to demonstrate the presence of the typhoid bacillus by means of cultivation.

After the development of the disease the most convenient division of stages is into septenary periods. The career of the disease will embrace the first, second, third, and sometimes a fourth, fifth, sixth, or even a seventh, week.

In a large proportion of cases patients are unable to fix the precise date of their ailments, so imperceptible is the beginning of the disease. It is therefore often not easy to determine accurately the duration of the prodromic period. This period ends when the disease is developed. My rule has been to consider the fever as established when the patient takes to the bed. This is an arbitrary criterion, and not always accurate, but the instances in which patients take to the bed before and after the full development of the disease will about compensate for each other. The first chill or chilly sensations and an increase of the temperature are more correct criteria; but in a large majority of cases patients do not come under observation until the fever is developed, and they often cannot recall the first chill or chilly sensations. Judged by the rule just stated, the prodromic period varies between one day and ten days, and the mean duration is about five days. Exceptionally, the attack is abrupt, the patient taking at once to the bed.

The following are the prodromic symptoms: Chills, more or less pronounced, or chilly sensations, recurring irregularly, sometimes followed by perspiration and sometimes not; cephalalgia, the pain generally referred to the frontal region; mental irritability, with difficulty of concentrating the attention or exerting the faculties of the mind; loss of appetite, occasional nausea, and sometimes slight vomiting; epistaxis in a pretty large proportion of cases; pain in the loins and limbs; looseness of the bowels or hypercatharsis if a mild purgative be given (the bowels may at first be constipated); lassitude and progressive debility until at length the patient, who up to this time has kept up with more or less effort, feels compelled to take to the bed. The duration of this period is of importance in diagnosis.

The symptoms which after this period make up the clinical history may be distributed into those referable to the countenance or general aspect, the nervous system, the digestive system, the skin, the respiratory system, the circulation, the temperature, and the urinary system.

Countenance and General Aspect.—There is no marked alteration of the countenance for the first few days. The face in the early period of the disease is usually more or less flushed. Afterward the countenance presents a dull or listless expression, and in severe cases there is lack of expression or an appearance of stupidity. The latter corresponds with the gravity of the disease, and is more and more marked as the disease continues. These alterations of the physiognomy are dependent on the mental condition.

The surface presents slight or moderate capillary congestion, like that produced by the action of cold. This is most marked on the face, especially on the cheeks. Distinctly circumscribed redness of the cheeks is rare save in the cases in which the disease is complicated with pneumonitis. The redness disappears on pressure, and returns more or less quickly. In some cases the hue of the surface is slightly dusky. The capillary congestion observable on the face is diffused over the body, but, next to the face, it is most marked on the hands and arms. It is rational to consider this appearance as denoting paresis of the peripheral arteries. Slight or moderate congestion of the conjunctiva is not infrequently observed.

Nervous System.—Pain in the head is more or less complained of during the first week. It is not always a prominent symptom, and it never has the intensity which belongs to the pain in the first stage of acute meningitis. It gradually becomes less and less a subject of complaint, and usually ceases during the second week. The cephalalgia is not accompanied with notable

intolerance of light and sounds. Pain in the back is also complained of in the early part of the disease, but this is rarely a very prominent symptom.

Delirium is manifested in the majority of cases. As a rule, it is not manifested until the second week, and sometimes not until the third or fourth week. Exceptionally, it is manifested in the first week, and even when the patient first takes to the bed. Cases differ much as regards the degree of delirium. It may be slight, or, on the other hand, a very prominent symptom. Generally, the first evidence of mental aberration is temporary confusion on awakening from sleep, the patient being unable to recall where he is and asking incoherent questions. Increasing, the patient talks incoherently and mutters like a person talking in sleep. Efforts to get out of bed are common, and when asked where they would go patients often say they wish to go home. In most cases they are easily persuaded to lie down, but after a few moments the effort to get up is repeated. If not watched, they sometimes get up and succeed in getting on their clothes. The delirium is always greater during the night, and it may be manifested only at that time. In the great majority of cases the delirium is of a quiet, passive kind. It apparently proceeds from weakness of mind, there being inability to carry on connected trains of thought. The incoherent talking or muttering usually relates to habitual pursuits. The patient is in a dreamy state, a succession of disjointed ideas passing through the mind.

There are occasional exceptions to the rule regarding the kind of delirium. It is sometimes noisy and active. The patient shouts and makes strong and persistent efforts to get up. Constant forcible restraint may be necessary. Fixed delusions, either of the senses or ideas, during the progress of the disease are certainly rare; but they may occur at the time of convalescence. In one of my cases the patient fancied that he had become immensely rich, and this delusion continued for several days after convalescence. In another case, the patient being a young woman, the delirium in convalescence had the character of delirium tremens. The delirium during the course of the fever is in general marked in proportion to the intensity of the disease. So far as my observations go, persisting, active, or violent delirium, requiring restraint, is an extremely unfavorable symptom.

Patients are sometimes perfectly coherent, but not rational. They reply to questions at haphazard, and no reliance is to be placed on their statements with respect to the events of their illness. In some cases there are no manifestations of delirium during the whole course of the disease, but after recovery there is very little recollection of anything that occurred. The delirium sometimes has an hysterical character, consisting in emotional manifestations—weeping and sobbing—the emotions being very rarely mirthful.

Delirium, however prominent as a symptom, is no evidence of encephalic inflammation: The appearances of meningitis are not found after death in cases characterized by very active delirium, nor is there an abnormal amount of congestion.

Irrespective of delirium, the mental condition in the second, third, or fourth week, or later, is characterized by hebetude, indifference, and inanimation. Blunted perception is shown by various circumstances. The patient asks for nothing—not for drink, although the mouth may be dry and desiccated, or for change of the position of the body. Flies creeping over the face may occasion little or no annoyance. In grave cases the urine and feces may be passed in bed, not from paralysis of the sphincters, but through indifference and a reluctance to make any effort. The special senses are impaired, especially the sense of hearing, and deafness in one or both ears is frequently marked. General and special sensibility are diminished, as a rule, in pro-

portion to the intensity of the disease. Frequently there is dilatation of the pupils.

Wakefulness is complained of during the first few days, the patient experiencing discomfort from the want of refreshing sleep. Afterward the want of sleep may not be appreciated, owing to the mental condition. The patient, indeed, may seem to doze most of the time, but without obtaining true sleep, being easily aroused, but soon relapsing into a pseudo-somnolent state. This state, in which the patient may be said to be both sleeping and wakeful, is called *coma-vigil*, the significance of the term depending on the incongruity of the words which it combines. This name is also applied to a state occasionally observed in which the patient is unconscious with the eyes open. In coma-vigil or the pseudo-somnolent state, from which the patient is readily aroused, the mind is frequently occupied with a series of disconnected ideas or dreamy delusions which give rise to the muttering delirium. This combination of stupor and delirium is expressed by the term *typho-mania*. The want of true sleep doubtless contributes not only to the exhaustion, but to delirium and other disordered nervous phenomena, as in delirium tremens.

Coma-vigil and typho-mania do not involve a tendency to true coma; but in a certain proportion of cases coma is gradually developed in the latter part of the career of the fever, and under these circumstances a fatal result is to be expected. In a certain proportion of cases coma is sudden. It occurs unexpectedly, and in mild as well as in severe cases. These cases end fatally, the mode of dying being by apnoea. This apoplectic coma is often preceded by disturbance of the rhythm of respiration, the inspiratory act being shortened and quickened.

Other symptoms referable to the nervous system, or ataxic symptoms denoting gravity of disease, are—grasping at invisible objects or carphologia. pulling up of the bedclothes or fumbling with the body-linen, visible twitchings of the muscles of the face and of the extremities, and movements of the tendons of the wrist perceptible to the touch (the latter called *subsultus tendinum*), rigidity of the muscles of the neck or extremities, and convulsions. Muscular rigidity and convulsions are very rare, and betoken a fatal termination. There is reason to believe that the pathological condition giving rise to convulsions with coma is frequently, if not always, uræmia. In these cases the urine will be found to be albuminous.

Digestive System.—Anorexia is the rule, but to this rule there are exceptions; the appetite being sometimes preserved throughout the disease. Food is sometimes acceptable when, owing to the mental condition, it is not asked for. Thirst is usually a prominent symptom until perception becomes blunted. Drink, although not asked for, is often taken with avidity when given. The condition of the mouth would involve a desire for drink were the ability to perceive morbid sensations not impaired.

The tongue generally presents morbid appearances. It may be simply furred or frosted, but it is oftener covered with a coating more or less thick, which in different cases is whitish, yellowish, brownish, or even black. Not infrequently the coatings are thrown off once or repeatedly, and the surface is then usually reddened. Exfoliation of the coating or its gradual thinning, the surface being moist and of a natural color, betokens convalescence. The varied appearances of the coatings have no special significance. The surface of the tongue is sometimes reddened and smooth or glazed. It sometimes becomes dry and hard. This occurs in coma-vigil. The patient breathing with the mouth open, the surface is desiccated. It sometimes becomes cracked and deeply fissured. Tremulousness of the tongue, as in cases of *trismus* tremens, is sometimes observed, usually preceding or accompanying ataxic symptoms. The tongue in some cases at an advanced period is

protruded with apparent hesitation and difficulty, and when protruded may not be withdrawn, apparently from forgetfulness. The delay in protruding and withdrawing the tongue represents the weakness and slowness of the mental acts.

Dark or black matter, called *sordes*, after the first week often accumulates upon the teeth and lips, especially in grave cases. Hemorrhage from the gums is an occasional symptom, occurring in mild as well as in severe cases. Redness of the gums and bleeding on slight pressure are common.

A rare complication is inflammation of one or both of the parotid glands. It leads to notable enlargement, and the appearance is like that of ordinary *parotiditis* or *mumps*; but, unlike the affection just named, in the great majority of cases suppuration takes place, and not infrequently there is more or less sloughing of the areolar tissue. This complication adds to the danger and retards convalescence. It may occur at any period of the febrile career or during convalescence. It is not to be regarded as a critical event. The discharge of pus is sometimes into the meatus auditorius. This complication occurs in typhus as well as in typhoid fever. It occurred in 5 of 30 cases of typhus and typhoid fever which I recorded in the winter of 1849-50. Prior to that year I had never met with an instance, and since that year I have met with a very few examples, but in a much larger field of observation.

Vomiting is an occasional symptom. Generally it is a result of over-ingestion. As regards the occurrence of this symptom, typhoid fever is in striking contrast with remittent fever.

Diarrhœa or looseness of the bowels exists in a large majority of cases, and this belongs among the diagnostic symptoms of the disease. The dejections often have a yellow, ochre color. They give an alkaline reaction, but this is not distinctive of the disease. Exceptionally, constipation exists, and the dejections may have a natural appearance throughout the disease. The bowels are often evacuated in bed, either from indifference or from paralysis of the sphincter ani. Involuntary evacuations denote gravity of disease.

Hemorrhage from the bowels is an important event in the clinical history of this disease. It occurs in a proportion of between 5 and 8 per cent. The hemorrhage may be slight, moderate, or profuse. It may cease after a single occurrence, or there may be a greater or less number of recurrences. The loss of blood is sometimes the immediate cause of death. Statistics, however, show that in the larger number of cases patients recover. Even very profuse hemorrhages do not always prove fatal. I have known the loss of blood to occasion complete collapse for several hours in cases which ended in recovery. The hemorrhage occurs late in the disease, and in most instances is from the intestinal ulcers. Its occurrence may be foreshadowed by a sudden and notable decline of the temperature of the body. I have met with a case in which the decline of the axillary temperature to 98° was for a time considered as evidence that the fever had ended, but within a few hours profuse hemorrhage from the bowels occurred and the patient died from the loss of blood.

Other abdominal symptoms are—meteorism or tympanites, tenderness or pain on pressure, and gurgling. The abdomen is always resonant from the presence of intestinal gas. Frequently there is more or less distension, and sometimes the tympanitic enlargement is great. Tenderness on pressure in the iliac region, especially on the right side, is very rarely absent. Sudden and forcible pressure may be required for the manifestation of pain if perception be much blunted. The tenderness is often marked, and sometimes it extends over the greater part of the abdomen. Gurgling on pressure in the iliac region as a sound and as a tactile sensation is a frequent symptom. These three symptoms—namely, meteorism or tympanites, iliac tenderness

and gurgling, especially the two former conjoined with diarrhoea or looseness and ochre-colored discharges—form a group of abdominal symptoms highly diagnostic of this form of fever. They may, however, all be absent. The tympanites, tenderness, and gurgling, as regards their prominence, are not proportionate to the amount of intestinal lesions. By percussion and by palpation over the region of the spleen this organ is found to be enlarged.

Perforation of the small—or in rare instances the large—intestine takes place in a certain proportion of cases; namely, in between 8 and 10 per cent. of fatal cases, and between 1 and 2 per cent. of all cases. It takes place late in the disease or during convalescence, and sometimes even after apparent recovery from the fever. It occurs as often in mild as in severe cases. It occurs oftener in men than in women, and is very rare in children.

Perforation gives rise to peritonitis, which is generally developed abruptly. The sudden occurrence of notable tenderness diffused over the abdomen, abdominal pain, increased tympanitic distension, rigidity of the abdominal walls, with marked frequency of pulse, prostration, haggard expression of countenance, etc., point to peritonitis from perforation. Replacement of hepatic flatness by tympanitic resonance usually occurs in perforative peritonitis, but it may be absent, and this symptom may be present without pneumo-peritoneum. In some cases, the perforation being quite small, the development of the peritonitis is gradual, and it may be circumscribed under these circumstances. Peritonitis does not invariably denote perforation. It may be caused by the evacuation into the peritoneal sac of liquefied matter within a mesenteric gland. It may occur irrespective of either this cause or perforation. Probably in most of the reputed cases of recovery after the occurrence of peritonitis perforation was not involved. Peritonitis from perforation is almost certainly fatal.

Skin.—Of the symptoms referable to the skin, the most important is a characteristic eruption. The eruption consists of isolated papules, generally limited to the trunk, of a rose or pink color, called by Louis lenticular rose-colored spots. They are slightly elevated, and therefore are *papulae*, not *maculae*. The elevation is distinctly felt if the finger be carried lightly over them. They are slightly oval in form, and are from one to two lines in diameter. The redness momentarily disappears on light pressure. The number of papules is generally small, in the majority of cases not exceeding fifteen or twenty, and sometimes only four or five can be discovered. Exceptionally, they are abundant over the trunk, and the eruption sometimes extends to the extremities. Fresh papules appear from time to time during the course of the fever, taking the place of those of anterior date. They are to be sought for over the chest and abdomen in front and over the back, and they are sometimes found exclusively in the latter situation.

Dating from the time of taking to the bed, the average time of the appearance of the eruption is about the seventh day. Papules continue to disappear and to appear during the career of the disease, and sometimes the eruption persists into the stage of convalescence. The papules are not apparent after death.

The eruption is not invariably present. The proportion of cases in which it occurs varies in different years, as my statistics show. It appears to be less frequent in the country than in the city. It is less frequent in children than in adults. The copiousness of the eruption is no evidence of the severity of the fever, and on the other hand it is as likely to be absent in mild as in severe cases. A scarlet rash occasionally precedes the characteristic roseolar eruption.

Miliary vesicles or sudamina are not infrequently observed in the middle and latter part of the disease on the neck, chest, and abdomen. This erup-

tion is observed in various affections in which perspiration occurs. Petechiæ or minute ecchymoses are occasionally observed. These do not denote unusual gravity of the disease. They occur in mild as well as in severe cases. Herpes labialis is so rare an occurrence in typhoid fever that its presence is evidence against the diagnosis of this disease.

Bluish patches (*petiomata* or *tâches bleuâtres*) of irregular form, from three to eight lines in diameter, are occasionally observed on the abdomen, back, and thighs. They are not peculiar to this disease, and are more likely to occur in mild than in severe cases.

Perspiration, more or less abundant and recurring more or less frequently, is observed in about one-half of the cases, exclusively of its occurrence at the time of convalescence or just before death. It occurs in about an equal proportion of fatal cases and of those ending in recovery. Observation does not show a connection between this symptom and any particular antecedent events; but, taking the frequency of the pulse as a criterion of the gravity of the disease, and comparing the pulse before and after the occurrence of perspiration, in the majority of cases improvement follows. While this symptom, therefore, has no bearing on the prognosis, it often betokens some amelioration. As a rule, during the greater part of the career of the fever the skin is dry.

Gangrene is liable to occur in situations exposed to pressure. Spontaneous gangrene of the extremities has been observed, the probable explanation being arterial thrombosis. Gangrene and troublesome ulcers are liable to follow vesication. The liability to bed-sores on the nates, hips, and shoulders is to be borne in mind. These may be prevented by changing from time to time the position of the body, by the use of air-pillows, etc. Erysipelas is an occasional complication of typhoid fever.

Respiratory System.—Cough is not a prominent symptom unless an important pulmonary complication exist, but slight or moderate cough is almost invariably present, proceeding from subacute bronchitis. A sibilant râle is frequently heard over the chest on auscultation.

Pneumonia is a not infrequent complication. It is rendered probable by prominence of cough and accelerated breathing, but the proof of its existence is afforded by the physical signs. It is sometimes latent as regards diagnostic symptoms, and is determinable only by physical exploration. Its occurrence adds to the danger, but it by no means precludes recovery. Hypostatic congestion and œdema of the posterior portions of both lungs are incident to the feeble circulation in the latter part of the disease. These physical conditions are represented by dulness on percussion, weak respiratory murmur, and subcrepitant râles. Irrespective of any pulmonary complication except subacute bronchitis, the frequency of the respirations is increased, the average being about 21 per minute.

Frequent sighing in the early part of the disease is a forerunner of ataxic symptoms of grave omen. A spasmodic or jerking inspiration when pneumonia does not exist is a precursor of coma. This statement holds good in other forms of fever. The importance of this symptom is enhanced by the fact that it may sometimes be observed when no other symptoms denote impending coma. This was true of several cases which I have observed.

Epistaxis has been mentioned as a symptom of diagnostic value early in the disease. It occurs not infrequently afterward. Generally the hemorrhage is small, but occasionally it is profuse, and it may require to be arrested by mechanical means. When slight or moderate it does not appear to have any influence on the progress of the disease. Uterine hemorrhage is not uncommon. Its occurrence is not limited to the period when menstruation should take place.

aryngitis, laryngitis, and œdema of the glottis are occasional complications of typhoid fever.

Acceleration.—More or less acceleration of the pulse belongs to the history of the disease. The acceleration varies considerably in different cases, and at different periods of the disease in the same case. There is a greater average frequency in fatal cases than in those ending in recovery. The danger is only considerable if the pulse for many days exceed 120 per minute, and danger is augmented in a geometrical ratio as the frequency rises higher than this. The mean frequency in cases not proving fatal of those which I analyzed was 93; and in the fatal cases, 110. In some mild cases the average frequency during the whole of the disease is less than the average frequency of health. In one of my cases the average frequency was 69. In some cases, however, the pulse at times exceeds the healthy standard, hence the pulse may at times fall below the standard of health. This is not infrequently observed at or near the time of convalescence. I have noted it as 64, 60, and 40. Others have observed it to fall still lower. Oftener the pulse continues more or less accelerated after convalescence is declared. A sudden and considerable increase of the frequency of the pulse often denotes the occurrence of some important event, such as pneumonia or peritonitis.

As regards characters of the pulse other than frequency, it is quick and strong, not hard or resisting. It denotes increased action, but not increased power, of the ventricular systole. It becomes feeble or compressible in proportion as it is frequent. The force is always notably diminished if the frequency much exceed 120. An unfavorable progress of the disease toward asthenia is shown by progressive increase in frequency and diminution of force. Under these circumstances the first sound of the heart, on auscultation over the apex, is notably weakened and may be inappreciable. The character of the pulse, as traced by the sphygmograph, presents the following features: a short and nearly vertical line of ascent, indicative of weakness and quickness of the ventricular systole; a line of descent, denoting the free escape of blood from the arteries in the capillaries, and notable diastolic murmur. Diastolic murmur of the radial artery is sometimes appreciable by the touch. The characters belong to the graphic pulse also in cases of typhus and in convulsions with which is associated the typhoid condition.

Temperature.—More or less increase of the heat of the body is invariable. Generally, the thermometer in the axilla shows a daily increase of temperature for the first five or six days. This gradual rise of temperature from day to day during the first week is diagnostic of typhoid fever. At the end of this period the temperature rises to at least 103° F. If, in the progress of the disease the thermometer show much increase above this, the prognosis is unfavorable, whereas a decline of the temperature in the morning to near normal standard is evidence of convalescence. During the progress of the disease there is, as a rule, an oscillation of temperature between morning and evening, the difference varying between half a degree and a degree and a half up to the time of convalescence, when the oscillations become much greater, the difference being four to five degrees, the temperature in the morning falling to the normal standard, 98°, or lower. The difference between the morning and evening temperature at the time of convalescence has been observed to be more than nine degrees. The temperature in typhoid fever does not always follow the typical course which has been described. The temperature may reach its acme by the end of the third day. Not very infrequently the course of the temperature is of a remittent type, and even distinctly intermittent. Oscillations of temperature have been observed during the first and second weeks. A high elevation of temperature in the morning—namely, 106° to 108°—

indicates the approach of death. The laws of the disease as regards temperature are sufficiently characteristic to render the thermometer useful in diagnosis as well as in prognosis. A sudden and considerable rise of temperature during the progress of the disease points to the occurrence of an inflammatory complication. A sudden and considerable fall of temperature, other symptoms not denoting convalescence or improvement, is unfavorable. This often indicates hemorrhage from the bowels. It is important, however, to note that, irrespective of complications, the temperature in some cases becomes increased, and the rise may continue for several days; and on the other hand a decline of from one to two and a half degrees sometimes takes place, lasting for several hours, without any obvious cause and having no special significance.

Urine.—The urine is usually scanty and of high specific gravity until the approach of convalescence, when it becomes abundant and of a low specific gravity. During the progress of the disease, as a rule, the urea and uric acid are absolutely increased and the chlorides are diminished. The coloring matter is also more abundant than in health.¹ The presence of albumen during a part of the febrile career is common. An abundance of albumen denotes gravity. This symptom occurs in the middle or latter part of the disease, and it may continue for a period varying between twenty-four hours and twelve days. In the fatal cases in which it occurs it continues up to the time of death. In these cases the kidneys after death may be found to be simply congested, no deposit or structural change existing.

A genuine acute diffuse nephritis may develop during the course of typhoid fever, even in the early stages. Cases in which the renal symptoms predominate have been designated as renal typhoid. Such cases are rare, and may offer considerable difficulty in diagnosis. It is probable that coma and convulsions occurring in the progress of typhoid fever are due to uræmic poisoning. I have met with a case in which, following a large hemorrhage from the bowels, profuse hæmaturia took place, the blood passed from the bladder forming clots after its emission. The patient became much blanched from the loss of blood, but he recovered.

The urine is sometimes retained in cases of typhoid fever, and owing to the blunted perception the bladder may become greatly distended. The practitioner should not omit to ascertain the condition of the bladder by examination of the abdomen during the progress of the disease, and resort seasonably to the use of the catheter when required. On the other hand, the urine is often passed in bed, sometimes from indifference and sometimes from incontinence.

In order to determine the duration of the disease it is necessary to fix upon certain points which shall mark the beginning and the end of the febrile career. The time of taking to the bed is a convenient, and in a collection of cases a tolerably correct, criterion of the development of the fever. It is difficult to find any one circumstance which will answer equally well to denote the date of convalescence. The career of the fever rarely ends abruptly; the termination in convalescence, like the development, being gradual. The decision that a patient is convalescent is a matter of judgment, and is to be based on the *ensemble* of symptoms. Of 42 cases ending in recovery, analyzed with reference to the duration of the fever, dating from the time of taking to the bed

¹ The so-called diazo-reaction, first described by Ehrlich, can usually be produced in the urine of typhoid-fever patients. The test consists in mixing the urine with a solution of sulfo-diazo-benzol, and then adding ammonia, when, if the reaction is present, the urine acquires a red color which is followed by the precipitation of a greenish sediment. The reaction is found chiefly, although not exclusively, in febrile diseases. Its diagnostic and prognostic importance is not yet established, the results of different observers being contradictory (Ehrlich, *Charité Annalen*, Jahrg. viii., and *Deutsche med. Wochenschrift*, 1883, No. 38).

to the time when the improvement in all the symptoms was sufficient for the patients to be considered convalescent, the average duration was sixteen days. The maximum duration was twenty-eight days, and the minimum five days. The longest duration in any case under my observation was in a female hospital patient, the disease continuing in this case without any important complication fifty-eight days. It is perhaps of importance to state that these cases were observed long before the recent introduction in medical practice of antipyretic measures of treatment. The mean duration in 75 cases observed by Murchison was a fraction more than twenty-four days. This greater duration, as compared with my cases, is probably owing to the beginning being fixed at an earlier period than the date of taking to the bed. Of 45 fatal cases in my collection, the mean duration was a fraction more than fourteen days, the maximum being twenty and the minimum nine days. The mean duration in 12 fatal cases observed by Murchison was a fraction more than twenty-two days. The average duration of convalescence is between one and two weeks. The return of the axillary temperature to the normal standard—that is, complete defervescence—shows of course that the febrile career is ended. Sometimes the defervescence is rapid, and the temperature quickly falls to that of health; but generally it is gradual, and paroxysms or exacerbations of fever, as indicated by the thermometer, are liable to occur for some days after the appetite, mental condition, and other symptoms denote convalescence. The temperature may be kept up by complications which persist after the career of the fever is ended. A temporary fever often accompanies the change of diet from liquid to solid animal food.

Relapses of typhoid fever sometimes occur. Many examples have fallen under my observation. A return of the fever may take place after ten days or a fortnight from the date of convalescence, and the patient pass through a second career, the eruption and other characteristic symptoms being reproduced. The duration of the second career is usually shorter and the severity greater than the first, but a fatal termination is rare.

Complications which are likely to arise in the course of typhoid fever have been noticed in connection with the anatomical appearances and with the symptoms referable to different anatomical systems. The occasional occurrence of thrombosis of the iliac or femoral vein on one side or on both sides is not rare, and is attended with swelling and pain of the corresponding limb. This complication rarely leads to evil consequences, but sudden death has been known to occur from an embolus detached from the thrombus and occluding the pulmonary artery. Typhoid fever may be associated with intermittent fever (typho-malarial fever), scarlatina, rubeola, diphtheria, and perhaps with typhus. Occasional sequels are acute miliary tuberculosis, pulmonary phthisis, and subcutaneous abscesses. Progressive emaciation and death from inanition have been known to follow; but in many instances nutrition becomes extremely active after recovery and the patient attains a greater weight than ever before. The mental powers in some cases are enfeebled for a considerable period.

CHAPTER II.

CONTINUED FEVERS (CONTINUED).

Causation of Typhoid Fever; Diagnosis; Prognosis.—Typhus Fever: Anatomical Characters; Clinical History; Causation; Diagnosis; Prognosis.

THE anatomical characters and clinical history of typhoid fever have been described in the preceding chapter; and it remains to consider the causation, diagnosis, and prognosis of this disease before entering on the consideration of typhus fever.

CAUSATION.—Typhoid fever is not restricted within any geographical limits. It is endemic in every quarter of the globe. It prevails, however, often within circumscribed districts, and not infrequently does not extend beyond a few houses or even a single house. Although it now prevails within many malarial regions, it is certain that in some situations in this country well-marked cases of typhoid fever were hardly known so long as malarial fevers were rife, but the former became the common form of fever after intermittent and remittent fever ceased to prevail. As regards the season of the year, it shows in this latitude a decided predilection for the autumn.¹ It is stated that a warm, dry summer favors the occurrence of the disease in the following autumn. According to Buhl and Pettenkofer, the disease prevails in Munich when the level of the ground-water is low, and the prevalence has been observed to end when the level of the water has been raised by abundant rain. A similar relation has not been observed in all places.

The susceptibility to typhoid fever is greatest between the ages of fifteen and twenty-five, next between ten and fifteen, and next between twenty-five and thirty. It is rare in infancy, but not infrequent in childhood. A considerable proportion of cases of so-called infantile remittent fever are cases of typhoid fever. The susceptibility is much diminished after sixty, but the disease may develop in persons more than seventy years of age.

Both sexes appear to be about equally liable to the disease. Generally, persons are in good health when attacked. Other diseases do not seem to predispose to typhoid fever. No causative influences relating to social position, occupation, or habits of life have been ascertained. A certain degree of protective influence against typhoid fever seems to be exerted by phthisis and other diseases attended by cachexia and severe anæmia, but this protection is not absolute. A protective influence exerted by pregnancy and lactation, if it exist at all, is much less than was formerly supposed. Typhoid fever developed soon after delivery is liable to be mistaken for puerperal fever. Pregnant women when attacked with typhoid fever generally abort, but this does not seem to influence the prognosis unfavorably. The fœtus is generally dead or dies soon after birth. The typhoid bacillus has been found in the fœtus, in which have also, but very rarely, been found the lesions of the disease.

New-comers in an infected district are more likely to be attacked than those who have long resided there. As of those who are exposed to the typhoid-

¹ Of 5988 cases admitted during twenty-three years in the London Fever Hospital and analyzed by Murchison, 41 per cent. occurred in autumn, 21.3 per cent. in winter, 12.7 per cent. in spring, and 24.8 per cent. in summer.

Of 45 cases which I have analyzed with reference to this point, 16 were in October, 9 in November, and 12 in December.

poison only a certain number are attacked, it is evident that a certain amount of individual immunity exists.

Three reasons have already been given for believing that the so-called bacillus typhoid fever is the specific cause of the disease. Of the properties of the organism bearing upon the causation, may be mentioned its growth at many temperatures, although best at a temperature between 85° and 100°; its growth upon a great variety of substances, such as vegetables, milk, infusions, etc.; its formation of spores; and its presence in the typhoid

We may therefore infer that the typhoid bacillus may grow readily under ordinary conditions outside of the body, as in the soil or in liquids containing sufficient nutriment, and that by the formation of spores it may preserve its vitality for a long time, even under unfavorable conditions. There is evidence that the typhoid bacillus exists in the exhalations from the patient.

Typhoid fever is communicable, but rarely if ever in the same way as strictly contagious diseases, such as typhus fever, smallpox, scarlet fever, relapsing fever. Emanations from the bodies of those affected with the disease do not infect the surrounding atmosphere, and hence in hospital wards the disease is not diffused by typhoid cases among patients affected with other diseases if care be taken to thoroughly disinfect the dejecta. Physicians, nurses, and members of families brought into close proximity to cases seldom contract the disease in consequence. Nevertheless, the causative germs multiply within the bodies of typhoid patients, and are expelled from the body with the intestinal dejections. It is not necessary to suppose that the germs, the typhoid bacilli, must undergo any further modification or development outside of the body in order to communicate the disease. It is possible to explain the infrequency with which those in attendance upon typhoid patients contract the disease by the fact that with ordinary care portions of typhoid stools are not likely to be taken into the alimentary canal, and there is no reason to suppose that any exhalations from the patient contain the bacillus. Washerwomen not infrequently contract the disease from using linen soiled with typhoid excreta, and it is easy to understand how infection might take place in this way.

It is probable, however, that the typhoid stools are the chief source of infection of a locality in which the disease becomes endemic. Instances might be multiplied to show that persons who have contracted typhoid fever in one locality, then go to another locality and become a source of infection in a region in which the disease has not hitherto prevailed. In the preceding instances of this work I have reported a remarkable instance of this nature: an instance in which a stranger ill with typhoid fever came to a little settlement

North Boston, consisting of nine families. Up to this time typhoid fever had never been known in that neighborhood. In a few days the stranger died, and in a month more than one-half of the population, numbering 43, were affected, and 10 died. Both the symptoms and post-mortem examination showed the disease to be typhoid fever. Of the nine families, one escaped which obtained its water from a source different from the others, which used a common well.¹

It is not infection with typhoid fever often takes place from the drinking-water that can be doubted. The typhoid bacilli have been found in the drinking-water of regions where typhoid fever was prevailing as an epidemic (Mörs, 1861). Such water may be perfectly clear and apparently pure. Meade has shown that typhoid bacilli may exist in drinking-water for at least a month, although they do not multiply unless the water contain an amount

¹ For fuller details concerning these cases, vide A. Flint, *Clinical Reports on Continued Typhoid*, 1852, and *American Journal of the Medical Sciences*, July, 1845.

of organic matter not likely to be present in any water which would be used for drinking purposes. In a number of instances of infection through the water it has been possible to show some communication or leakage between a well used for drinking purposes and a privy-vault, cesspool, sewer, or drain. That such contamination, as well as the contamination of the soil in a similar way, is an important factor in the causation of the disease seems certain; but, in accordance with our present views, we must suppose that no amount of contamination by the ordinary products of decomposition is capable of causing typhoid fever, and that the typhoid bacillus must always be present when this occurs.

Allied to epidemics traceable to the drinking-water are epidemics referable to the milk-supply. A number of such epidemics have been reported, especially in England.¹ Here it is probable that the vehicle of infection is the water used in cleansing the cans or in diluting the milk. As already mentioned, milk is a favorable medium for the growth of the typhoid bacillus. Boiling the milk is the only sure preventive.

Some believe that the chief source of infection is through the atmosphere in regions in which the ground contains the specific germ. It is probable that infection may take place from uncooked food, especially from fruits and vegetables which are contaminated by the presence of the specific organism.²

A question of importance is whether an outbreak of typhoid fever be always referable to the introduction of the typhoid germ derived directly or indirectly from a person affected with the disease, or whether the special poison may be generated outside of the human body. That the former method of infection is a common one cannot be doubted, but the properties of the typhoid bacillus are such that it is capable of living independently of the animal body, and there is therefore no *a-priori* objection to the assumption that typhoid fever may develop in regions which have never been visited by any one affected with the disease. It is, however, very difficult to prove the latter view, for the typhoid germ may be transported by an individual who does not contract the disease, and it is certain that this germ may preserve its vitality for a long time, at least for several years.³

The early and predominant involvement of the intestine in typhoid fever seems to indicate that the infection takes place primarily from the alimentary tract. Even if the typhoid bacilli should be inspired, it is not necessary to suppose that the infection is through the respiratory organs, for after reaching the mouth or throat the organisms could be swallowed.

The agency of bad cesspools, sewers, and privies in the causation of typhoid fever seems to be that here the bacilli, derived usually from typhoid dejecta, find suitable conditions for their growth, and that with imperfect drainage from these sources the surrounding soil and neighboring waters may become infected with the specific organism. This important agency enforces the necessity of measures of prophylaxis consisting of effective sewerage, provision against obstructions of house-drains, prevention of leakage from these and cesspools, care that the trapping of hand-basins, sinks, and water-closets

¹ Dr. F. C. Curtis, in the *Fourth Annual Report of the State Board of Health of New York*, gives an account of an outbreak of typhoid fever at Port Jervis in the autumn of 1883, traceable to milk-supply. (See, also, *The Lancet*, Feb. 7, 1885.)

² In Switzerland epidemics of typhoid fever have been reported in which the infection has been referred to eating the meat of diseased calves; but this interpretation of the cases is not free from doubt.

³ According to bacteriological nomenclatures, the typhoid bacillus may be regarded as a saprophyte and a potential parasite; that is, all of the conditions for its development are present outside of the animal body, and it may therefore exist as a saprophyte. It occasionally makes incursions into the human body, where it becomes a parasite.

is complete, and the disinfection and speedy removal of the excreta of patients affected with the disease.¹

The interval between the introduction of the germs and the first manifestation of the disease, or the period of incubation, is usually about two weeks. The duration is longer than this in some instances, but probably never several months, as has been supposed. On the other hand, the duration sometimes does not exceed one or two days.² This disease is one of those which are very rarely experienced twice; and a person who has had the disease, as a rule, is thereafter unaffected by the special cause. As already stated, however, a relapse sometimes occurs shortly after the date of convalescence.

DIAGNOSIS.—Typhoid fever is to be discriminated from other essential fevers, especially typhus, remittent, and typho-malarial fever. The differential diagnosis cannot be fully considered without anticipating the diagnostic events which belong to the clinical history of these fevers. The discrimination is to be made by ascertaining the presence of more or less of the events which are diagnostic of typhoid fever and the absence of events diagnostic of other fevers. The points in the clinical history which are distinctive of typhoid fever are as follows: the gradual development; the absence of marked remissions; the abdominal symptoms—namely, diarrhœa with ochre-colored dejections, tympanites, tenderness and gurgling in the right iliac region; the occurrence of epistaxis; and the characteristic eruption. As regards the eruption, a fact important to be borne in mind is that rose-colored papules, like those belonging to the history of typhoid fever, are sometimes found in other affections. Other points to be taken into account are the autumnal season and the youth of the patient. The foregoing points, taken in connection with the absence of features distinctive of other fevers, generally render the diagnosis easy after a certain duration of the disease. In typho-malarial fever, as will be seen, the symptomatic phenomena of typhoid and malarial fever are commingled in variable relative proportions in different cases.

Other affections with which typhoid fever may be confounded are—cerebral and cerebro-spinal meningitis, bronchitis, pneumonitis, acute tuberculosis, and enteritis.

Acute meningitis, as distinguished from typhoid fever, is characterized by more intense cephalalgia, by intolerance of light and sounds, early and active delirium, frequently by vomiting as a prominent symptom, by rigidity of the muscles at the back of the neck, sometimes by paralyses, and by somnolency and coma succeeding the delirium. There generally is constipation. The abdomen is not tympanitic, but frequently depressed, and iliac tenderness is wanting. This differential diagnosis is required chiefly in children.

Subacute bronchitis is an element of typhoid fever. If the bronchitis be unusually prominent and the fever unusually mild, the latter may be overlooked and the disease considered a primary bronchitis. This error can only happen in the early part of the fever; and the duration and progressive increase of the disease, together with the characteristic events of the fever, will lead to a correction of the diagnosis. If the bronchitis be capillary, owing to the predominance of the pulmonary symptoms, this may be supposed to be the primary and sole disease. An instance has fallen under my observation, but capillary bronchitis as a complication is extremely rare.

Typhoid fever may be confounded with pneumonitis when the latter exists

¹ A full account of the different agencies involved or supposed to be involved in the etiology of typhoid fever will be found in J. H. Hutchinson's article on this disease, in *Pepper's System of Practical Medicine*, by American Authors, Philadelphia, 1885, vol. i.

² Vide Murchison, in *St. Thomas's Hospital Reports*, vol. ii.

as a complication. The existence of pneumonitis is shown by its physical signs. The differential diagnosis is to be based on facts which show the existence of fever prior to the occurrence of the pneumonitis, and on the events characteristic of typhoid fever—namely, the abdominal symptoms and eruption. Cases of primary pneumonitis in which the existence of typhoid fever may be suspected are cases of so-called typhoid pneumonitis; that is, pneumonitis with phenomena denoting the typhoid state—namely, low delirium, prostration, subsultus tendinum, etc.

Acute miliary tuberculosis has not infrequently been mistaken for typhoid fever. The former is to be discriminated by the notable frequency of the respirations, the prominence of the cough, the occurrence of hæmoptysis in some cases, the abundance of subcrepitant râles; by marked lividity in some cases; by the presence of choroid tubercles; and by the absence of the abdominal and other characteristic events of typhoid fever.

Typhoid fever may be considered as primary enteritis when the abdominal symptoms are unusually prominent from the beginning. The liability to this error is chiefly in cases occurring in children. Events other than the abdominal symptoms belonging to the history of typhoid fever are to be sought after. Some of these are not so readily appreciated in children as in adults, especially those relating to the mind, and the eruption is oftener wanting. Hence typhoid fever in children is not infrequently called enteritis. With due care in tracing the development and progress of the disease this error of diagnosis should generally be avoided.

It is evident that familiarity with the phenomena and laws of typhoid fever and of the diseases with which it is liable to be confounded—namely, other fevers and the local affections just referred to—is an essential qualification for accuracy in diagnosis. This remark is of general application to diagnosis.

The thermometer may be brought to bear upon the diagnosis of this disease at an early period, before the eruption or other distinctive features are fully declared. A moderate increase of temperature daily for several successive days, with an evening exacerbation, points to typhoid fever as contrasted with typhus, periodical, relapsing, or an eruptive fever, assuming the disease to be an essential fever and not an inflammatory disease. Various circumstances, however, may occasion deviation from this gradual increment of fever in typical, uncomplicated cases.

In some cases the disease may be overlooked in consequence of the phenomena being imperfectly developed. These cases were called by Louis cases of "latent typhoid fever." They are called by German writers cases of "*typhus ambulatorius*;" and the term "walking cases" is in use in this country. The patients do not take to the bed, and perhaps they continue their usual avocations. They complain only of debility, loss of appetite, and mild diarrhoea. Under these circumstances death sometimes takes place from intestinal perforation, profuse hemorrhage, or some grave complication, and on post-mortem examination the characteristic typhoid lesions of the intestine are found. The only explanation of these cases to be given is that the effects of the special cause are concentrated on the glandular elements of the small intestine.

Errors of diagnosis are likely to be made in cases of abortive typhoid fever, in very mild cases (*typhus levissimus*), and in cases in which the temperature-curve has a remittent or possibly intermittent character. In children the existence of typhoid fever is doubtless often overlooked.¹ Here abdominal symptoms may be slight, particularly intestinal hemorrhages and peritonitis, while severe cerebral symptoms are usually present. In old per-

¹ Henry D. Chapin, *Am. Journ. of Obstetrics and of Diseases of Women and Children*, July, 1883.

the course of the disease is often irregular, pulmonary and cerebral symptoms frequently being most marked. The occurrence of cases of typhoid in which the symptoms of an acute Bright's disease appear early is rare, this should be borne in mind.

PROGNOSIS.—Of 18,612 cases aggregated by Murchison, the mortality was 52 per cent., or 1 in 5.4. Of 303 cases received in the Massachusetts General Hospital and analyzed by James Jackson, 42 were fatal, being 1 in 7 cases, or a fraction less than 13 per cent. Of the 73 cases which I have analyzed, 18 were fatal, nearly 1 in 4, or about 24 per cent. These facts show a variation in the death-rate in different collections of cases occurring at different places and periods. That the variation is often considerable at different seasons in the same place, and under similar circumstances as regards surroundings and treatment, is shown by the ratio of deaths in successive years in the Massachusetts General Hospital.¹ In 1828, of 22 cases, 2 died; in 1829, of 25 cases, 1 died; in 1830, of 14 cases, 4 died; in 1831, of 29 cases, 2 died; in 1832, of 23 cases, 4 died; in 1833, of 37 cases, 6 died; in 1834, of 34 cases, 6 died; and in 1835, of 35 cases, 6 died. Statistics show that the average mortality from typhoid fever in recent years is less than formerly, being about 10 per cent. This diminution in mortality may be fairly attributed to improved methods of treatment. It is, however, evident that there are wide differences in the intrinsic tendency of the disease to a fatal issue at different periods and places—a fact to be considered in estimating the influence of therapeutical measures.

As regards age, Murchison's statistics show the lowest rate of mortality to be in cases between ten and fifteen years, and the next lowest between five and ten years, the number of cases analyzed at less than five years being insignificant. The highest rate at less than fifty-five years is between thirty and thirty-five years. Jackson's statistics show the death-rate to be greater above than below thirty years of age, and they show a greater mortality in the cold than in the warm months. It is a matter of common observation that vigorous persons are more likely to succumb than those of feeble constitution.

A fatal result in a considerable proportion of cases is attributable to complications or accidents, such as pneumonitis, peritonitis, and hemorrhage. A pre-existing disease may lead to a fatal result, as, for example, chronic disease of the kidneys. Unusual severity of the abdominal lesions is sometimes a cause of death. In the great majority of fatal cases the mode of dying is apnoea. Apnoea is combined with asthenia in the cases in which sudden death precedes death.

Coma and convulsions, probably uræmic in most cases, render the prognosis extremely unfavorable. Other marked ataxic symptoms, such as carphologia, delirium, etc., are ominous. Cases characterized by active persistent delirium usually end fatally. The prognosis is unfavorable whenever the pulse becomes extremely frequent and feeble and the first sound of the heart is abnormally weakened. The immediate cause of death in these, as in all cases in which the mode of dying is by slow asthenia, is the giving way of the power of the heart's action. Great prostration is evidence of much danger. The chances of recovery may be good, notwithstanding the occurrence of pneumonitis limited to one lobe. Intestinal hemorrhage is less serious than has been supposed by some; recovery taking place in the majority of the cases in which this event occurs. Death may be caused by gangrene or bed-sores on parts exposed to continued pressure from the weight of the body. An increase of the axillary temperature above 105° denotes great danger, and a

¹ Report on Typhoid Fever, by James Jackson, M. D.

temperature of 106° or 107° or upward is a fatal prognostic. On the other hand, a considerable decrease of temperature below the minimum of health is ominous. In general, after the first few days of the disease, the temperature having daily increased up to this time, the heat as shown by the thermometer varies in the morning between 102° and 103° , and in the evening between 103° and 105° .

A favorable prognosis may be entertained so long as ataxic symptoms are not marked, the adynamia is not great, the pulse not very frequent or feeble, and there are no serious complications; but under these circumstances the prognosis should always be guarded, in view of the liability at any period of the disease to serious complications or accidents. Let it be borne in mind that sudden coma and perforation of intestine are not less liable to occur in mild than in severe cases. The liability to perforation during convalescence is to be recollected. On the other hand, recovery may be hoped for in cases in which the symptoms denote the utmost gravity.

Typhus Fever.

The fever called typhus, known from the earliest antiquity, has received a great variety of names. The name typhus, introduced by Sauvages in 1759, and now generally adopted by writers of all countries, has the negative merit of not involving any hypothesis concerning the nature and seat of the disease. Derived from *τυφος*, denoting stupor, it relates to a feature which is usually more or less prominent in this disease. In this country, from the fact that the disease is imported in vessels bringing emigrants from Ireland, it has been commonly known as *ship fever*.

This fever has many features in common with typhoid fever. The identity or non-identity of the two affections was once a mooted question. They present points of contrast amply sufficient to show that they are distinct diseases. In considering typhus it will suffice to present the traits by which it is distinguished from typhoid fever.

ANATOMICAL CHARACTERS.—In typhus the abdominal lesions which are characteristic of typhoid fever are wanting. The Peyerian and solitary glands of the small intestine are either unaffected or they are simply more conspicuous than usual, sometimes presenting a number of black points, giving rise to what has been called the *shaven-beard appearance*. The mesenteric glands are not infiltrated as in typhoid fever, and are generally healthy.

The disease has no known special anatomical characters; that is, there are no lesions peculiar to the disease and constantly present. Morbid appearances in different parts are frequently found after death, but they are due to complications or are such as belong to infectious diseases in general.

The spleen is usually large, soft, and of a dark, bluish-red color. In very rare instances there is no enlargement of the spleen. The heart is often flabby and softened. The blood in the heart and large vessels is unnaturally dark and fluid, and coagula, if they exist at all, are dark and soft. Hypostatic congestion of the lungs, bronchitis, lobular pneumonia, and pulmonary edema are very frequent. Slight extravasation of blood into the arachnoid cavity occurs in a small proportion of cases. Cerebral congestion and effusion of serum into the ventricles of the brain, the subarachnoid space, and the arachnoid cavity are not uncommon, but they are usually unattended by inflammatory exudation. Meningitis is a rare complication. The same parenchymatous degenerations which are present in typhoid fever may occur in typhus. The kidneys are often congested. They are sometimes enlarged, and may present the appearances of an acute nephritis. Nephritis is more

common in typhus than in typhoid fever. Subserous ecchymoses are common. The granular and hyaline changes in fibres of voluntary muscles, noticed as occurring in typhoid fever, have also been observed in typhus.

CLINICAL HISTORY.—The duration of the access is shorter than in typhoid fever, and cases of an abrupt invasion are not as rare. Patients in the great majority of cases take to the bed on the second or third day after the first manifestation of illness. The symptoms during the development of the disease are essentially the same as in typhoid fever, with this important difference—namely, the abdominal symptoms of typhoid fever, diarrhœa, meteorism, iliac tenderness, and gurgling, are wanting. Pain in the back and limbs and muscular weakness are more prominent as prodromata of typhus than of typhoid fever.

Countenance and General Aspect.—Capillary congestion of the face, extremities, and trunk is more marked in typhus than in typhoid fever. It gives to the surface, especially of the face, a dusky or dingy hue, so distinctive of typhus as compared with typhoid fever that even nurses and attendants, after becoming conversant with the two diseases, learn to discriminate them by the physiognomy. The conjunctiva is more frequently and more deeply congested. A besotted or expressionless countenance is earlier and more strongly marked.

Nervous System.—The symptoms referable to the nervous system which belong to the clinical history of typhoid fever occur in typhus. Coma-vigil and typho-mania are observed in a larger proportion of cases of typhus, they are oftener present in a marked degree, and they occur earlier in the career of the disease. Other ataxic symptoms, such as subsultus and carphologia, are of more frequent occurrence. Prostration is generally more marked and is earlier manifested. Persistent active delirium, in my experience, has occurred oftener in typhoid than in typhus fever. Contraction of the pupil often accompanies delirium or stupor, and is sometimes extremely marked, called by Graves the *pinhole* pupil. I have observed oscillations of the eyeballs occurring in a marked degree, the movements being lateral and notably rapid. The oscillations occurred whenever the patient was raised. The cases ended fatally. Coma and convulsions occurring in typhus as in typhoid fever are generally attributable to uræmia. Hyperæsthesia of the surface, even when the mental perception is notably blunted, is sometimes manifested.

Digestive System.—The tongue, more frequently than in typhoid fever, becomes covered with a thick brown or black coating. It is less frequently reddened, glazed, and fissured. It is oftener with difficulty protruded. Sordes occur more frequently, earlier, and in greater abundance. As regards the abdominal symptoms which are highly diagnostic of typhoid fever, the two diseases present a striking contrast. Diarrhœa very rarely occurs in typhus, and if present it is almost invariably slight. The stools have not the ochre color of those in typhoid fever. Tympanites is much oftener wanting, and generally when present it is slight in typhus. This statement applies also to iliac tenderness. Intestinal perforation does not occur in typhus. Hemorrhage from the bowels is one of the rarest of events, exclusive of cases in which dysentery is a complication.

Parotiditis is liable to occur, and the remarks made with reference to this complication in typhoid fever are equally applicable to its occurrence in typhus.

Skin.—A characteristic eruption occurs in a larger proportion of cases of typhus than of typhoid fever. Murchison states that of 3506 cases received at the London Fever Hospital, it was not observed in 403, or a fraction more than 11 per cent. Of 65 cases which I have analyzed, it existed in 57. It is oftener wanting in children than in adults. The eruption appears earlier in

typhus. The average period from the time of taking to the bed to the first appearance of the eruption is a little less than three days. The eruption in typhus is much oftener abundant, frequently being copious over the extremities as well as on the trunk, and sometimes appearing on the face.

Other distinctive points relating to the eruption are as follows: It is a maculated, not a papular, eruption. The spots become of a dull, dingy or dark-red color, and after the first two or three days the redness cannot readily be made to disappear by pressure. In some cases in the latter part of the disease the spots become truly petechial. They are smaller than the papules of typhoid fever. They do not come and go like the rose papules of typhoid; they all appear in the course of three or four days, and remain during the greater part or the whole course of the disease, sometimes even continuing into convalescence. They are often apparent after death.

The copiousness of the typhus eruption represents generally a corresponding gravity of disease. This statement does not hold good with respect to the eruption in typhoid fever.

In a certain proportion of cases of typhus intermingled with the characteristic maculæ are more or less of the rose papules which are characteristic of typhoid fever.

Petechiæ are observed in some cases of typhus, as in cases of typhoid fever, as well as in various other diseases. As already stated, the characteristic typhus-spots sometimes become petechial. The eruption of typhus is sometimes called a petechial eruption. This is incorrect. *Petechiæ* are spots caused by minute extravasations of blood; that is, they are ecchymoses, and these are not distinctive of typhus. *Vibices* are occasionally observed in cases of typhus. *Sudamina* or miliary vesicles occur in cases of typhus as well as of typhoid fever.

The statements with respect to sweating and moisture of the skin in typhoid are also applicable to typhus fever.

The odor from typhus patients is stated to be characteristic. I have met with persons who declared that they were able to discriminate cases of typhus from typhoid fever by the sense of smell. I can bear testimony to an offensive odor emanating from patients affected with either disease, but I have not been able to appreciate its value as a diagnostic symptom.

Erysipelas sometimes occurs in typhus as in typhoid fever. Bed-sores are less liable to occur, in consequence of the shorter duration of typhus. Spontaneous gangrene, not produced by pressure, is an occasional event. I have seen a case in which gangrene of both feet took place. The nose, penis, and scrotum have been known to slough away. Ulceration or sloughing of the cornea has been observed. The affection known as *noma* is another serious complication occurring sometimes, not only in children, but in adults. These complications occur in hospitals among patients who prior to the disease were suffering from innutrition.

Respiratory System.—The account of symptoms referable to the respiratory system in typhoid fever is mainly applicable to typhus. The significance of a spasmodic inspiration occurring without any pulmonary complication is the same in the latter as in the former disease. Cough from bronchitis is generally more prominent than in typhoid fever. Pseudo-pneumonitis—that is, hypostatic congestion and œdema—is more frequent, whereas true pneumonitis appears to be less frequent than in typhoid fever. Epistaxis occurs less frequently. It appears to be established that the expired breath contains more ammonia than in health.

Circulation and Temperature.—The average frequency of the pulse in cases of typhus is greater than in typhoid fever. The significance of frequency and other characters of the pulse, and of weakness or absence of the first sound

of the heart over the apex, as representing the state of the vital forces, is not less in typhus than in typhoid fever.

The temperature of the body, as determined by the thermometer, is more or less increased, varying between 102° and 107° F. The increase of temperature corresponds to the intensity of the disease. A decline of temperature is coincident with the occurrence of convalescence. The defervescence in some cases is notably rapid, but in other cases it is gradual. At the time of convalescence the temperature frequently falls below the standard of health. As in typhoid fever and in other essential fevers, a sudden and considerable rise of temperature renders probable some inflammatory complication; and on the other hand a sudden fall of temperature below the average range in health denotes a serious change for the worse. As a rule, the increase of temperature daily is progressive from the beginning of the disease to about the fifth day, and the daily oscillations of the morning and evening temperature are not observed prior to this period. An analysis by Dr. MacLagan of 58 cases ending in recovery gave, as the average temperature in the morning, a fraction over 102°, and in the evening a fraction over 103° F. The highest point reached in any of these cases was a fraction over 105°. In typhus, as in other fevers, a fall of temperature not infrequently denotes approaching convalescence, prior to any appreciable improvement in the pulse and other symptoms.

Urine.—The urea and uric acid are generally increased, as in cases of typhoid fever. According to Murchison, the chlorides are greatly diminished or disappear entirely.

Albuminuria is of more frequent occurrence in typhus than in typhoid fever. Murchison found it in 20 out of 28 cases, or a fraction more than 71 per cent. In about one-half of the cases the amount of albumen was considerable. In most of the latter cases there was no evidence of pre-existing renal disease. In typhus as in typhoid fever the early appearance of albumen in the urine, its abundance, and its duration, denote gravity of disease. Epithelial and blood-casts are sometimes observed.

The duration of typhus is less than that of typhoid fever. Of 53 uncomplicated cases ending in recovery analyzed by Murchison, the duration varied between eight and twenty days, the mean duration being a fraction more than fourteen days. The mean duration in 10 fatal cases was fifteen days. Of 45 cases ending in recovery which I have analyzed, the maximum duration was twenty-six and the minimum nine days, the mean being fourteen days. The mean duration in 9 fatal cases was ten days. In my cases the beginning of the disease was reckoned from the time of taking to the bed.

Relapses of typhus are extremely rare. Examples of this fever having been experienced more than once are also very infrequent. There are no special sequels, and in the great majority of cases the health is excellent after recovery. Temporary loss of the hair is a common consequence of both typhoid and typhus fever. Mental imbecility sometimes remains for a certain period after the general condition of the body denotes recovery.

Typhus fever is sometimes associated with dysentery. Typhus and variola have been known to be combined. Probably typhus and typhoid fever may coexist.

CAUSATION.—The contagiousness of typhus is shown by the occurrence of successive cases in particular houses and neighborhoods, by the number who are attacked of persons brought into contact with typhus patients, especially in hospitals, either as physicians, attendants, or fellow-patients, and by the importation of the disease in localities where it did not previously exist. Referring the reader to works on fever for the further evidence of the con-

tagiousness of typhus, I shall subjoin some illustrative facts falling within my own knowledge:

In 1850, 1851, and 1852, I was engaged in the clinical study of typhus and typhoid fever in the Buffalo Hospital of the Sisters of Charity. I recorded during these years 65 cases of typhus. Twelve Sisters of Charity were assigned to this hospital during the period just named. Of these twelve sisters, five contracted typhus fever. These five sisters alone had charge of the fever patients; and the remaining seven sisters, performing other duties, were not brought into contact with the fever patients. Thus, every sister who nursed fever cases had an attack of the disease. During the last of these years eleven patients, admitted for other affections, contracted the disease, the number of cases of typhus received during this year being considerably larger than during the preceding two years.

Typhus fever began to prevail in certain parts of the city of New York as an epidemic in 1861, the disease having been imported from Ireland. From Jan. 1, 1861, to Nov. 1, 1864, 1428 cases were admitted into Bellevue Hospital, more than 500 cases having been received during the six months preceding Nov. 1, 1864. Of 22 members of the house staff during the time above stated, 15 contracted the fever. Of persons employed in the hospitals as orderlies, watchers, etc., 16 were attacked with fever. From June, 1863, to June, 1864, 26 patients, admitted into the hospital for various affections, contracted the fever. In May, 1864, the fever patients were transferred to tents, and no new cases were received. There was subsequently no development of the disease in the hospital.

The infectious poison emanating from typhus patients rarely communicates the disease except to those who are in immediate proximity to patients. Concentration of the poison is generally necessary. Hence, the disease is likely to be contracted by those who render personal attentions to patients, and especially by those who are exposed to the atmosphere of ill-ventilated fever-wards containing a large number of cases. A single patient in a spacious, well-ventilated apartment seldom communicates the disease. All persons at all times, moreover, are not equally susceptible, and hence some contract the disease after comparatively slight exposure, while others who are much exposed escape. There is no proof that the disease is diffused from one house to another or from hospitals to adjoining houses, except by intercommunication. Facts show that the disease may be communicated by fomites, but a considerable impregnation of articles of clothing, etc. is necessary. Exposure of infected clothing to a dry heat of 200° F. probably destroys the miasm. Some facts appear to show that the disease may be contracted by dissecting bodies dead with typhus, but this is not certain. The period of the disease in which it is most likely to be communicated is after the first week. Facts appear to show that it may be communicated during convalescence.

The fact that in the emanations from the bodies of patients a contagium exists capable of producing the disease is distinctive of typhus as contrasted with typhoid fever. There is no reason for supposing that the infecting capability of the typhus germs depends on any changes taking place after they are thrown off from the body.

There is considerable variation in the estimation by different observers of the period of incubation. Probably this period varies considerably in different cases. Murchison has determined the average period to be about twelve days. Exceptionally it is longer than this, but it rarely if ever exceeds three weeks. On the other hand, in many cases it is less than twelve days, and occasionally the symptoms begin almost at the instant of

exposure.¹ Persons have sometimes had an impression that they received the poison at a particular moment when they were conscious of a peculiar sickening odor inhaled from the body of a typhus patient. Little or no reliance is to be placed on this impression as evidence of the reception of the infection. Probably physicians have very many times experienced this sickening odor without having had typhus. Such has been repeatedly my experience.

As a rule, in this country typhus fever is an imported disease and is diffused exclusively by contagion. It is, however, difficult to trace all outbreaks of the disease to contagion, and hence the opinion is held by some that the special cause is sometimes produced outside of the body. The disease sometimes appears to be developed as a consequence of overcrowding and deficient ventilation; in other words, the concentrated emanations from the bodies of healthy persons apparently suffice for the generation of typhus germs.² Outbreaks in jails, hospitals, workhouses, ships, and unventilated tenement-houses crammed with occupants are thus accounted for in some instances irrespective of contagion.

In 1841, I reported four cases of typhus developed in the Erie county almshouse. They occurred during the winter months. The wards in this institution were quite small and crowded, and for the sake of warmth fireplaces, which had previously been used, had been bricked up and close stoves substituted. There was an abundant eruption in all these cases, and an examination after death in the only case which proved fatal showed the absence of the typhoid lesions. In these cases overcrowding and want of ventilation seemed to be important elements in causation.³ No cases of typhus occurred out of the almshouse, and the disease was not imported.

Overcrowding, deficient ventilation, especially if conjoined with innutrition, are powerful auxiliary causes acting in conjunction with contagion. The causative influence of destitution and starvation is strikingly shown by the prevalence of typhus in Ireland in periods of famine, and by the large proportion of cases among those received in hospitals in which the deprivations and hardships of poverty had been experienced prior to the attack of fever.

Typhus attacks the two sexes in about an equal proportion. Persons are more liable to be attacked during adult age, but children are not exempt, and this fever does not, like typhoid, spare those who are beyond the middle period of life. It is more likely to prevail in the winter and spring months than in autumn, in this respect differing from typhoid fever.

DIAGNOSIS.—The remarks on the discrimination of typhoid fever from remittent fever and several local affections will apply to typhus fever. (Vide p. 918.) The discrimination of typhoid and typhus fever is to be here noticed. The following are the more important points in this differential diagnosis: The relatively long duration of the forming stage in typhoid, and its short duration in typhus; the prominence of pain in the loins and limbs and muscular prostration at an early stage of typhus; absence, in typhus, of the characteristic abdominal symptoms of typhoid—namely, diarrhœa, meteorism, iliac tenderness, and gurgling—or their presence in comparatively a slight degree; the dusky or dingy hue of the surface in typhus; the appearance of the eruption earlier in typhus, and the different characters of the eruption—namely, in typhoid, papular, rose-colored, the redness disappearing on pressure; in typhus, after two or three days, if not at first, maculated, the color dark red, and the

¹ Vide *St. Thomas's Hospital Reports*, vol. ii.

² For facts bearing on this point, vide Murchison, *op. cit.*

³ Vide *Boston Med. and Surg. Journal*, June, 1841.

redness not disappearing on pressure. Other distinctive points relate to the eruption—namely, the sparseness in typhoid and the copiousness in typhus; the frequent extension in the latter of the eruption over the extremities; the persistence of the spots in typhus, and the disappearance of papules with the production of fresh papules in typhoid. It is to be borne in mind that in some cases of typhus rose papules are intermingled with the characteristic maculæ. In typhoid fever the temperature reaches its acme at a later period than in typhus. The rise of temperature is more gradual and regular in typhoid than in typhus. In typhus the average duration of the fever is shorter than in typhoid, and the defervescence is more rapid.

Corroborative diagnostic points are—the occurrence of peritonitis and hemorrhage from the bowels in some cases of typhoid, and the earlier occurrence of delirium, coma-vigil, and other ataxic symptoms in typhus.

If the eruption be present, typhus is generally recognized without difficulty. The eruption is not always present, and the diagnosis may then involve delay and difficulty. The prevalence of typhus and exposure to contagion are to be taken into account in doubtful cases.

PROGNOSIS.—Of 18,592 cases aggregated by Murchison, occurring at the London Fever Hospital in fourteen years, at King's College Hospital, the Edinburgh Infirmary, and at Glasgow, Scotland, the mortality was 18.78 per cent., or 1 in 5.27. This rate of mortality differs only by a small fraction from the rate in about the same number of cases of typhoid fever analyzed by Murchison. The death-rate is found to vary at different times and places between 9 and 25 per cent., the variations being due to differences as regards an intrinsic tendency of the disease to a fatal result. In epidemics of typhus, as of other diseases, it has been often observed that the fatality is greatest at first and decreases as the number of cases diminish. The ratio of fatality is greater among males than females. The fatality is less in early life than subsequently. It is greater at less than ten years of age than between ten and twenty years. After thirty years of age the fatality progressively increases, and after fifty years the proportion of deaths is nearly one-half.

Of the 63 cases which I have analyzed, 12 were fatal; that is, 1 in a fraction more than 5, or a fraction more than 18 per cent.

A fatal result is oftener due to the intensity of the fever—that is, occurring irrespective of complications—in typhus than in typhoid fever. Peritonitis, which destroys a certain proportion of patients with typhoid fever, does not occur in typhus. This is true also with respect to intestinal hemorrhage. Pneumonitis is less frequent in typhus, and there are no complications peculiar to the latter. Acute diffuse nephritis attended by uræmic symptoms is more liable to occur in typhus than in typhoid fever. A fatal result appears to be oftener attributable to feebleness of constitution, or to causes which impair the power of resisting the disease, in typhus than in typhoid fever. Of 38 cases which occurred among the members of the resident medical staff and persons employed in Bellevue Hospital, 17 ended fatally, whereas of 1428 patients admitted with fever during the same period, the number of deaths was 243, or 1 in 5.87. This difference in the mortality in the two classes of cases is the more remarkable because the resident physicians and persons employed in the hospital were treated for the disease under more favorable circumstances than the hospital patients. It is difficult to account for the greater fatality among the former class, except by supposing that living in the hospital involved exposure to nosocomial depressing influences which rendered the system less able to resist the disease.

In general, the symptoms pointing on the one hand to a favorable, and on the other hand to an unfavorable, prognosis are the same in both typhoid and typhus fever.

CHAPTER III.

CONTINUED FEVERS (CONTINUED).

Treatment of Typhus and Typhoid Fevers.—Relapsing Fever; Anatomical Characters; Clinical History; Causation; Diagnosis; Prognosis; Treatment.—Erysipelatous Fever.—Epidemic Fever characterized by Mild Erythematic Pharyngitis.

THE general principles of TREATMENT in typhoid and typhus fever are essentially similar, and indeed are applicable to all the fevers. It will suffice to notice incidentally indications pertaining exclusively either to typhus or typhoid fever, without considering the treatment of each fever separately.

It must be admitted that the known resources of therapeutics do not afford reliable means for the arrest of these fevers, nor even for shortening the duration of the febrile career. Quinia, so potential in arresting malarial fevers, has no abortive potency in the continued fevers. Calomel in doses of from ten to fifteen grains repeated daily for several days has been recommended by Wunderlich, Liebermeister, and other German writers as shortening the course of typhoid fever, diminishing the mortality, and sometimes causing the disease to abort. Iodine or the iodide of potassium and carbolic acid have been thought to have a special influence over this fever. Liebermeister states that the iodide of potassium in doses of a scruple to a drachm daily, given in more than two hundred cases, while it produced no appreciable effect upon any of the febrile phenomena, apparently diminished the rate of mortality. That the mineral acids—namely, the dilute phosphoric, hydrochloric, nitric, and nitrohydrochloric—have a favorable modifying influence upon the disease there is abundant testimony. In 1863 and 1864, I instituted a comparison in the male fever-wards at Bellevue Hospital of the rate of mortality during six months without, and the same period with, the use of dilute sulphuric acid, eliminating all cases in which death took place within forty-eight hours after admission. Of 70 cases treated from January 1 to July 1, 1863, without acid the death-rate was 20 per cent.; of 78 cases treated with acid from July 1, 1863, to January 1, 1864, the death-rate was 10.25 per cent. The treatment of the two collections of cases was the same, exclusive of the acid.¹ My observations do not enable me to state which one of the mineral acids is to be preferred. They are generally relished by fever patients if sufficiently diluted with the addition of syrup of orange-peel or simple syrup, and are usually given, not as a medicine, but as a drink. The death-rate, however, in cases treated with the acid was not below that in 307 cases treated at the Hospital of Boston without drugs of any kind. The rate in these cases was 10 per cent.

Of all therapeutic measures, those directed toward the reduction of fever take the first rank. The *modus operandi* of antipyretics is not thoroughly understood, but there is no doubt that their effect is something more than the mere reduction of the temperature. Indications for their employment are to be sought not only in the elevation of temperature, but especially in symptoms denoting severe febrile action, as stupor and other ataxic disturbances.

Reduction of the intensity of the fever may be effected by the application of cold or by the administration of antipyretics.

¹ Vide report by Dr. Irving W. Lyon, then chief of the fever-wards of Bellevue Hospital, in *American Medical Times*, Feb., 1864.

a century ago pointed out the efficacy in fever of water employed as a cold affusion. The modern revival of the use of cold water for an antipyretic effect in typhoid fever is attributable to a publication by E. Brand in 1861. Bartels, Jürgensen, and Liebermeister are to be named as especially prominent in bringing to the test of clinical experience antipyretic measures of treatment. There is no doubt that a remarkable reduction in the death-rate of typhoid fever has been brought about by systematic antipyretic treatment.

The methods of refrigeration by cold water now in vogue are the bath, sponging the body, and the wet sheet with sprinkling. The bath is the method chiefly employed by German physicians. The following method of administering the bath may be recommended: The bath-tub should be drawn up beside the bed. The patient should be lifted and placed in the bath by attendants without any exertion on his part and with as little disturbance as possible. The temperature of the bath should be from 75° to 80° F., and the patient should be removed after ten minutes from the bath and dried. It is not necessary to use baths at a temperature much if any below 75°, but it may be advantageous to immerse the patient in water of a temperature of about 90°, and then gradually cool the water down to about 75°. It is important to know that the rectal temperature sinks for half an hour after removal from the bath. If the patient feels very cold after the bath and there are any symptoms of collapse, heat should be applied and stimulants administered. Generally in from two to three hours the temperature has risen, sometimes to its former height. It is generally sufficient to administer three to five baths during the day, and it is rarely desirable to give them at night. It is usually stated that a temperature of 103° or upward is an indication for the bath, but, as has already been mentioned, other symptoms than the temperature are also to be considered. When it is apparent that notwithstanding the temperature named the patient's general condition is good and is not suffering from the pyrexia, there is no necessity of the bath; on the other hand, when there are stupor and other symptoms to indicate that the system is being overpowered by the severity of the infection, then it may be desirable to employ the bath even at a temperature lower than 103°. Contraindications to the use of the bath are intestinal hemorrhage, perforation of the bowel, and great weakness of the heart's action.

[It cannot be denied that the statistics of the Brand method of treatment are far more favorable than those of any other. In fact, Brand declares, after an experience of thirty years in the treatment of typhoid fever with cold baths, that every case treated according to his method will recover, provided the baths are begun before the fifth day. In support of this statement he gives the following figures:

Jürgensen (Tübingen)	217 cases,	1 death.
Vogl (Munich)	221 "	6 deaths.
Military Hospital (Stralsund)	257 "	1 death.
" " (Stettin)	186 "	3 deaths.
Brand (private practice)	342 "	1 death.
	1223 "	12 deaths.

And not one of these twelve deaths occurred in a case that came under treatment before the fifth day.—H.]

Although the bath is the most effectual mode of reducing the temperature, the method is open to objections on the score of inconvenience, especially in private practice, and of the excitement of the patient which it is apt to occasion. Considerable judgment is required in its employment to avoid unpleasant depressing influences. For these reasons other measures are more commonly employed in this country. Sponging is the simplest

method, involving the least inconvenience to the patient and others. It should be first employed, and in a large proportion of cases it will suffice. Sponging either the whole body at once or different parts in succession with water at a temperature not uncomfortable to the patient for as long a period as it is unattended by discomfort, repeating the measure as often as indicated by a rise of temperature, will generally prove successful. If not conducted by a skilled nurse, it is difficult often to have this method properly carried out—in part, because persons cannot appreciate that so simple a measure can have much potency, and partly from the popular fallacy that there is danger of “taking cold.” The sponging should be resorted to when the axillary temperature is 103° and that of the rectum $102\frac{1}{2}^{\circ}$. It should be continued until the temperature in the rectum falls to 100° or 101° , and repeated whenever it again rises. A little wine or spirits should be given if the patient manifest chilliness.

If this method prove ineffective, the wet sheet and sprinkling may be employed. The patient is placed on a cot, wrapped in a wet sheet without any other covering, and the body sprinkled with cold water at short intervals. For sprinkling a common watering-pot is suitable. This may be continued for half an hour or even longer, according to the effect on the temperature and other symptoms. The thermometer must be introduced into the rectum. This method is to be repeated as often as the temperature rises. The temperature will be found to fall after the patient has been transferred from the cot to the bed. A cot with arrangements for the drainage of the water is convenient. A sense of chilliness, feebleness of the pulse, and cyanosis contraindicate the continuance of the sprinkling and are indications for wine or spirit.

We possess a considerable list of drugs which have antipyretic effects. The most important of these are quinia, salicylic acid, kairin, resorcin, hydrochinon, antipyrine, and thallin. Of antipyretic drugs, quinia, administered in doses of 20 to 40 grains before the evening exacerbation, until recently held the first rank. Antipyrine, however, is at present the favorite drug for reducing temperature. This remedy has many advantages, and is attended with but few secondary disagreeable effects. The taste is slightly bitter, but not particularly unpleasant. It is readily soluble in water, and may be administered either in powder or in solution. The method of administration recommended by Filehne, who introduced the drug into medicine, is to give at first 30 grains, followed in an hour by another 30 grains, and at the end of another hour by 15 grains. Striking reduction of temperature is obtained by the administration of smaller doses, which are less likely to be attended with any unpleasant effects. The fall in temperature is considerable and rapid. The heart's action is usually at the same time increased in force and decreased in frequency, and the mental state of the patient is improved. In a few instances symptoms of collapse or of notable prostration have followed the administration of antipyrine. The unpleasant secondary effects which have been noted in some cases are vomiting, profuse perspiration, and an erythematous eruption. Should the drug excite vomiting, it may be given hypodermically or preferably by the rectum. The eruption often resembles somewhat that of measles. It disappears, as a rule, soon after the cessation of the drug. The other antipyretic drugs which have been mentioned are less commonly used, and are accompanied by more or less disagreeable secondary effects.

Good results have been obtained by the use of *veratrum viride*, *digitalis*, salicin, and salicylate of sodium, but these drugs are to be given circumspectly and are not very commonly employed.

Valuable as are the antipyretic remedies in typhoid fever, there is no proof

that they exert any specific effect upon the special poison of the disease or that they shorten the duration of the disease. The injurious effects of pyrexia *per se* have undoubtedly been much exaggerated. Some late writers have even revived the old notion that a certain amount of increase of heat in the infectious diseases has a useful purpose. Probably too much weight has been assigned to the mere abstraction of excessive heat in the treatment of fever. The beneficial effects of antipyretic treatment are manifested even more in the removal of other symptoms, such as somnolence, delirium, dryness of the tongue, weakened heart's action, and adynamia; and when such symptoms are not present it is not necessary to resort to vigorous measures to reduce temperature.

[Intestinal antiseptics are of undoubted value in the treatment of typhoid. In fact, considering that the disease has its origin in the gastro-intestinal tract, it is a question whether intestinal antisepsis be not the primary indication. The best drugs of this class are thymol and naphthalin. Under the use of the former the writer has repeatedly observed a steady descent of the temperature, a gradual diminution in the daily number of stools, and a speedy cleansing of the tongue—in short, a diversion of the disease into a progressively favorable course. There can be no doubt concerning the powerful antiseptic action of thymol, for during its administration phenol, which is a constant product of intestinal putrefaction, disappears from the urine.

Owing to its insolubility, a property upon which its value as an intestinal antiseptic largely depends, thymol must be administered in pill or capsule. As to the dose, I have given from 30 to 40 grains in twenty-four hours—two 24-grain pills every three or four hours—although much larger quantities may be given with safety, and perhaps with still better results.

Many other drugs recommended as intestinal antiseptics are not worthy of this title. According to Bouchard—and there is no better authority—as intestinal antiseptic must be more or less insoluble and exert no toxic action on the organism.—H.]

Indications for treatment relate to particular symptoms or events and complications embraced in the clinical history of these fevers.

In the early part of the disease cephalalgia claims palliative measures. This symptom is relieved by ice-water, spirit and water, distilled vinegar, or cologne-water freely applied to the head, and if more efficient measures be required the cold douche or ice-cap may be employed. As soon as the existence of either typhus or typhoid fever is declared the hair should be closely cut. This renders the patient more comfortable and facilitates local applications.

Insomnia is a symptom calling for treatment. To procure sleep is desirable, not only for immediate comfort, but as a means of averting ataxic symptoms. An opiate often proves beneficial. It may procure refreshing sleep in place of pseudo-somnolence or coma-vigil. The latter condition, not denoting a tendency to true coma, does not contraindicate the trial of opium. Other remedies which may be prescribed are hyoseyamus and the bromide of potassium, either separately or in combination.

Delirium, if slight or moderate, does not call for remedies; but if prominent as a symptom, as shown by constant talking and attempts to get out of bed, it leads to other ataxic symptoms and to exhaustion. Opium in some form, and other anodynes, are indicated. If these fail, the combination of antimony in small doses with opium, as recommended by Graves, will often prove efficacious. An eighth or a sixteenth of a grain of the tartrate of antimony and potassa may be given hourly or half-hourly until the patient becomes quiet, unless nausea or vomiting occur, when it is to be at once suspended. The remedies given for insomnia in addition to opium are appropriate. The time

ture of digitalis in half-drachm doses sometimes has a happy sedative effect upon the nervous system. The wet pack—that is, the body wrapped in a wet sheet and covered with a blanket—is a soothing measure which may often be resorted to with advantage. It is also an antipyretic measure, although less effective than continued sponging or the wet sheet with sprinkling. Insomnia, delirium, and other symptoms denoting disorder of the nervous system are less marked in proportion as the antipyretic treatment is effective. This statement is probably applicable in general to the complications and serious events liable to occur during the course of the disease, including perhaps perforation of the intestine and intestinal hemorrhage.

Nausea and vomiting seldom occur spontaneously in either typhoid or typhus fever to an extent to call for anything more than regulation of the ingesta. Diarrhoea in typhoid fever may require to be restrained, and for this end opiates and astringents, given by the mouth or rectum, may be employed. Mere looseness of the evacuations without undue frequency does not call for treatment. On the other hand, in typhus and sometimes in typhoid fever constipation may furnish an indication for treatment. As a rule, cathartics, or even laxative remedies, are not required for constipation. Simple enemata suffice and are to be preferred. Evacuations may be delayed for two or three days, or even longer, without injury if there be no evidence of discomfort and if the abdomen be not distended. Tympanites, if great or considerable, occasions discomfort and embarrasses respiration by interference with the descent of the diaphragm. Large enemata may suffice to relieve this symptom. Turpentine should enter into the enemata. If these fail a saline laxative may be given. A stomach-tube introduced into the rectum and carried as far as practicable sometimes occasions the discharge of gas in considerable quantity. Turpentine given by the mouth is supposed to relieve this symptom. Turpentine stupes to the abdomen are useful. Charcoal given freely is sometimes effective. Mechanical compression by means of a band applied over the abdomen sometimes affords relief.

Two important events connected with the abdominal lesions are liable to occur in cases of typhoid fever—namely, perforation of the intestine followed by peritonitis, and intestinal hemorrhage. The probability of the successful treatment of the former is almost *nil*. The small chance of success to be hoped for depends on the free use of opium and measures to support the powers of life. Local depletion and blisters are not admissible. Peritonitis not dependent on perforation claims the same treatment and is not so hopeless. Intestinal hemorrhage if profuse involves danger. This event calls for hæmostatic remedies. The peristaltic movements should be arrested by opium. Ergotin may be given hypodermically. The acetate of lead, given by the mouth, is preferable to tannic acid or the astringent preparations of iron, as less likely to occasion vomiting. Cold applications should be made to the abdomen. Absolute quietude is to be enforced.

Cough, although generally existing, is seldom sufficiently troublesome to require palliation. Pneumonia should not be treated with local or general depletion, blisters, or mercury, or with nauseant sedatives. This, as well as other serious complications, contraindicates depressing measures. The position of the patient should be occasionally changed to prevent hypostatic congestion of the lungs. Epistaxis is sometimes so profuse or persisting as to indicate local astringent remedies, and sometimes even plugging of the anterior and posterior nares.

Coma is to be treated by sinapisms or blisters to the back of the neck, and if dependent on uræmia by saline hydragogues if they be not contraindicated by the abdominal symptoms. If contraindicated reliance must be had on measures to produce copious perspiration. For the latter object the pilocarp-

pine, administered hypodermically, may prove efficient. Strong coffee is useful as a palliative of undue somnolency or semi-coma apparently due to nervous exhaustion.

It is important to prevent accumulation of urine from retention, and to resort to the timely use of the catheter if required.

Bed-sores are to be guarded against by having the position of the patient often changed and by attention to cleanliness. If they occur, the ulcerated parts are to be relieved from pressure by air-cushions and treated with appropriate local applications.

Hygienic and supporting measures constitute a most important part of the treatment of typhoid and typhus fever. Hygienic measures indicated are—complete ventilation, cleanliness, regulation of temperature (which should be about 60° F.), changing frequently the position of the body, and the varied attentions involved in good nursing.

Foremost among the hygienic conditions for passing safely through the disease is an abundance of pure air. In private practice the sick-room should be large and ventilated as completely as possible. In hospitals, fever-wards, in addition to ample provisions for ventilation, should not be crowded; 1500 cubic feet of air should be allowed to each bed. The evacuations should invariably be instantly removed. When practicable it is advisable that the bed- and body-linen should be changed daily.

The importance of fresh air is shown by the reduced rate of mortality when patients are treated in sheds and tents, as compared with the death-rate in even well-ventilated hospital wards. Striking evidence of this was afforded by the transfer of fever cases (chiefly typhus) from Bellevue Hospital to tents on Blackwell's Island. A comparison of the mortality in 520 cases treated in tents from May 17 to November 1, 1864, with the average mortality in the Bellevue Hospital wards, shows a marked difference. The average death-rate in the hospital wards was 1 in 5.97; in the tents, 1 in 16.77, excluding the cases in which death took place within forty-eight hours after admission. Making the fullest allowance for the conjecture that the cases in the tents were milder than those in the hospital wards, it can hardly be doubted that the superior ventilation in the tents was the means of saving many lives.

In a paper communicated to the New York Academy of Medicine in June, 1853, by Dr. John H. Griscom, an account is given of 82 cases of typhus transferred from an emigrant ship at Perth Amboy, N. J., to wooden shanties with sail "roofs." The ship brought over between three and four hundred passengers, and a number had died on the passage. There being no hospital or other accommodations in the town, two shanties were erected, "thirty feet long and twenty feet wide, boarded on three sides about four feet up, and over them old sails were stretched." 82 fever patients were transferred to these shanties, of whom 12 were in a state of insensibility when removed. On the night after their removal there was a violent thunder-gust accompanied by torrents of rain, and the following morning the clothes of all were saturated with water. The medical treatment consisted "of an occasional laxative or enema; vegetable acids and bitters were liberally administered, together with the free use of cold water, buttermilk, and animal broths." 4 sailors who sickened after the arrival of the vessel were removed to an ordinary dwelling-house, and of these cases 2 proved fatal. Of the 82 cases treated in the shanties, not one proved fatal.¹

Fever patients should not only be allowed to take water as freely as they may desire, but it should be systematically given when from the blunted state of the perception they manifest no desire for it. There is reason to

¹ *Transactions of the New York Academy of Medicine*, 1853, vol. i. part ii.

think that death is sometimes attributable to an insufficient supply of liquid. The importance of this should not be overlooked by the physician, inasmuch as it is a popular notion that the free use of water in fevers is hurtful. Iced water is not objectionable. It may be acidulated with lemon- or orange-juice if rendered thereby more agreeable to the patient.

The importance of support is based on the plain fact that, typhus and typhoid fever being self-limited diseases, if the patient can be kept alive, after three, four, or more weeks recovery will take place, provided there be no serious complication. In a case of severe uncomplicated fever the patient is in a situation not unlike that of a person in danger of drowning not far from or perhaps very near the shore. If he drown, it is because his strength gives way before the shore is reached. As a person in this situation requires only to be buoyed up by some support, so the fever patient in a similar emergency may only need supporting measures to live until the disease ends. Death may take place at a juncture when, could it have been averted a few days, or perchance even a single day, the period of danger might have passed.

Supporting measures embrace tonic remedies, alcoholics, and alimentation, especially the two latter. Of tonic remedies, the most efficient and convenient of administration is quinia, which may be given in doses of two or three grains twice or thrice daily.

Alimentation ranks first in importance. It is desirable for the patient to take as much nutritious food as will be digested and assimilated. In nutrition in cases of fever, as in other affections, enhances and adds to the morbid phenomena belonging to the disease. Graves uttered an important truth in saying that a great object of treatment is to prevent patients from dying from starvation. In the early part of the disease there is generally a repugnance to food, and afterward, owing to the mental state and the condition of the mouth, taste and appetite are wanting. Under the latter circumstances food is to be given, although not desired by the patient, and even when there is a disinclination to take it. The indifference to food may proceed, measurably, from an unwillingness to be disturbed and a reluctance to make any exertion.

The supporting diet should be in a liquid form, embracing the necessary variety of alimentary principles. The animal broths, eggs, and milk, with the addition of some farinaceous preparation of food, fulfil these requirements. Different articles should be given in alternation and at regular intervals. The intervals should be between two and four hours long. It is injudicious to give food every half hour or hour, or after even shorter intervals, as is not infrequently done. The amount of food given at a time must vary according to circumstances, the object being to give as much as can be taken without risk of either vomiting, discomfort from over-accumulation in the stomach, or indigestion. If the patient be in a condition to feel and express a choice for particular kinds of food, the preference should as far as practicable be consulted. The physician should have an oversight of the preparation of food, lest through ignorance or carelessness it be unpalatable, innutritious, or improperly served. Precise directions and attention to the details of dietetics form an important part of the physician's duty, not only in fevers, but in all cases of disease in which supporting treatment is indicated. Of the different articles of food just named, milk is by far the most valuable as entering into the fever diet. It is taken, if not with relish, at least with less reluctance than other articles, and it has the great advantage of embracing in proper combination all the alimentary principles required for nutrition. The "beef-tea," as it is often prepared, is little more than warm water flavored with the meat. The different so-called meat extracts contain little or no nutriment. It has been considered, indeed, that they are injurious from the amount of excrementitious principles entering into their composition. Prepared in any

mode and as carefully as possible, the essence of meat and broths are ^{very} inferior in nutritive value to milk. They should, therefore, never be relied upon to the exclusion of the latter. If the same article of animal diet—for example, beef-broth—be given day after day, the patient acquires for it after a time an intolerable disgust. The form should therefore be varied, beef-, mutton-, and chicken-broth being given in alternation. They may be rendered more nutritious by the addition of barley or some other farinaceous article, and by adding the yolk or albumen of eggs. It is desirable that from one to two quarts of milk *per diem* should be ingested; but since the value of a milk diet in fevers has come to be appreciated its use has frequently been pushed to an injurious excess. I have met with instances in which an abundance of hard curds was passed from the bowels after much abdominal distress and general disturbance. Coffee or tea, if acceptable to patients, is allowable. It may be made nutritious by a large addition of milk.

Alcoholics have entered largely into the treatment of fevers in this country during the last thirty years. That they have been used too freely and indiscriminately can hardly be doubted. As a natural consequence, there is perhaps at the present moment a tendency to undervalue their importance. It does not follow that they are never useful because in mild cases or in those treated under most favorable hygienic conditions the rate of mortality is small although they were not used. Observation of their immediate effects in certain cases shows their utility, often in a very striking manner. Indiscriminately and excessively used, they are not useful; but used with proper application and moderation, they form an essential part of the supporting treatment of fevers, as well as of all other diseases which destroy life by asthenia.

The supporting effect of alcoholics is directed chiefly to the circulation. Hence the indications respecting their use are derived especially from symptoms relating to the heart. Feebleness of the circulation, as denoted by the pulse and the heart-sounds, calls for their use, and they are to be given, as regards quantity, in proportion to the degree of feebleness of the circulation and according to their effect. The characters of the pulse denoting feebleness of the heart's action are smallness and compressibility, frequently combined with considerable or great frequency. A pulse in the adult exceeding 120 per minute never denotes strength, and above this number it is feeble in proportion to frequency. Above 130 the pulse always denotes a degree of feebleness of the circulation rendering supporting measures highly important. The heart-sounds also constitute a good criterion for estimating the degree of feebleness of the heart's action. In proportion as the action of the heart is weakened, the intensity of the first sound over the apex is diminished; it is shortened, and in quality it resembles the second sound. If the heart be notably weakened, the first sound may be inappreciable over the apex. Stokes was the first to direct attention to these changes as criteria for the administration of alcoholics.

Alcoholics are rarely indicated in the early part of either typhus or typhoid fever. They are oftener and earlier indicated in typhus than in typhoid fever. Brandy or some form of spirit, and wine, sherry or Madeira, may be employed. Beginning with a moderate quantity, half an ounce of spirit or an ounce of wine, the effect on the circulation and other symptoms should be observed. A good effect is shown by increased force, with diminished frequency, of the pulse, perhaps some reduction of the temperature of the body, diminution of delirium, etc. The intervals should vary, according to the urgency with which this supporting measure is indicated, between six or eight hours and each successive hour. The quantity given at a time should rarely exceed that just stated. Guided by the true indications and by the

effect, alcoholics will not do harm, and will often do much good in the treatment of typhus and typhoid fever. I have repeatedly tried their suspension for a few hours in cases in which they appeared to be urgently indicated, in order to become fully satisfied of their utility, and have found the pulse becoming more frequent, with increase of delirium and other ataxic symptoms, until their use was resumed. While a certain proportion of cases do well without them, and they are therefore not always indicated, I cannot doubt that I have seen not a few cases in which life was saved by their employment.

In these fevers, as in some other diseases, the tolerance of alcohol is often notably greater than in health. A patient may take from one to two pints of spirit per day who in health could not have taken one-fourth of this quantity without inebriation. The excitant or toxic effects of alcohol should never be produced in cases of fever. If these effects be produced, the indications for alcohol are not present or it is too largely given. In extreme cases an ounce or even more of spirit, given hourly, may be necessary; but in the majority of the cases in which alcoholics are indicated not more than six or eight ounces in the twenty-four hours are needed.

During convalescence alcoholics should be given moderately. If they have been used freely during the career of the fever, when convalescence begins their excitant effect may be for the first time apparent. Frequently malt liquors or light wines are best suited to convalescence. Solid food should be allowed as soon as convalescence is declared. The processes of digestion and assimilation are usually active, and the appetite may be voracious. The cautions to be observed relate to the kinds of food and the quantity taken at one time. The patient should be restricted to plain, wholesome, well-cooked articles of diet, and excess may be avoided by taking food at shorter intervals than in health. Convalescence from typhoid, more than from typhus fever, requires care as regards diet, in view of the probable existence of intestinal ulcerations. Gestation in the open air may be allowed early in the stage of convalescence, and as soon as their strength will permit patients may walk out of doors. Care with respect to much muscular exertion is important in convalescence from typhoid fever in consequence of a liability to intestinal perforation.

Measures of the utmost importance relate to the *prophylaxis* of typhus and of typhoid fever. It is established that by the introduction of modern sanitary arrangements these diseases have been made to disappear from districts where they formerly prevailed. These measures relate chiefly to matters of public hygiene which are beyond the power of the individual physician to accomplish, but which he may do much to advance by his advice. First in importance in cities is a good system of sewerage and a supply of good water.

In the prevention of typhus fever it is important to avoid overcrowding and to secure free ventilation. Patients with typhus should not be treated in hospital wards with other cases. This statement does not apply to patients affected with typhoid fever, as there is no risk of the diffusion of the latter among patients. The custom of transferring to fever-wards with cases of typhus patients affected with typhoid fever is objectionable in view of the risk of the latter contracting typhus during convalescence. Repeated instances in which this has occurred have fallen under my observation.

In every case of typhoid fever the disease should, if possible, be traced to its source, and continued exposure of the patient and others to the cause should be prevented. Careful examination for defects or leakage in water-closets, sinks, stationary washstands, drains, and soil-pipes should be made, and such defects remedied.

Drinking-water should be boiled if there be any ground for suspecting its

purity. In order to prevent diffusion of the disease the intestinal dejections should be disinfected by adding a solution of the sulphate of iron and carbolic acid or, better still, slaked lime, and they should not be thrown into privies or water-closets, but buried, so as to avoid the possibility of their infecting either drinking-water or the atmosphere. Articles of clothing or bed-linen soiled by intestinal dejections should be at once plunged in boiling water or disinfected.

Relapsing Fever.

A form of continued fever heretofore known by a variety of names, but now called *relapsing fever*, received very little attention in this country prior to 1870. It has never been indigenous in this country. In June, 1844, 15 cases were admitted into the Philadelphia Hospital presenting the characters of relapsing fever, this name, however, at that time not being in use. These were probably the first cases reported in this country. The patients were Irish immigrants, all coming over in the same vessel. The cases were observed by Dr. Meredith Clymer, and were reported in his treatise on fevers.¹ In addition to these, so far as I know, the only cases observed are a few reported by Dr. A. Dubois in 1848,² and 15 cases which came under my observation in 1850-51, an account of which is contained in my *Clinical Reports on Continued Fever*.³ The cases reported by Dr. Dubois and by me were among recent Irish immigrants. It is highly probable that other cases have occurred among immigrants which have not been reported, and which may have been confounded with typhus and typhoid fever. In the winter of 1869-70 the disease was imported by foreign immigrants, and it prevailed to a considerable extent in New York during this winter and the following summer. It prevailed also to some extent in others of the large cities of this country. At this time the wards of Bellevue Hospital afforded an ample opportunity for the clinical study of this disease; and my observations were the basis of a lecture published in the spring of 1870, to which was appended a statistical report of 103 cases prepared at my request by Dr. Thomas J. Moore, then one of the house-physicians of the hospital.⁴

It is not long since the distinctive features of relapsing fever have been pointed out and its claims to be considered as a distinct species of fever established. It is by no means, however, a new disease, and there is evidence of its having existed from a very early period in the history of medicine. In modern times it has prevailed at different epochs, especially in Ireland, Scotland, and England. It prevailed as an epidemic in Upper Silesia, a province of Prussia, in 1847, and among the troops in the Crimea during the war of France and England with Russia. In 1863 it again appeared in Russia, and in 1865 there was a great epidemic in St. Petersburg. Since this date there have been several epidemics of relapsing fever in Russia and in North Germany, particularly its eastern part. Among the different names heretofore applied to the disease are the following: *Febris recurrens*, *typhus recurrens*, *spirillum fever*, "five-day fever," "seven-day fever," "short fever," "mild yellow fever," "famine fever," "hunger-pest." The name *relapsing fever* is based on one of the most striking of the peculiarities of the disease, and involves no hypothesis; it is therefore to be preferred to any of the other

appellations. The disease described by Griesinger as bilious typhoid fever is a severe form of relapsing fever.

ANATOMICAL CHARACTERS.—The lesions are those of an acute infectious disease. The *spleen* is enlarged, of a dark-red color, and of soft consistence. The enlargement is in many cases extreme, and resembles that which occurs in typhoid fever. In a few instances rupture of the spleen has taken place. Infarctions in this organ are not rare. Abscesses also occur, but they are less frequent. The Malpighian follicles are indistinct, although often swollen. They are sometimes the seat of small abscesses and of necrotic softening. The enlargement of the spleen is due to congestion and hyperplasia of its lymphoid elements. The *liver* is also enlarged, and of a reddish-gray or yellowish-brown color. It is the seat of parenchymatous and often of fatty degeneration. The *kidneys* are swollen, especially the cortex, and often present a number of small hemorrhages. The epithelial cells of the cortical tubes undergo granulo-fatty degeneration. Ponfick observed lymphoid cells in the interstitial tissue. These are the changes of an acute diffuse nephritis. They are not present in all cases, but they are not rare. There is usually a moderate degree of inflammation of the *intestinal tract*, the mucous membrane being congested, swollen, and coated with mucus. The solitary follicles are somewhat enlarged. Ponfick attributes the icterus often present in relapsing fever to gastro-duodenitis. *Ecchymoses* are often met with in the stomach. Subpleural and pericardial ecchymoses are not uncommon. Small hemorrhages have also been found in the brain. Petechiæ of the skin are present in about 10 per cent. of the cases. The striated *muscular substance* is the seat of parenchymatous and of hyaline degeneration, as in typhoid fever. The degeneration is frequent, and of especial importance in the muscular substance of the *heart*. The myocardium may be affected with a fatty degeneration almost as intense as that in phosphorus-poisoning. This degeneration may be the immediate cause of death. Ponfick observed in some cases changes in the *marrow of the bones*. These changes were partly diffuse and partly circumscribed. The diffuse changes consist in the appearance of large cells filled with fatty granules, especially in the course of the small arteries, and in an increase in the number of lymphoid elements. Another alteration of the marrow occasionally found is the presence of circumscribed foci of necrotic softening. The *blood* is dark in color and fluid or imperfectly coagulated. When examined during life the number of white corpuscles is often found notably increased (1 white to 50–20 red).

In 1873, Obermeier in Berlin discovered a spiral-shaped bacterium in the blood of relapsing-fever patients. This parasitic organism is called the *spirochæte Obermeieri*, or the spirochæte of relapsing fever. It belongs to the group called spiro-bacteria. This parasite has been found in the blood in no other disease.¹ The spirochætæ are sometimes, but not usually, found in the blood after death, and if found, they are observed to be motionless. These spiral organisms are extremely delicate, and are readily seen only with the high powers of the microscope. The diameter of a spirochæte is about that of the finest fibrils of fibrin. Its length varies between ten and forty micro-millimetres, or from one and a half to six times the diameter of a red blood-corpuscle. In a drop of blood drawn during life the spirochætæ are in rapid motion, which resembles somewhat that of the spermatozoa. The parasite has been found only in the blood, and not in the other fluids or in the organs of the body. It differs from most bacteria in the readiness with which it is

¹ The spirochæte Obermeieri resembles the *Spirochæte plicatilis* discovered by Cohn in mucus from the mouth, and a spirochæte previously discovered by Ehrenberg in water. Similar spiral-shaped bacteria have been found elsewhere.

destroyed by the action of various reagents. It is found almost invariably during the febrile paroxysms, and disappears during the intermission. It is occasionally found during the intermission, especially for a few hours after the crisis and for a few hours preceding the relapse. We are ignorant as to the life-history of this organism. Attempts to cultivate it artificially have failed. We do not know how it gains access to the body, or in what relation it stands to the phenomena of the disease. It is held by many writers that the spirochæte develops from spores which are present in the body during the intermissions.

CLINICAL HISTORY.—Under this head I shall state succinctly the symptomatic features which are characteristic of this fever. These relate to two or more successive paroxysms of fever separated by an apyrexial period or intermission. The recurrence of the paroxysm of fever, or the relapse, is the distinctive feature whence the name of the disease derives its significance.

Abruptness of invasion characterizes the disease. The attack is sudden. There is no prodromic period. The seizure is almost always marked by a well-pronounced chill which is immediately followed by febrile movement. Usually, the patient at once takes to the bed; but in some cases one, two, or three days pass before there is this evidence of yielding to the disease. Moderate perspiration occurs shortly after the fever begins in a considerable proportion of cases. The perspiration in some cases is abundant, and it may recur repeatedly during the continuance of the febrile paroxysm.

The fever attains quickly either considerable or great intensity, as denoted by the pulse and axillary temperature. Thus, of two cases in which the disease was developed in Bellevue Hospital, in one the pulse on the first day was 120 and the temperature 103° ; in the other case the pulse on the first day was 130 and the temperature was 103° . During the continuance of the first paroxysm the pulse and temperature generally denote a persistent intensity of fever, the pulse ranging in different cases between 100 and 140 and the temperature between 100° and 105° . The oscillations are rarely great, and those which are observed are irregular in their occurrence.

The cessation of the fever is as abrupt as its invasion. The pulse and temperature quickly fall to nearly or quite the normal standard. The transition from high fever to complete apyrexia takes place often in a few hours; and usually this is accompanied by profuse perspiration, which continues for several hours, and even an entire day. Not infrequently the pulse and temperature fall below the standard of health. I have observed the pulse to fall as low as 54 and the temperature as low as 95° . In a day or two both the pulse and temperature rise again to the normal standard. Symptoms of collapse sometimes occur soon after the fall of temperature. They are usually of short duration.

The duration of the primary paroxysm in the majority of cases is between five and seven days. Exceptionally, it is only two days, and it may be fourteen days.

During the apyrexial period or intermission the absence of fever is complete. It is incorrect to call this period a remission. The fever does not remit, but it intermits. The average duration of this period is about seven days, but it may not exceed two or three days, and it may extend to twelve days or even more.

The relapse, like the primary attack, is sudden. It is generally ushered in by chilly sensations, but not so constantly by a well-pronounced chill as in the case of the first paroxysm. The fever in the relapse quickly becomes more or less intense. The intensity may exceed that of the first paroxysm, but in the

majority of cases it is less. The relapse also ends suddenly, and in most cases with profuse perspiration.

The duration of the relapse varies between three and five days. It is sometimes, however, only twenty-four hours, and it may extend to ten days.

It is to be borne in mind that the relapse does not always take place. On the other hand, a second, a third, and even a fourth and a fifth relapse have been observed. In some epidemics there have been two relapses in the majority of cases. In others a second relapse has been the exception. The duration of the second intermission is eight or nine days, and that of the third paroxysm about three days. The duration of the disease averages about twenty-five days, but is longer if more than two febrile paroxysms occur. In none of the cases which I have seen has there been more than a single relapse.

The foregoing points are those most highly distinctive of relapsing fever. It remains to notice other points belonging to the clinical history which are more or less characteristic.

Of symptoms referable to the digestive system, nausea and vomiting occur sufficiently often to be somewhat distinctive, especially when this disease is contrasted with typhus and typhoid fever. Not infrequently, these symptoms are prominent and persistent during the febrile paroxysms. The matter vomited is green or yellow from the presence of bile. The tongue is generally coated, and in most cases it is moist. This moisture of the tongue in connection with high fever is somewhat distinctive of this disease. The tongue may, however, become dry and fissured. Herpes labialis sometimes occurs. Vomiting of blood presenting the character of "black vomit" has been observed, but it is a very rare symptom. It is generally associated with hemorrhage in other situations, and it is to be considered as an accidental event, not as an element of the disease. Epistaxis is a more frequent form of hemorrhage, and is observed especially during a crisis. In some epidemics a moderate diarrhoea has been the rule, and in others constipation. There is nothing characteristic as regards the condition of the bowels. Meteorism in a moderate degree is not uncommon. Tenderness on pressure over the epigastric region is frequent. Slight tenderness in the iliac region is not uncommon. Notable tenderness exists in most cases over the liver and spleen, and enlargement of these organs is determinable by palpation and percussion. I have not observed a craving for food during the paroxysms, which, according to some writers, is distinctive of this form of fever. The appetite, however, returns during the intermission, and the digestion may be active in this stage.

The occurrence of jaundice may be mentioned in this connection. A dirty, yellowish color of the skin is present in most cases, and to it has been assigned some diagnostic value. True jaundice occurs in a small proportion of cases, but its infrequency in the other continued fevers renders it somewhat distinctive of relapsing fever. It is doubtful if the statement that this event is an element of gravity be correct. The event is much more frequent in some epidemics than in others. The name "mild yellow fever" derives whatever pertinency it has from the occurrence of jaundice sometimes in a considerable proportion of cases, and also from the occasional occurrence of black vomit.

A symptom referable to the nervous and the muscular system is highly characteristic of the disease under consideration. I refer to arthritic and muscular pains, especially the latter. During the first paroxysm pains in the loins, the calves of the legs, and the muscles in other situations are generally much complained of. They are never wanting, although, as regards intensity, they differ considerably in different cases. The muscular pains do

not cease with the ending of the paroxysm, but they continue during the intermission; they are more or less prominent during the relapse, and they often persist into convalescence. The muscles, especially those of the calf, are sensitive to pressure. The pains are sometimes referred to the bones. Ponfick thinks that this may be explained by the changes in the marrow which he observed.

The mental condition perhaps, in a measure, accounts for the suffering from these pains. The perceptions are not blunted in this disease, as they are in typhus and typhoid fever. This is a negative point of distinction in contrast with the fevers just named. Another negative point is the absence of the delirium which characterizes typhus and typhoid fever. Delirium is by no means absent in all cases of relapsing fever; but the delirium is such as may occur whenever there is high febrile movement, whether the fever be essential or symptomatic, and it is generally manifested only at night. In the daytime the mental faculties are generally intact. The condition known as coma-vigil does not belong to the clinical history of relapsing fever. This statement is also true of subsultus, carphologia, and other ataxic symptoms which occur in grave cases of typhus and typhoid fever. Deafness is also a rare symptom in relapsing fever.

A distinctive point, in comparison with typhus and typhoid fever, is the absence of a characteristic eruption. In most cases there is no eruption. Sudamina or miliary vesicles are sometimes observed at the time when profuse perspiration occurs, but this eruption is incident to various affections. The same is true of petechial spots which occur in some cases of relapsing fever. Other kinds of eruption are sometimes accidentally associated. Even the rose papules of typhoid fever sometimes occur in this as they do in various other diseases.

The physiognomy presents nothing distinctive. The face is more or less flushed, as in cases of symptomatic fever. There is not that degree of capillary congestion, marked especially on the cheeks, which exists in typhoid fever, or the dingy complexion which characterizes typhus. The expression of indifference, vacuity, or stupidity which is a notable characteristic of the fevers just named is rarely observed in relapsing fever.

The urine during the paroxysms is usually concentrated, dark in color, and rich in urates. In some epidemics albuminuria has been a not uncommon symptom. Blood-corpuscles and hyaline casts have also been found, but in the majority of cases neither albumen nor casts are present. Great diminution, and even suppression, of the urine, however, are sometimes observed, uræmic coma and convulsions taking place, but these cases are exceedingly rare.

It may be stated, as a point somewhat distinctive of relapsing fever, that there is very little liability to serious complications. In this fact we have an explanation, in part at least, of the very small rate of fatality from the disease.

What has just been stated with respect to complications holds true as regards sequels. As a rule, important sequels do not occur. The most frequent are ocular affections, particularly iritis and irido-choroiditis. Otitis media has also been repeatedly observed, although less frequently. Other complications or sequels of some clinical importance are parotiditis, laryngitis, dysentery, pneumonia, and acute diffuse nephritis. Relapsing fever, when it attacks pregnant women, always leads to miscarriage or abortion. The mother almost invariably recovers, but the child, no matter how near may be the end of gestation, as a rule is either stillborn or dies shortly after birth. The spirœchæ have been found in the blood of the fœtus.

DIAGNOSIS.—The diagnosis of relapsing fever is made certain by the discovery of the characteristic spirochætæ in the blood during a paroxysm of the disease. The cases in which competent observers have failed to find the organisms after searching for them are so very few that they may be left out of consideration. Other distinctive features of relapsing fever are such as to leave hardly any room for doubt concerning the diagnosis after the disease has ended. The distinctive characters are—the abruptness of the invasion, the rapid increment of fever, the frequent occurrence of moisture on the skin or perspiration more or less abundant without any marked abatement of the fever, the prominence of muscular and arthritic pains, and in certain cases the occurrence of jaundice. These are the positive points which are diagnostic. The fevers to be excluded are the eruptive fevers, febricula, remittent fever, and typhus and typhoid fever. Scarlet fever and measles are readily excluded by the absence of the eruption and of the characters which are distinctive of these fevers during the period of invasion. Small-pox is excluded after the third day by the continuance of fever and the absence of the eruption. It is not always practicable to decide at once that the disease is not a febricula, but the intensity of the fever and the notable muscular pains do not belong to the latter. Doubt, however, is soon removed by the persistence of the fever. Typhoid fever is excluded by the absence of a prolonged access and of the abdominal symptoms before sufficient time has elapsed for the appearance of the eruption, and by absence of the characteristic mental condition. Typhus is excluded by the absence of the eruption, which appears earlier than in typhoid fever, of the dusky complexion, and of the mental condition—the latter also being apparent earlier than in typhoid fever. Remittent fever is excluded by the absence of remissions, these being determinable by a notable diminution of the axillary temperature in some cases in which they are not distinctly denoted by the pulse. Of course the prevalence of relapsing fever is taken into account in arriving at the diagnosis.

CAUSATION.—Relapsing fever is undoubtedly a communicable disease. This statement rests on facts derived from the different sources of evidence, exclusive of inoculation, which establish the contagiousness of other diseases; as, for example, typhus fever. Of those who are attacked during the prevalence of the disease, a large proportion are known to have been brought into contact with, or close proximity to, patients affected with it. The disease is diffused in hospitals among fellow-patients and those who have charge of the sick. During the period in which cases were received in Bellevue Hospital after the disease began to prevail in this city—namely, between November 14, 1869, and February 6, 1870—twelve persons contracted the fever in the hospital. These twelve persons were especially brought into contact with patients affected with the disease, and in no instance did it attack one who had not been thus exposed. One of the senior assistant physicians residing in the hospital had the disease. The orderly in one of my wards contracted it, and his wife, who came to nurse him, was attacked by it. The disease has often been diffused after the importation of a case in localities in which it did not previously exist.

Facts, however, go to show that it is not a highly contagious disease. Considerable exposure is generally necessary. The area of the infection appears to be limited, and it remains to be ascertained whether it may be transported by fomites. Some facts cited by Murchison render it probable that it may be diffused in this way. It is especially communicable when the miasm is derived from a number of patients in the wards of a hospital or in close apartments. The disease is not likely to be contracted from single patients

in well-ventilated rooms. The investigations of the Metropolitan Board of Health in New York during the prevalence of the disease showed that it is diffused chiefly among those living in overcrowded, ill-ventilated tenement-houses. Of the propriety and importance of removing these patients to hospitals or wards devoted specially to cases of this disease there can be no doubt.

Destitution, deprivations, and especially deficient alimentation, are powerful auxiliary causes. Of this fact the past history of the disease at different times and places furnishes abundant evidence. The significance of the name "famine fever" and "hunger-pest" relates to this fact. Statistics do not show any notable etiological influence pertaining to age, sex, or season.

Although its diffusion involves generally, and perhaps always, a contagious principle, the history of the disease in other countries shows that it occurs as an epidemic, and after continuing for a certain time it disappears completely. Thus, in the city of London for the fourteen years preceding the winter of 1868-69 there had been no cases of the disease. The complete disappearance of the disease for so long a period tends to show the necessity of co-operating causes in conjunction with the special poison on which the production of the disease depends. The effective means for arresting the spread of the disease are—thinning the population of overcrowded tenement-houses, dispersing the occupants of insalubrious dwellings, relieving destitution, especially as regards food, and promptly removing patients to hospitals devoted to cases of relapsing fever. An attack of this disease does not secure exemption from subsequent attacks. The period of incubation in more than one-half of the cases in which it is determinable does not exceed five days. It rarely exceeds nine days. Occasionally, as in typhoid and typhus fever, the symptoms begin almost immediately after the exposure.¹

That the spiral bacteria discovered by Obermeier in the blood during a paroxysm of relapsing fever have an essential pathological connection with the disease is universally admitted. That they or their spores constitute the contagium, and that the phenomena of the disease are due to their presence in the blood, are conclusions vastly more probable than that either are effects of the fever or accidentally associated with it. That the agent of infection is contained in the blood does not admit of doubt. Motschutkoffsky has produced relapsing fever in human beings by inoculating them with blood taken during a paroxysm from a patient affected with the disease. Koch and Carter have produced the disease in monkeys by inoculating them with blood from a case of relapsing fever. Other animals do not appear to be susceptible to the disease. Blood taken during a paroxysm only is capable of producing the disease. Nothing is known of the life-history of the spirochæte of relapsing fever. It has not hitherto been possible to cultivate it artificially. It is more probable, for various reasons, that the spores of the spirochæte are the usual agents of contagion than that the spirochæte itself is the contagium. Nothing is positively known, however, concerning these spores, although it has been suspected that small round glistening bodies frequently found in the blood of relapsing-fever patients are such spores.

In accordance with the germ theory, the first paroxysm of relapsing fever is due to a brood of spirochætae. Their existence terminates in about a week, as a rule, and the first febrile paroxysm then ends. In a small proportion of cases the conditions required for the production of a second brood of these organisms are wanting, and the disease then consists of a single paroxysm of fever. In the great majority of cases, however, these conditions are not wanting; hence the germs remaining in the body give rise to a second brood, and there is the relapse of the fever. In rare instances a third and a fourth brood are produced, but in most persons the conditions therefor are extinguished after

¹ Vide Murchison, *St. Thomas's Hospital Reports*, vol. ii.

a second paroxysm of fever. The conditions, however, are never permanently extinguished, as in cases of typhus and typhoid fever, yellow fever, small-pox, and the other eruptive fevers, for after a certain period they who have had relapsing fever are again susceptible to the contagium. The extinction of the conditions for the development and reproduction of the spirochætae within the body is only temporary.

The contagium is probably contained in the breath and cutaneous exhalations. There are no facts tending to show that the intestinal dejections have any part in the diffusion of the disease.

PROGNOSIS.—It is, at first view, remarkable that a fever of such intensity, and prevailing especially among a class of persons whose powers of tolerance are impaired by previous hardships and want, should have such a small rate of mortality. The mortality in different collections of cases varies between 2 and 11 per cent. Dr. Moore, in his statistical report, states that of 103 cases admitted into Bellevue Hospital between November 14, 1869, and February 6, 1870, only 2 proved fatal. In some epidemics the mortality has been as high as 10 or 11 per cent., but as a rule it has not exceeded 2 to 4 per cent. In epidemics with the higher rates of mortality the complications have been many and the disease has presented the so-called bilious type. What is the explanation of the low rate of mortality? An explanation which perhaps is sufficient to account for the fact has been already given—namely, the disease is very rarely accompanied by any serious complications. The comparatively greater fatality of typhus and typhoid fever is due mainly to complications. These fevers rarely kill *per se*; that is, death is not purely an effect of the intensity of the disease.

Of the fatal cases of relapsing fever, the death in a certain proportion is attributable either to complications, such as pneumonia and dysentery, or to antecedent affections—as, for example, disease of the kidneys and chronic alcoholism—but this fever may destroy life irrespective of any important complications or antecedent affection. Several observers have reported cases in which sudden death occurred apparently from syncope. Dr. Moore's report exemplified this fact. The death in one case was sudden and unexpected during the night on the seventh day of the disease. At the time of death the primary paroxysm seemed about to end, free perspiration having taken place. Neither coma nor convulsions occurred, and, so far as information could be obtained, the dying was by syncope. The fatty degeneration of the heart explains, in many cases at least, death by syncope.

Suppression of urine followed by uræmic coma and convulsions is sometimes a cause of death. This fact was exemplified by one of the two fatal cases occurring in Bellevue Hospital. These symptoms are due to acute diffuse nephritis, which is one of the recognized complications of relapsing fever.

TREATMENT.—There are no known means which can be relied upon for cutting short this disease. With our present knowledge there are no remedies which, employed in the intermission, will prevent the relapse. Quinia has been used freely, but with no success. Its inutility as a prophylactic has been abundantly shown by different observers. It has been recently claimed that calomel exerts a favorable influence upon the progress of the disease. The treatment, with our present knowledge, must be expectant, meaning by this term that it is to consist of palliative measures and those addressed to the particular indications in individual cases.

The intensity of the fever during the paroxysms may be lessened by sponging the body with water and by the wet sheet. Cold water may be taken into

the stomach freely. Ice-cold carbonic-acid water is an acceptable and useful drink to allay thirst. Cephalalgia may be relieved by cold applications to the head. The bowels should be kept open by saline laxatives. The muscular and arthritic pains call for the use of opium, especially if it produce no unpleasant after-effects. Irrespective of the pains, opiates are indicated to relieve sleeplessness.

The dietetic treatment is important, especially in the cases in which deficient alimentation has been an auxiliary cause of the disease. In this fever, as in other fevers when alimentary support is indicated, milk is the form of diet to be preferred; and it is to be borne in mind that in this, as in most diseases, there is never any danger of the over-appropriation of nutriment, the only risk being in the ingestion of more food than can be digested. It is desirable that during the paroxysms one or two quarts of milk should be taken daily. In the intermission, when the appetite returns, as much substantial food as can be digested should be allowed; and the more food is appropriated in this stage the better is the patient enabled to tolerate the relapse. Tonic remedies are indicated throughout the disease, especially in the intermission. Quinia in small doses and some preparation of iron are the tonics to be preferred.

If the symptoms denote asthenia, alcoholics are indicated. The occasional occurrence of death from syncope renders it important to watch carefully for this indication. When there is room for supposing that alcoholics may be useful they should be given tentatively, and continued or not according to the effect, especially on the pulse and temperature. They are of course urgently indicated if the symptoms denote danger in the direction of asthenia.

Attention to the urine is important. It is to be remembered that a cause of death is suppression of urine. If the urinary excretion be deficient in quantity, or if, the quantity being sufficient, there be a deficiency of urea, diuretics are indicated. If the kidneys do not respond to diuretics, hydragogue cathartics are indicated, with a view to eliminate urea through the alimentary canal. Active hydragogues are of course indicated if uræmic coma or convulsions supervene.

It is stated that convalescence from relapsing fever is notably slow, patients remaining for a long time much enfeebled, and tolerating with difficulty affections which may occur before the recovery is complete. This has not been a marked peculiarity in the cases which have come under my observation. It is doubtless more likely to be marked in the cases in which there has been impairment of the vital powers from innutrition and hardships before the fever was contracted; and also it is more likely to be marked when abundant alimentation and the judicious use of alcohol have not entered into the treatment of the disease.

Erysipelatous Fever.

Erysipelas, considered as a local affection, belongs to surgery rather than to medicine. For an account of this form of inflammation, therefore, the reader is referred to surgical works. It occurs as an occasional complication of the continued fevers which have been considered. A form of continued fever distinct from the fevers which have been considered is characterized by the frequent occurrence of erysipelas, and hence it is called *erysipelatous fever*. As a distinct form or species of fever this is to be distinguished from erysipelas occurring as a local affection and accompanied with more or less febrile movement. The fever in the latter is symptomatic, whereas in erysipelatous fever it is primary or essential. On the other hand, erysipelatous fever is to be

distinguished from typhus, typhoid, and relapsing fever with erysipelas as a complication.

Erysipelatous fever occurs as a sporadic and as an epidemic disease. As a sporadic disease it is rare, and has not been as yet sufficiently studied by means of the analysis of recorded cases. The invasion is either abrupt or there is a forming stage of variable duration. The erysipelas may be developed within a few hours from the attack or after the lapse of one, two, or three days. The head is oftenest the seat of the erysipelas, but it may be developed in any part of the body. Different parts may be successively invaded. I have known it to extend over the whole surface of the body. The febrile movement is more or less intense. Passive delirium and other ataxic symptoms are not infrequently developed; in other words, the typhoid state exists. The abdominal symptoms of typhoid fever are wanting, and the career of the disease is shorter than that of typhoid fever. The symptoms are modified, and the disease, as regards duration and danger, is affected materially by the degree of intensity, the extent, and the local results of the erysipelas. The general principles of treatment are the same as in other of the continued fevers. In the existing state of our knowledge of this fever I shall pass it by with this brief notice. It is sometimes classed among the eruptive fevers, but the erysipelas is hardly to be considered as a cutaneous eruption.

Epidemic erysipelatous fever I shall also notice very briefly. It prevailed extensively in this country between 1841 and 1846. It was not confined to a particular section, but prevailed in certain districts in the New England, Middle, Western, and Southern States. In some localities great numbers were affected and the mortality was large. It was commonly known in certain parts of the country as the "black tongue," from an appearance of the tongue occasionally observed. The medical journals of this country during the years just named and afterward contained many articles relating to the prevalence of the disease in different localities. Of these, an article by Drs. Hall and Dexter, giving an account of the disease as it prevailed in Vermont,¹ and a paper by the late Dr. Bennett of Bridgeport, Conn., are especially deserving of notice. The latter gives an analysis of various articles contained in different medical journals.²

The epidemic prevailed in isolated sections. It did not appear to migrate or to be transported from place to place. Its course was "irregular and erratic." Dr. Bennett, however, states that it sometimes appeared to follow the direction of rivers, small streams, and lakes. The attack was sometimes sudden and sometimes preceded by premonitions, the latter rarely existing longer than twenty-four hours, and being the same as those belonging to the access of other fevers. A pronounced and frequently a prolonged chill, with or without rigor, ushered in the disease, accompanied often by pains in the extremities and in some cases by great prostration. Pharyngitis was at once or speedily developed; and this local affection was constant. It varied much in intensity in different cases. Not infrequently it was attended with great swelling of the tonsils, and sometimes sloughing occurred. The inflammation sometimes involved the larynx, and in a certain proportion of cases death was due to either laryngitis or œdema of the glottis. The lymphatic glands of the neck became more or less swollen, the swelling in some cases being very great, and occasionally suppuration taking place.

Erysipelas was far from being constant. The frequency of its occurrence varied at different times and places. Dr. Bennett observed it in only one-sixth of one hundred and fifty cases. In view of the fact that erysipelas

¹ Vide *American Journal of the Medical Sciences*, January, 1844.

² Vide *New York Journal of Medicine*, July, 1853.

occurs in only a certain proportion of cases, the propriety of calling the disease erysipelatous fever rests upon the absence of any other and better name. The erysipelas was seated in different parts. It frequently led to suppuration, gangrene, and sloughing. The danger and protracted character of the disease depended on the degree, extent, and local results of the erysipelas.

The febrile movement was more or less intense. Erratic pains, like those of neuralgia and muscular rheumatism, were common during the course of the disease. Typhoid delirium and other ataxic symptoms occurred in severe cases. Petechiæ were sometimes observed. Abscesses without erysipelas occurred in some cases. The disease was not infrequently complicated with inflammation of serous membranes, as the pleura, peritoneum, and the cerebral meninges. Pneumonitis was an occasional complication.

Different cases differed much as regards the gravity of the disease. In many cases the disease was mild and ended in five or six days. The severity and danger were generally due to the complications. Of the cases complicated with laryngitis or œdema of the glottis, extensive erysipelas, serous inflammations, or pneumonitis, a large proportion ended fatally, the duration being very prolonged.

Puerperal peritonitis prevailed in conjunction with this epidemic so uniformly as to show a pathological relationship between these two affections. The opinion was generally held that the peritonitis was caused by a virus or miasm carried by the obstetrician from patients affected with the epidemic disease. Assuming this to be true in certain cases, puerperal peritonitis was by no means uniformly to be accounted for in this way. A rational explanation in many, if not in all, cases is that labor acted as an exciting cause and determined the situation of the local affection in those predisposed to the disease from the action of the epidemic influence. Many, if not most, practitioners held that the disease was communicable. Its contagiousness, however, cannot be considered as established.

As regards TREATMENT there was a diversity of opinion. Some practitioners advocated bleeding and other of the measures called antiphlogistic; but the majority, before the epidemic ceased to prevail, were convinced of the impropriety of these measures. In view of the symptoms, the nature of the disease, the tendency to suppuration and gangrene in the cases in which erysipelas existed, and the other complications which were liable to occur, there can hardly be a question as to the propriety of measures of an opposite character. Tonic remedies, alimentation, and alcoholic stimulants—in other words, supporting measures of treatment—were indicated. Mild cases required little or no treatment, but in grave cases were applicable the principles which should govern the management of other essential fevers with serious local complications.

Epidemic Fever characterized by Pharyngitis.

In the winter and spring of 1857 an epidemic fever prevailed in the western part of the State of New York, in the adjacent parts of Pennsylvania, and in Canada, characterized by inflammation of the pharynx of a mild grade of intensity, and unaccompanied by either diphtheritic exudation or much submucous infiltration. I reported the results of an analysis of 23 cases which I observed and recorded. A report of this epidemic, based upon notes of 37 cases, was at the same time made by Prof. Rochester.¹ The different cases presented great uniformity as regarded the general and local symptoms. The fever was ushered in with a chill without rigor. The febrile movement

¹ For both reports, vide *Buffalo Med. Journal*, 1857.

in all the cases was considerable or marked. The severity of the disease was generally sufficient to keep the patients in bed for several days. The lymphatic glands of the neck were in most cases moderately enlarged, but without suppuration. Soreness of the throat was not a prominent symptom, even when the pharyngitis was marked. There was in no case an eruption. Vomiting did not occur, and generally the bowels were constipated. There were no symptoms of importance referable to the pulmonary and nervous system. The duration of the fever was between three and six days. It affected persons of either sex and of all ages. The epidemic continued about two months, reaching its acme gradually and gradually declining. In no case under my observation did it prove fatal.

The disease was not scarlatina, as shown by its affecting persons who had had that disease, by the fact that scarlatina did not prevail at the time, by the absence of an eruption in all the cases, by the non-occurrence of dropsy as a sequel in any case, and the fact that middle-aged and aged persons were attacked as well as children and infants. There were no cases of epidemic pharyngitis with exudation or diphtheria in that part of the country. The fever resembled the mild cases of erysipelatous fever which occurred during the epidemic prevalence of that disease, but erysipelas was not developed in any case. The cases bore a close analogy to those of influenza, except that the local affection was seated in the pharynx, and not in the Schneiderian and bronchial mucous membrane.

Dr. Harvey E. Brown, Assistant Surgeon U. S. Army, kindly communicated to me an account of an epidemic similar to that just described which prevailed among the United States troops stationed at Hart's Island, Long Island Sound, in January and February, 1866.

Palliative measures of TREATMENT only were indicated.

CHAPTER IV.

PERIODICAL FEVERS.

Intermittent Fever: Anatomical Characters; Clinical History; Causation; Diagnosis; Prognosis; Treatment.—Pernicious Intermittent Fever.

THE periodical are distinguished from the continued fevers by the occurrence of febrile paroxysms or marked exacerbations in a regular order of succession, thereby exemplifying a law of periodicity. This distinction applies especially to the fevers called intermittent and remittent. Yellow fever is generally included among the periodical fevers, and it belongs perhaps more appropriately here than in any other nosological division. The intermittent and remittent fevers are often distinguished as *malarial fevers*. These fevers will be found to present many striking points of difference as contrasted with the fevers which have been considered in the preceding chapters. They differ not only in the events of the clinical history, but as regards the laws governing their causation, duration, complication, sequels, and the extent to which they are controllable by known remedies.

Intermittent Fever.

An intermittent fever is characterized by the occurrence of febrile paroxysms in regular succession and by the absence of febrile movement between the paroxysms. The intermission is the distinctive feature of this form of fever, as its name implies. Popularly, the disease is known as "fever and ague," "chill fever," "the shakes," and by names expressive of the locality in which it is produced, as "swamp fever," "Panama fever," "Chagres fever," etc. Although essentially the same disease, intermittent fever as ordinarily presented in practice is unattended with danger to life, but occasionally it is one of the most dangerous of maladies. I shall consider first simple or ordinary intermittent fever, and afterward the grave forms of the disease under the head of *Pernicious Intermittent Fever*.

ANATOMICAL CHARACTERS.—The essential anatomical lesion in all forms of malarial fever is the presence of dark pigment in the blood and in certain organs. A certain amount of this pigment is formed in simple intermittent fever. The quantity of this pigment and other malarial anatomical changes are so much greater in the more severe forms of malarial poisoning that the consideration of these changes will be referred to the article on Remittent Fever. The spleen is more or less enlarged in simple intermittent fever.

CLINICAL HISTORY.—The clinical history will embrace an account, *first*, of the paroxysm; and *second*, of the intermission.

In the majority of cases the attack is sudden. In a certain proportion of cases, however, there are premonitions for a variable period. The premonitions are not very distinctive of this disease, consisting of pain in the head, yawnings, indisposition to exertion, loss of appetite, and general malaise. Although not very definite, they sometimes suffice to lead patients who have been repeatedly affected with intermittent fever to anticipate an impending attack.

A paroxysm, when complete, consists of three distinct periods or stages—namely, the cold, the hot, and the sweating stage.

Cold Stage.—This stage presents first a feeling of chilliness, beginning in the loins and extending thence over the back and limbs. The chill is more or less intense, in some cases consisting of a slight creeping sensation of coldness with shiverings, being in other cases extremely severe. Muscular tremor, commonly known as rigor, may or may not accompany the chill. I have met with a single example of distinct rigor without a sensation of chilliness. During the chill bristling of the hairs over the body, or horripilation, and the appearance familiar as "goose-skin," are often observed. Notwithstanding the sensation of coldness which the patient experiences, and the feeling of coldness when the hand is placed on certain parts, the thermometer in the rectum shows an increase of the temperature of the body. The thermometer, however, applied to the extremities shows a decrease of temperature below that of health. The increase of the temperature of the body begins prior to the paroxysm. The sensation of coldness is sometimes limited to a part of the body, as the back or the extremities. During the rigor frequently the teeth chatter and the movements of the body and limbs are sufficient to shake with considerable violence the bed on which the patient lies.

During this stage the patient frequently sighs, the pulse, which is usually accelerated, is small and feeble, the countenance has an expression of anxiety, the prolabia and face are pale or frequently livid, and lividity is often marked at the roots of the nails. The general appearance is as if the person had been exposed to intense cold. The circulation is sometimes completely suspended

in the fingers, which are waxy in appearance, devoid of sensibility, and bleed less than usual if wounded. Other symptoms are—mental irritability, a sense of oppression referred to the præcordia, pain in the head and limbs, and palpitation.

The duration of this stage varies between a few moments and two hours or even longer. The average duration may be estimated at from a half to three-quarters of an hour. The transition to the next stage is sometimes abrupt, but is generally gradual. Flushings of heat are felt, the rigor ceases, the coldness, as it were, melts away, febrile movement is developed, and the cold stage is then ended.

The cold stage is not infrequently wanting, the paroxysm beginning with the hot stage. I have known a state of intense nervousness to take the place of the cold stage. Gastralgia or gastric irritability, denoted by pain or incessant vomiting, is a morbid condition which sometimes takes the place of this stage, as well as drowsiness or stupor and a condition resembling hysterical coma. Veritable coma is liable to occur in this stage in a form of the disease which will be noticed separately under the head of *Pernicious Intermittent Fever*. In young children convulsions are liable to occur in the cold stage.

Congestion of internal organs is necessarily involved in the cold stage, inasmuch as there is less blood in the vessels of the surface and the whole mass of blood is not diminished; but the primary and essential morbid condition underlies the congestion, and it is probable that the latter is an effect of an active contraction or spasm of the peripheral vessels, the blood accumulating in the internal organs in consequence of its being driven from the surface of the body. That the congestion incident to this stage does not stand in a causative relation to the other stages is shown by the fact that the cold stage is sometimes wanting, and that the other stages in these cases are not less marked than when the cold stage occurs.

Hot Stage.—This stage is characterized by more or less intense pyrexia. The skin becomes hot, the pulse is accelerated and full or bounding, the face is flushed, the cephalalgia continues, but the pain in the limbs and the præcordial oppression disappear. The axillary temperature rises notably, usually reaching 105° or 106° F. Thirst is usually a prominent symptom. The intensity of the pyrexia varies considerably in different cases. The duration of this stage is between three and eight hours. It is evident that in this stage the spasm of the vessels of the periphery which existed in the cold stage has ceased, and that, on the contrary, the distributing vessels of the surface of the body are abundantly dilated.

Sweating Stage.—Perspiration appears first on the face, and afterward on the trunk and extremities. The pyrexia gradually abates, and at length disappears. The heat of the surface, cephalalgia, thirst, restlessness, etc. cease. The thermometer indicates a rapid defervescence, the heat falling to the normal standard. The patient obtains refreshing sleep. With this stage the paroxysm ends. As regards the amount of sweating cases differ, it being sometimes profuse and sometimes slight. The duration of the sweating stage is variable, the average duration being three or four hours. The sweating is evidence that the pyrexia is about to end. That it is the means of bringing the paroxysm to a close is by no means certain; it is a sign of the approaching intermission, and it may be an effect rather than a cause of the decrease of the pyrexia. During and succeeding the paroxysm, urea, uric acid, and the chlorides in the urine are increased. The urine is not infrequently albuminous, and occasionally there is hæmaturia.

The intermission, called also the apyrexial period, is the space of time between two successive paroxysms. The period from the beginning of one to the beginning of the next paroxysm is called the interval in distinction

from the intermission. The duration of the interval is the basis of a division into varieties commonly known as the different types of the disease. Each variety or type observes a law of periodicity in the succession of paroxysms. There are three simple types of intermittent fever—namely, the *quotidian*, the *tertian*, and the *quartan* type. In the *quotidian* type the interval is about twenty-four hours, or the paroxysm recurs daily, as the name imports. In the *tertian* type the interval is about forty-eight hours, or the paroxysm recurs on the third day, reckoning the days on which two successive paroxysms take place. In the *quartan* type the interval is about seventy-two hours, or the paroxysm recurs on the fourth day. As a rule, the paroxysms are uniform in each individual case as regards the occurrence of the cold stage, the duration of the several stages respectively, the severity of each, etc., but they present considerable diversity in different cases. Of the three simple types, the *quotidian* and *tertian* type are by far the most frequent. Examples of the *quartan* type are comparatively rare. Of 98,237 cases of intermittent fever in the United States army, only 1757 were of the *quartan* type.¹

As regards the relative frequency of *quotidian* and *tertian* cases, either variety may predominate at particular seasons. In the same locality the majority of cases are at one season of the *quotidian* and at another season of the *tertian* type. In an aggregate of cases occurring in a series of years the *quotidian* type predominates. Of 98,237 cases in the United States army, 51,623 cases were of *quotidian* and 44,857 cases of *tertian* type.² Cases have been observed in which the paroxysm has recurred on the fifth, sixth, seventh, and eighth day, and hence there may be a *quintan*, a *sextan*, a *heptan*, and an *octan* type of intermittent fever. Such cases, however, are among the rare curiosities of clinical experience. In some cases during the continuance of the disease the type changes, the *quotidian* succeeding the *tertian*, or *vice versa*; such cases, however, are rare.

Cases are observed occasionally in which one of the simple types is duplicated; that is, two sets of paroxysms of the same type coexist. Thus, one compound type is called a *double quotidian*, two paroxysms occurring daily. Another compound type is a *double tertian*. In a *double tertian* a paroxysm occurs daily, but the paroxysms on successive days take place at different hours, and may differ in various ways, whereas on alternate days they occur at the same hour and correspond in other respects. Again, a *tertian* is doubled or duplicated when two paroxysms occur on alternate days. Another compound type is a *double quartan*. In this type a paroxysm occurs on two successive days, and on the third day there is no paroxysm. Finally, a *triple quartan* is a compound type in which a paroxysm occurs on three successive days, the paroxysms on these days presenting notable points of difference, but each paroxysm corresponding with that which recurs on the fourth day. These compound types, except the *double tertian*, are extremely rare, and are interesting merely as curiosities of clinical experience. The *double tertian* is not very infrequent.

Paroxysms may occur at any hour of the day. They rarely occur during the night. In a large majority of the cases of the *quotidian* and *tertian* type the paroxysms occur before noon. *Quartans* are as likely to occur after as before the middle of the day. In infants the type is almost uniformly *quotidian*. As a rule, the successive paroxysms recur precisely or nearly at the same hour; but sometimes there is a variation from this rule, and the variation is in accordance with a certain law whenever the paroxysms are said to be either anticipating or retarding. They are anticipating when each successive paroxysm recurs earlier by the same period than the last. Thus, they may

¹ Vide Woodward, *Camp Diseases of the United States Army*, Philadelphia, 1863.

² *Ibid.*

regularly anticipate half an hour, an hour and a half, etc. The paroxysms are retarding when each successive paroxysm is in like manner delayed. This variation in time of recurrence is generally evidence that the disease is about to end.

During the intermission there is much difference in different cases as regards freedom from ailments. In some cases the patient complains only of a certain amount of debility; the appetite and digestion are good, and there is no apparent disorder of any of the functions. In other cases marked prostration follows, the appetite and digestion are more or less impaired, and various disturbances exist.

Probably more or less enlargement of the spleen occurs in all cases of malarial fever. The enlargement is often sufficient for the organ to be readily felt through the abdominal walls, constituting what is commonly known as the "ague cake" in districts where the disease prevails. The organ in some cases becomes enormously enlarged. A splenic tumor of large size is not very frequent. It occurs in some cases when the disease has been of short duration, and it is by no means developed in the majority of the cases in which the disease has existed for a long period. It may continue for a considerable period after the paroxysms cease.

Anæmia is incident to the disease, especially if it have been of considerable duration. The pallor of the face in cases in which the disease has been protracted or in which frequent relapses have taken place is often associated with a yellowish or sallow tint and with more or less œdema, giving rise to a characteristic facies. These characters denote what is called the *malarial cachexia*. General dropsy is an occasional concomitant or sequel. Notable anasarca with effusion into the serous cavities is sometimes incident to the disease, and does not, therefore, necessarily denote either a cardiac or a renal affection. An herpetic eruption about the mouth is a frequent concomitant.

The DURATION of the disease is indefinite. It not infrequently ends spontaneously after a few paroxysms, but in many cases it continues for weeks, and even months, if not arrested by curative means. Its indefiniteness of duration is a striking point of difference as contrasted with the continued fevers; and its self-limitation is not, as in the latter, restricted within a certain period. Another not less striking point of difference relates to the liability to relapses. Subsequent attacks occur in the great majority of cases. The liability to relapse remains for many years. In some cases successive attacks occur regularly after a certain period, showing that in these cases the relapses take place in accordance with an intrinsic tendency; that is, irrespective of external causes. The notion was formerly entertained that the tendency to relapse was lessened if the disease were left to end of its own accord or "wear itself out." So far from this being true, I believe that clinical experience shows a diminished tendency to relapse in proportion as the paroxysms are speedily interrupted by therapeutical interference. After the paroxysms have ceased to recur, either spontaneously or from the use of remedies, thermometric observations may show more or less increase of the heat of the body at the time when the paroxysm was to be expected. So long as these fluctuations of temperature exist the disease has not completely disappeared and relapses are liable to occur.

Physicians in malarial districts become familiar with cases which may be called cases of *latent intermittent fever*. In these cases paroxysms are not fully developed, but the patient complains of indefinite ailments, to which the term *bilious* is frequently applied. The appetite is impaired or lost; and there may be nausea and occasional vomiting, with pain in the head, indisposition to exertion, etc. The tongue is frequently covered with a thin and very white

coating. A close examination will sometimes disclose evidence of periodicity in an increase of ailments at regular periods on successive days or on alternate days, and slight manifestations of the several stages of a paroxysm may be observed. The thermometer in the axilla is useful as a means of diagnosis in these cases, showing a periodical rise of temperature when the surface of the body may not show increase of heat and the pulse is but little accelerated. In a case under observation at Bellevue Hospital at the time of writing the morning temperature in the axilla was 105° F., the pulse being only 80, and at evening the temperature was 100° . Under the free use of quinia the daily increase of temperature rapidly diminished, and in a short time ceased. The prompt relief afforded by treatment addressed to a suspected malarial condition shows the correctness of the suspicion; and this treatment may be resorted to tentatively in cases of doubt. The affection in these cases is sometimes called *dumb ague*. This term is also applied to paroxysms in which rigors are wanting.

Intermittent fever is said to be *masked* in certain cases in which it is associated with other affections. It may exist in combination with various affections, such as bronchitis, pneumonitis, dysentery, etc. The association may render the periodical disease irregular and interfere with the full development of the paroxysms. In these cases it is not correct to apply to the associated affections the term malarial, meaning thereby that these affections are due to malaria. They are simply accompanied by phenomena proceeding from a malarial disease existing in combination. In malarial districts the influence of malaria is liable to pervade all affections and it claims special measures of treatment. Of this fact practitioners in these districts become fully aware. Paroxysms of neuralgia sometimes appear to take the place of the paroxysms of intermittent fever, recurring with the same regularity after intervals corresponding to those in the different types of intermittent fever, and a cure is effected by the remedies which are efficacious in the latter disease.

CAUSATION.—The causation involves a special morbid agent commonly known as *malaria*. The existence of a special cause is logically inferred from the peculiar character of the disease, its limitation to certain localities called malarial, and the fact that it is controlled by remedies having a specific operation. The production of the special cause was attributed to vegetable decomposition in marshy localities and called *marsh miasm* in 1717 by Lancisi, an Italian writer. This doctrine and the name have since been very generally adopted; but that something more than ordinary vegetable decomposition is requisite for its production is sufficiently proven by the disease being indigenous in certain localities, whereas in certain districts and countries in which vegetable decomposition must take place abundantly the disease never occurs. Observation shows that it is produced especially in marshy localities, but its production is not confined to such situations, and hence the name marsh miasm is inappropriate. The production of the special cause requires a temperature above 60° F. In so-called malarial districts it is more abundantly produced when a dry follows a wet period. Turning up of the soil is often followed by an increase of its production. It often disappears after the cultivation of soil for several years, so that highly malarial districts may after a time become free from malaria. On the other hand, the area of a malarial district is sometimes greatly enlarged by a gradual extension. During the last twenty-five years the malarial district near the city of New York has extended far upward on the banks of the Hudson River, eastward into the State of Connecticut, and along the banks of the Connecticut River into Massachusetts, periodical fevers until lately not having been endemic in these situations for a long period.

The telluric source of malaria is proven by the fact of its being endemic in certain localities. Facts show that the morbid agent remains near the surface of the earth. Persons sleeping in an upper story may escape when those sleeping on a level with the ground become affected. It is more abundant in the night-air than during the day, and hence the disease may often be escaped by avoiding exposure in the evening, night, or early in the morning. The special cause of this disease is not eliminated from the bodies of those affected in such a manner that the causation ever involves a contagium. Facts abundantly prove that the disease is not communicable from one person to another. The malarial fevers therefore belong among those distinguished as purely miasmatic.

Various attempts have been made to discover parasitic organisms in the blood of persons affected with malarial fever. The so-called ague-plants or palmellæ, which Salisbury in a paper published in 1866 claimed to be the special cause of malarial fever, have at present only historical interest. The same may be said of the bacilli which Klebs and Tommasi-Crudeli found in the ground of malarial regions, and which they supposed to be the special cause of malaria. There is no proof whatever that either the palmellæ of Salisbury or the alleged bacillus malarix of Klebs and Tommasi-Crudeli are in any way concerned in the production of malaria. Bodies which were discovered in 1881 by Laveran in malarial blood, and which have been more carefully studied since 1883 by Marchiafava and Celli in Rome, deserve more serious consideration.¹ These bodies are found usually within red blood-corpuscles, but they may exist free in the blood. They vary in size, the average being about one-third the size of red blood-corpuscles, but many are smaller and others are larger than this. Many of the bodies contain black or dark-brown pigment-granules, and others are free from pigment. When unstained the bodies are clear and homogeneous in appearance (with the exception, possibly, of included pigment), and so delicate that they are not readily detected. The bodies can be stained with fuchsin, methylene-blue and some other aniline dyes. In stained specimens the shape of the bodies varies, some being round, others elongated, crescentic, and of various other, often very irregular, shapes. In a drop of fresh blood the bodies are endowed with the power of movement, changing their shape in a manner analogous to the amœboid movements of white blood-corpuscles, and even more rapidly. Exceptionally, movable thread-like filaments are attached to the bodies. The main point in favor of these bodies being living organisms is their property of amœboid movement. They have been found only in the blood of malarial patients, and chiefly during a paroxysm of malarial fever. They may be present in only a few red corpuscles or they may be abundant. Marchiafava and Celli claim to have produced typical intermittent fever by the injection into a vein of a person free from malarial history of malarial blood containing these bodies, and to have afterward found similar bodies in the blood of the individuals experimented upon.² They consider these bodies to be parasitic organisms which penetrate the red blood-corpuscles, which they partly or wholly destroy.

¹ Laveran, *Traité des Fièvres palustres*, Paris, 1884; Marchiafava and Celli, several articles in *Fortschritte d. Medicin* in 1883 and 1885. The latter authors call this supposed parasitic organism, *Plasmodium malarix*.

Councilman and Abbot in 1885 described the presence in malarial blood of small hyaline corpuscles, most of which contain pigment. These corpuscles are probably identical with those found by Marchiafava and Celli. (See Councilman and Abbot, *Am. Journ. of the Med. Sciences*, 1885.)

In the preceding edition of this book the presence of a hyaline envelope around malarial pigment-granules was mentioned.

² Gerhardt had previously produced intermittent fever by the injection into human beings of malarial blood.

and in which they elaborate the characteristic malarial pigment. If these bodies be parasitic organisms, they are entirely different from bacteria and resemble amœbæ. It is urged, as a point in favor of the view that the parasitic organism of malaria is an amœba-like organism rather than a bacterium, that quinine exerts a much more powerful influence in arresting the vitality of the amœba than that of the bacteria. Attempts to cultivate these bodies have failed. It has been urged, in opposition to the view that these bodies are parasitic organisms, that they may be the result of some degenerative or other metamorphosis in the red blood-corpuscles. The possibility of such a metamorphosis cannot be denied, but it would be without analogy in any known pathological changes.¹ Should Laveran's corpuscles prove to be parasitic organisms peculiar to malarial blood, the evidence for regarding them as the specific cause of the disease would of course be very strong.²

[Since the last edition of this work conclusive evidence has been adduced in favor of the view that these bodies are the cause of the malarial fevers and that their different forms are dependent upon the rate of development of the parasite. The organism may be described in general terms as a polymorphous hæmatozoon. It has been studied more particularly in this country by Councilman, Osler, and Dock.—H.]

The period of incubation is indefinite. It may be a few days only or a few weeks, but it is not infrequently many months, and perhaps years may elapse after the reception of malaria before its morbid effects are manifested. Auxiliary conditions often appear to be necessary to give efficiency to the special cause. An attack is liable to occur after exposure to cold, over-exertion, excesses in eating or drinking, etc. The activity of the special cause is also often awakened by the occurrence of some other affection. The disease occurs especially in the spring and autumn, probably in consequence of the action of auxiliary causes in these seasons. The vernal intermittents are in general milder than the autumnal.

The disease shows no preference for either sex and it affects all ages.

If the paroxysms be caused by the development and multiplication within the body of vegetable organisms, it is to be supposed that a crop sufficient to occasion an attack either dies or is eliminated when the paroxysm ends, and that from germs remaining in the system other successive crops are produced after definite periods of time corresponding to the different types of the disease. These different types seem to imply different varieties of the ague-producing organism.

DIAGNOSIS.—In well-marked cases the diagnosis offers no difficulty. The type is to be determined by the duration of the intervals and a comparison of the paroxysms. Latent and masked intermittents are not so easily recognized; and in arriving at a positive diagnosis the effect of treatment is sometimes to be considered. Febrile paroxysms resembling those of intermittent fever are sometimes observed in connection with pulmonary phthisis. They may present the three stages well marked, and recur at regular intervals. They oftener occur in the afternoon than in the forenoon, whereas the reverse obtains in intermittent fever. The coexistence of phthisis is to be taken into account in making this differential diagnosis, as well as the known exposure to malaria or otherwise. The treatment appropriate to intermittent fever will sometimes arrest the paroxysms connected with phthisis. Chills connected with suppuration in some of the internal organs may suggest as probable the action of malaria in malarial districts. The irregularity of their

¹ Unless such an analogy exist in the "Würmchen" found by Gaule in frog's blood.

² Laveran's corpuscles have been demonstrated in malarial blood in Algiers, in Italy, and in this country.

occurrence, the inefficacy of treatment specially directed to a malarial affection, and the discovery of the local affection will in time clear up the diagnosis. Happily, the remedies indicated in malarial diseases are rarely hurtful in the cases in which intermittent fever is incorrectly supposed to exist. Operations on the urinary passages, such as catheterism and lithotomy, sometimes produce paroxysms resembling those of intermittent fever.

PROGNOSIS.—Ordinary or simple intermittent fever as regards immediate danger is not a grave affection. Whenever the disease involves immediate danger, it is to be considered as pernicious, and not therefore belonging under the head of ordinary or simple intermittent fever. An important fact is that an intermittent fever at first devoid of immediate danger may become pernicious. An ordinary or simple intermittent may prove remotely serious, if it continue long or recur frequently, by inducing anæmia, general dropsy, or the malarial cachexia. The remote effects of the disease, however, are rarely in themselves fatal. Death may result from the association of intermittent fever with other affections. It has been supposed that this disease exerts a protective influence against the development of pulmonary tuberculosis. So far from this being true, there is reason to believe that it promotes the development of the affection just named in those predisposed to it. It is not a small calamity to contract intermittent fever, on account of the liability to relapse and to its recurrence in connection with other diseases.

TREATMENT.—For the cure of intermittent fever medicine possesses specifics if any remedies be entitled to this appellation. This statement applies especially to the salts of quinia, of which the sulphate and the bisulphate are almost universally used in this country. The salts of quinia will promptly interrupt the recurrence of the paroxysms of intermittent fever in the vast majority of cases. It is always desirable to arrest the disease as speedily as possible. Its morbid effects are less in proportion as it is quickly arrested and the liability to relapses is diminished. There is no need of preparatory treatment. This position was taken by the author in an article published more than forty years ago.¹ An experience embracing many hundred cases in different climates since the date of that publication has abundantly confirmed the correctness of this position. Aside from the delay in arresting the disease, the measures heretofore employed to prepare the system for quinia or other special remedies were injurious. These measures were mercurial cathartics, emetics, and sometimes bleeding. They are not indicated in the treatment of intermittent fever. A consideration of no small importance, as enforcing an immediate employment of the abortive treatment, is the possibility of an intermittent fever, at first simple or ordinary, becoming after several paroxysms pernicious.

With respect to the time of giving the antiperiodic remedy, my experience has led me to the conclusion at which Bretonneau, Graves, Briquet, Trousseau, Murchison, and others have arrived—namely, that it proves most effective when given as near as possible to the paroxysm which has passed. It is probable that if it be given in the sweating stage the chances of preventing the next paroxysm are greater than if the administration be delayed until after this stage. As regards doses, the most efficient plan is to give the

¹ Vide *American Journal of the Medical Sciences*, October, 1841. This article contains a series of observations on the employment of quinia in single doses of from twenty to forty grains. At that time this treatment was novel and bold. The author believes that he was the first in this country to make observations with respect to the treatment of intermittent fever by large, single doses of quinia without preparatory measures and given at different periods in the paroxysm.

remedy so as to produce evidence of cinchonism as speedily as possible. The object may be accomplished by giving at a single dose the quantity supposed to be required. This quantity for an adult is between ten and twenty grains. A dose of ten or twenty grains is generally tolerated by the stomach as well as smaller doses. An objection, however, to this method is that the quantity estimated as sufficient may not be large enough or it may be larger than is required. A preferable method, therefore, is to give the remedy in smaller but not in small doses, which are to be repeated at intervals of two or three hours until cinchonism is produced. The latter is indicated by tinnitus aurium; and this effect is in general evidence that a sufficient quantity has been administered. For an adult five grains may be given at a dose, and repeated after four hours once, twice, or thrice if necessary for the effect just stated. By this method of treatment in a case of quotidian type the chances that another paroxysm will or will not occur are about even. In a case of tertian type the chances that another will not occur predominate. If another paroxysm occur the same method of treatment is to be repeated.

As regards the form in which the sulphate of quinia may be administered, it is most efficient when given in solution, its solvency being secured by the addition of a minim of the aromatic sulphuric acid for each grain of the salt. Owing to its greater solubility if given in pills, powders, capsules, or wafers, the bisulphate is to be preferred to the sulphate. If, owing to the irritability of the stomach, the remedy be not retained when given by the mouth, it may be given *per enema*. It is readily absorbed from the intestine, and the opinion has been held by some that it acts more efficiently when thus given. According to most observers, however, the quantity when given by the rectum should be larger than when given by the mouth.

The plan of treatment just described is almost invariably successful. If it fail, there is always reason to suspect that the preparation of quinia employed is spurious or adulterated. A difficulty in some cases relates to an intolerance of the remedy. Some persons are affected very unpleasantly by even small doses of a salt of quinia. This intolerance is not infrequently imaginary, but it is sometimes real. In such cases small doses must be given or some one of the remedies to be presently mentioned should be substituted. As a rule, small doses are curative in the cases in which the remedy is tolerated only in small quantities. On the other hand, some persons are affected by the remedy only when full or even large doses are given; and as a rule such persons require larger doses than others. Cinchonism is evidence that the requisite quantity has been given, but this need not be produced except in a slight degree. The coexistence of another affection does not contraindicate the plan of treatment which has been described. In all cases in which intermittent fever is complicated with other affections, the primary object of treatment is to interrupt the paroxysm as speedily as possible. In children and infants the doses are to be less than in adults in proportion to the age. In young children, owing to the difficulty of administration by the mouth, the remedy may be given *per enema*. It may also be employed effectively by inunction, an ointment containing it being rubbed into the axilla and groins and over the abdomen. I have met with a few instances in which moderate doses of quinia have produced menorrhagia, occurring at a period when menstruation was not due.

The hypodermic injection may be resorted to in cases of ordinary intermittents when the remedy is not retained either by the stomach or rectum. This mode of administration has the advantage of economy as regards the quantity of the remedy required, experimental observation appearing to show that the effect is three or four times greater when thus administered than when taken

into the stomach. The effect is also more quickly induced. It is, however, in cases of pernicious intermittent that the hypodermic injection of a solution of quinia is of special value, by reason of the certainty and promptness with which cinchonism may be induced by this mode of administration. In simple intermittents the risk of abscesses at the places where the injections are given renders them unadvisable. Binz states that pure amorphous hydrochlorate of quinia is especially well adapted for subcutaneous injection, dissolving in an equal weight of water, this not giving rise to abscesses.

After the paroxysms are interrupted, the remedy should be continued in small doses, between four and eight grains daily, for a considerable period. It is desirable to continue it for several weeks. If anæmia exist a chalybeate should be conjoined. Relapses are prevented by this after-treatment. The diet should be nutritious, and a little wine with meals is advisable. Cathartics are to be avoided. Given before the interruption of the paroxysms, they conflict with that object. If there be constipation, it should be remedied by mild laxatives or enemas.

The germ theory affords a rational explanation of the specific efficacy of quinia in this disease. This drug is destructive to certain low organisms, and its efficacy is due to its action as a parasiticide. This statement will probably apply to other remedies which have a controlling influence over the disease.

Preparations of cinchona other than the sulphate of quinia are more or less effective in arresting intermittent fever. The sulphate of quinidia appears to possess an antiperiodic power not less than that of the sulphate of quinia. It has less bitterness and is more soluble. The sulphate of cinchonina and cinchonidia are much less effective. Amorphous quinia, called quinoidia, chinoidine, or the precipitated extract of bark, must be given in doses of double the size of the doses of sulphate of quinia.

There are several succedanea of the preparations of cinchona which are capable of arresting the disease. Salicin is successful in a certain proportion of cases. Between 40 and 60 grains are to be given in an intermission. The sulphate of bebeerine is frequently successful, and it has been claimed in behalf of this remedy that it does not produce the unpleasant effects which are sometimes caused by the preparations of cinchona. From 15 to 30 grains are to be given in the apyrexial period. The ferrocyanide of iron, or Prussian blue, I have found an efficient antiperiodic in doses of between 1 and 2 drachms. Patients take it with reluctance, its appearance suggesting the idea of poison. Strychnia and nux vomica often succeed. Chloride of sodium, given to the extent of 8 or 10 drachms in the apyrexia, effects a cure in a certain proportion of cases. Piperine sometimes proves curative. Many practitioners give this remedy in combination with the preparations of cinchona. Arsenic is probably, next to the preparations of cinchona, the most reliable remedy. Fowler's arsenical solution is the form generally employed, given in doses of 5 to 10 drops three times daily to an adult. The muriate of ammonia, in doses of 2 drachm in the intermission, appears to exert an antiperiodic power. Nitric acid in doses of 8 or 10 drops continued during the intermission and paroxysm, once in six hours, has been found to be efficacious. The iodide of potassium has proved successful in some cases when the disease has resisted quinia. To the foregoing are to be added the eucalyptus globulus and hydrastia. This list might be extended. It is to be borne in mind, in judging of the effect of remedies in this disease, that it tends intrinsically to end after a few paroxysms in a certain proportion of cases. All the known remedies which may be employed as succedanea of the preparations of cinchona are much inferior to the latter. None are to be preferred except in some cases in which from an idiosyncrasy the preparations of cinchona are not tolerated. They may sometimes come into play where the preparations of

cinchona cannot be procured, and they have the advantage of being less costly than the latter.

The administration of pilocarpine at or shortly before the beginning of the paroxysm has been found by Dr. Gaspar Griswold to prevent or arrest the paroxysm, and in many instances there is no recurrence.¹ The remedy acts with most certainty if administered hypodermically. The dose for hypodermic use is one-fifth of a grain of the muriate of pilocarpine dissolved in ten minims of distilled water. Given by the mouth, the dose is one-fourth of a grain. For feeble patients these doses should be somewhat reduced. This method of treatment has sometimes succeeded in effecting a cure when the disease had resisted other measures. The efficacy of this treatment establishes the fact that to prevent a paroxysm or to render it abortive may be sufficient for the cure. A full opiate at the beginning of the cold stage often appears to shorten and modify the severity of the paroxysm. It sometimes, indeed, acts as an abortive measure, and may even effect a cure of the disease. I have known a sinapism applied over the whole length of the spine at the beginning of the cold stage to arrest the paroxysm and effect a cure. This result has been obtained by dry cups applied to the spine and by friction with the spirits of turpentine. The method of McIntosh—namely, bleeding in the cold stage—was sometimes effectual, but for obvious reasons it is not to be recommended. A paroxysm appears to be sometimes warded off by taking to the bed before the hour when it is expected, and keeping up warmth of the body by bottles of hot water or other means. External warmth is useful in the cold stage, and stimulants may be given internally if tolerated by the stomach. The internal use of chloroform has been highly recommended. Given in drachm doses (either alone, followed immediately with cold water, or suspended in mucilage) at the beginning of the paroxysm, it has been found to arrest the chill and induce a refreshing sleep, from which the patient awakes without prostration. The duration and severity of the paroxysm appear to be lessened by this treatment.

During the hot stage relief is procured by sponging the body with cold or tepid water. Pieces of ice, ice-water, or carbonated water may be taken freely. During the sweating stage comfort is promoted by wiping the body with warm flannel and changing the linen and bedclothes.

Anæmia and general dropsy, occurring as sequels, claim tonic remedies, into which the preparations of cinchona and iron should enter, with nutritious diet and other hygienic measures calculated to restore the strength and invigorate the body. Enlargement of the spleen is to be treated with the sulphate of quinia or other preparations of cinchona, and a belladonna plaster or anodyne embrocations applied over the enlarged organ. If these measures fail, the iodide of potassium may be tried. Faradization and the cold douche applied to the region of the spleen have been found useful.

The preparations of cinchona and other antiperiodic remedies are efficacious as prophylactics. Taken in small doses daily by persons exposed to malaria, they ward off attacks of intermittent fever and they prevent relapses. There is no foundation for the popular notion that the prolonged use of the sulphate of quinia in small or moderate doses is prejudicial to health. I have known an instance in which two or three grains had been taken daily for twenty years, the person having found by experience that by this means he was exempt from relapses of intermittent fever. Other means of prophylaxis have been already stated in treating of the causation.

¹ Vide *N. Y. Med. Journal*, Aug., 1880.

Pernicious Intermittent Fever.

Simple or ordinary intermittent fever is not attended with immediate danger; but the disease is sometimes presented in forms more or less dangerous, and it may prove fatal within a few days or hours. These forms of the disease are to be considered apart from simple or ordinary intermittent fever, and collectively they constitute a variety of the disease called *pernicious, malignant, and congestive*. Of these names the first is commonly adopted by writers. The term *congestive*, although much used in the Southern and Western portions of this country, is objectionable, as implying that the primary or essential pathological state is congestion—a doctrine which probably is incorrect.

Pernicious intermittent fever occurs in isolated cases wherever the simple or ordinary variety of the disease prevails; but, happily, such cases are extremely rare. It, however, prevails at certain epochs in malarial regions. Of the cases of intermittent fever which occur at these epochs, the proportion in which the disease is pernicious is more or less large. In some seasons the fatality from the disease is very great, and it constitutes one of the most formidable of the maladies which the physician has to encounter. In this country it has prevailed chiefly in the Southern and Western States. In view of the great danger attendant on pernicious intermittent fever, and of the fact that the success of prompt and efficient treatment is perhaps more conspicuous in this than in any other malady involving an equal amount of danger, the disease is one of great importance. It will, however, suffice to notice the symptomatic features by which the different forms are distinguished from simple or ordinary intermittent fever, together with the therapeutical indications.

Different observers agree that in many, if not in most, cases a pernicious paroxysm is preceded by one or more paroxysms not characterized by any symptoms denoting gravity of disease; hence the vast importance, especially whenever cases of the pernicious variety are known to have occurred, of resorting in every case at once to prompt and efficient measures to interrupt the paroxysms. In a certain proportion of cases, however, the pernicious character of the disease is manifested in the first paroxysm, and death may take place in that paroxysm. Drake states that the pernicious character is sometimes foreshadowed by some slight anomaly in the first paroxysms, such as "a partial numbness or coldness of the great toes instead of a regular chill, or a disposition to sleep at the access of the paroxysm." According to this author, in the cases in which the pernicious character is gradually developed the cold stage in the early paroxysms is not strongly marked, the hot stage is imperfectly developed, and in the intermissions the patient may be pursuing his usual avocations. Both patient and physician are liable to be thrown off their guard by the mildness of the paroxysms preceding the one which is pernicious.

The symptomatic features of pernicious paroxysms vary much in different cases; and on account of these diversities this variety of the disease may be considered as embracing several forms. More or less complete coma characterizes some cases, and these cases are distinguished as *comatose, soporose, or apoplectic* intermittents. Other cases are characterized by delirium preceding coma. The delirium is sometimes active, the patients requiring to be restrained. Examples have fallen under my observation. Epileptiform convulsions occur in some cases. Intense jaundice appears early in the so-called *icteric* variety. A form called *algid* is characterized by notable reduction of temperature, the extremities becoming cold as marble or the coldness being like that of a cadaver. Profuse sweating characterizes some cases. Vomiting and purging are not infrequently prominent symptoms, leading to a state of collapse like that in cases of epidemic cholera. The secretion of urine is

sometimes suppressed, and albuminuria is not infrequent. In a form which may be called *asthenic* there are great restlessness and prostration, with a notably small, feeble, and irregular pulse. The development of well-marked febrile movement, with a full, regular pulse and heat of skin, is evidence that the patient will struggle through the paroxysm. The danger to be apprehended from another paroxysm is proportionate to the severity of that from which the patient emerges with safety. If the latter have involved very great risk, the next will be likely to prove fatal. The prostration in the intermission is in proportion to the severity of the paroxysm.

Hæmaturic malarial fever, which is one of the most important forms of pernicious fever, has already been considered (p. 875).

The DIAGNOSIS of all the forms of pernicious intermittent fever is aided by the fact that as a rule the dangerous paroxysm is preceded by at least one paroxysm, and it may be two or three paroxysms, devoid of any symptoms denoting danger, and by the fact that the pernicious paroxysm occurs in accordance with the type of the disease. In the forms characterized by coma, delirium, or convulsions cerebral meningitis and uræmia are to be excluded. The former is excluded by the absence of symptoms of cerebral inflammation exclusive of those just named, and the latter is excluded by an examination of the urine. Microscopical examination may show the presence in a drop of blood of black pigment and of the peculiar bodies described under the head of Causation in the preceding article. Enlargement of the spleen also has diagnostic significance.

Of the pathology of the several forms of pernicious as compared with simple or ordinary intermittent fever, all that can be said, with our present knowledge, is, that the essential morbid condition existing in the latter variety is a degree not involving immediate danger exists in the former variety in such intensity as to prove highly dangerous. Intermittent fever is not the only affection which without any essential change in the nature of the disease is in some cases extremely mild and in other cases extremely formidable. Scarlet fever may be cited as another striking example. The difference as regards symptomatic phenomena and gravity between pernicious and simple or ordinary intermittent fever is not explained by lesions found after death.

Pernicious intermittent fever is often preventable, and many lives are saved by timely efficient TREATMENT. It is doubtless prevented by promptly interrupting paroxysms before they assume a pernicious character. In seasons when pernicious cases prevail there is much risk of lives being sacrificed by the delay in arresting the disease incident to the employment of the so-called preparatory measures of treatment. In these seasons especially the curative treatment should be resorted to at once in all cases of intermittent fever, and the disease should be arrested as speedily as possible. When the disease has become pernicious there are two great objects of treatment. One of these is to carry the patient safely through an existing paroxysm; the other is to prevent another paroxysm.

With reference to the first of these objects, the indications differ according to the differences of form which pernicious paroxysms assume and according to the symptoms whatever may be the form. Enfeebled action of the heart always calls for stimulants, alcoholic, ethereal, and aromatic, severally or collectively. In many cases the danger of the disease is manifested chiefly by the symptoms referable to the circulation. In these cases the all-important indication is to strengthen the heart's action. Coma, unaccompanied by augmented force of the circulation and increased heat, does not call for blood-letting. Bloodletting has been employed in the cold stage of pernicious paroxysms of intermittent fever. That patients have recovered under this treatment by no means proves that it is devoid of danger. It is admissible only

When the symptoms denote active cerebral congestion. Coldness of the surface is an indication for the external application of heat by means of warm blankets, bottles of hot water, etc., and for internal stimulants. Vomiting and purging are to be restrained by opiates given by the mouth or rectum. Opiates are also indicated by restlessness, delirium, and convulsions. In connection with the latter the kidneys are to be interrogated with reference to the existence of uræmia. Emetics given at the beginning of the paroxysm, although they have been much used, are of doubtful utility, and cathartics should never be given. Chloroform in drachm doses deserves further trial as a means of abridging the cold stage. The doses should be repeated until the hypnotic effect of the remedy is obtained. Pilocarpine, administered hypodermically, will become an invaluable remedy if it prove as successful in arresting a pernicious paroxysm as it is in cases of a simple intermittent fever.

The second object—namely, to prevent another paroxysm—should enter into the treatment before the paroxysm, attended with more or less immediate danger, is ended. With reference to this object nothing can take the place of the preparations of cinchona. The succedanea of these preparations are not to be relied upon if the latter can be obtained. The sulphate, bisulphate, or the muriate of quinia should be given during the paroxysm, and given in larger doses than in cases of ordinary intermittent fever, in view of the vastly greater importance of arresting the disease, and because the tolerance of the remedy is often much greater. It is to be given during the paroxysm, not for its immediate effect, but to render more sure the prevention of another paroxysm. A scruple of the sulphate of quinia may be given at once by the mouth to an adult, and a larger quantity if given by the rectum. After three or four hours, if there be no evidence of cinchonism, the dose may be repeated. It is to be continued after the patient has emerged from the paroxysm in doses of between 10 and 20 grains, the intervals between the doses being sufficient to indicate the effect of each dose. Cinchonism should be produced and maintained during the intermission without reference to the quantity required; but to produce this effect the enormous doses which have sometimes been given are never necessary. Promptness and boldness are important, but excessive cinchonism is not advisable, and it is to be borne in mind that permanent blindness and deafness have resulted from the use of quinia in enormous doses. By pursuing the plan just stated the remedy may be employed as freely as may be necessary to obtain to the fullest extent its remedial influence, without incurring much risk of injury from its toxical effect. In a case in which it was considered that the life of the patient depended on the prevention of another paroxysm, 120 grains of quinia were given in divided doses in about twenty-four hours. The paroxysm was prevented, but suddenly, without having previously had symptoms of much cinchonism, he became completely blind and almost completely deaf. As may be imagined, great anxiety was felt; but, happily, at the end of eight hours both the blindness and deafness had disappeared, and the patient recovered without any further untoward symptoms.

The administration of quinia by means of hypodermic injections has been found efficient in cases of pernicious intermittent characterized by coma and inability to swallow. It may be resorted to when, from irritability of the stomach, the remedy will not be retained if given by the mouth. [A more efficacious method of administering quinine in pernicious intermittent fever is by intravenous injection. Bacelli has treated 30 cases in this manner without a death, whereas in 16 cases which he treated with subcutaneous injections there were 5 deaths.¹ Bacelli employs the following solution for intravenous injection:

¹ *Verhandlungen des X. international medicin. Congresses*, Band ii. S. 143.

cells are considered by many writers to be derived from the spleen, as similar cells exist there and as the same cells are found in the blood of the splenic and portal veins. The melanæmic pigment does not exist within the hepatic cells. These cells, however, usually contain a considerable amount of yellowish-brown pigment derived from the biliary coloring matters. According to Kelsch, there is an increased number of lymphoid cells in the interlobular tissue. This writer also maintains that a form of cirrhosis may be produced by malarial affection of the liver.

Pigment is found in the marrow of the bones, both outside of and within the blood-vessels. It is contained in lymphoid cells. Pigmentation of the brain forms a marked lesion in some cases of melanæmia. The change in color is most evident in the gray matter, which acquires a dark-gray or slate color contrasting markedly with the white matter. When the change is intense the white matter also has a dirty grayish tint and presents many puncta vasculosa. In some severe cases capillary hemorrhages have been found in large number. These extravasations have been attributed to plugging up of the small cerebral blood-vessels with pigment. In melanæmic brains the pigment is present chiefly within the small blood-vessels. It is also found in the walls of the vessels and in the perivascular spaces. The pigment does not exist in large amount in the brain unless it be also present in the circulating blood. If pigment be present in the kidney, it is met with chiefly in the glomeruli. The accumulation of pigment in other organs than those named is not great. It may be found in lymphatic glands, in the spinal cord, in the lungs, in the pancreas, in the skin, in mucous membranes, etc. In these situations it is contained within the blood-vessels.

After death from remittent fever more or less congestion and inflammation of the stomach and of the intestine are frequently found. The mucous membrane of these parts may present ecchymoses. The solitary glands and Peyer's patches may be swollen. The latter often present the shaven-beard appearance.

The same parenchymatous and hyaline degenerations which have been described under the head of Typhoid Fever have also been found after death from severe malarial fevers.

Acute nephritis, dysentery, and pneumonia are rare complications of this disease.

In typho-malarial fever, in addition to appearances characteristic of malarial disease, the abdominal lesions which are essentially those characteristic of typhoid fever are found after death.¹

CLINICAL HISTORY.—Under this head I shall present a brief sketch of simple remittent fever as regards especially its distinctive features, and afterward of typho-malarial fever.

Simple remittent fever often begins abruptly, but in a certain proportion of cases it has a brief forming stage, the prodromes being the same as those attending the development of other fevers. The febrile career begins with a chill more or less pronounced, either with or without rigor. During the chill, as in the cold stage of an intermittent paroxysm, the temperature of the body is actually raised, as shown by the thermometer in the axilla. The attack is oftener before than after mid-day. Febrile movement follows, varying in intensity in different cases, accompanied with cephalalgia, pain in the loins, etc. The thermometer in the axilla shows an increase of temperature of between 2° and 10° above the range of health. The febrile movement continues unabated for six, twelve, eighteen, twenty-four, and even

¹ Woodward at first believed that the intestinal ulcers of typho-malarial fever present certain peculiarities which distinguish them from those of ordinary typhoid fever. Extended studies led him to abandon this view.

Joseph J. Woodward.¹ I shall adopt this name, and consider remittent and typho-malarial fever conjointly. The facts which show the blending of remittent and typhoid fever will be noticed under the heads of Pathological Character and Causation.

Simple Remittent and Typho-malarial Fever.

By the term simple remittent fever is meant remittent not associated with typhoid fever and not accompanied by symptoms of gravity entitling it to be called pernicious. Pernicious remittent fever will claim a brief separate notice. Typho-malarial fever will be considered in conjunction with simple remittent fever.

ANATOMICAL CHARACTERS.—The characteristic lesion of remittent fever consists in the presence of dark pigment-granules in the blood and in various organs of the body. The parts chiefly affected are the spleen, the liver, and the marrow of the bones. When contained in the circulating blood the pigment may be found in the blood-vessels of any part of the body. The presence of the pigment in the blood constitutes the condition called *melanæmia*. The pigmentation of organs is sometimes called *melanosis*. Melanæmia and melanosis attend remittent fever, pernicious malarial fevers, long-continued intermittent fever, and sometimes the malarial cachexia. The degree of pigmentation depends upon the duration and the severity of the malarial affection. It is therefore most intense in connection with the severe malarial infection of warm climates.

During a paroxysm of malarial fever the spleen is enlarged from hyperæmia. This swelling at first subsides during an intermission, but under the influence of prolonged malarial infection the organ becomes permanently enlarged, constituting the so-called *ague-cake*. The color of the swollen spleen varies between dark-red or brownish- and bluish-black in proportion to the amount of pigment present. The consistence is soft when the enlargement is recent or when death has occurred during a febrile paroxysm. If there have been no recent attacks the consistence is firm. The swelling at first is due to hyperæmia; and subsequently there is hyperplasia of the cellular elements of the spleen, with new formation and thickening of its connective-tissue framework. The pigment is in the form of granules and of larger masses, and is contained chiefly within cells and within the hyaline bodies described on p. 955. In recent cases its color is reddish-brown, and later it becomes black. The pigment is in the splenic pulp, and is also accumulated about the blood-vessels, especially around the veins. It is contained also within the splenic veins. Little or no pigment is found in the Malpighian bodies in most cases. The cells containing the pigment are chiefly the lymphoid cells, which constitute the principal cellular elements of the spleen. Pigment is also contained in larger and more granular cells, and in long fusiform cells which are considered to be endothelial cells of the veins.

The liver in most cases is enlarged, but in cases of long duration it may be atrophic. The consistence is usually more or less softened. The organ presents a bronze, chocolate, or slate color. It is called the bronzed liver and the pigment liver. It usually is hyperæmic. The pigment-granules are found both in the interlobular tissue and within the lobules. They are enclosed chiefly within cells. They exist partly within the blood-vessels and partly in the extravascular tissue. The pigment is chiefly found within lymphoid cells, but also in fusiform, and sometimes in stellate, cells. The fusiform

¹ Vide *Outlines of the Chief Camp Diseases of the United States Army, etc.*, by Joseph Janvier Woodward, M. D., Assistant Surgeon U. S. Army, etc., 1863.

cells are considered by many writers to be derived from the spleen, as *similar* cells exist there and as the same cells are found in the blood of the *splenic* and portal veins. The melanæmic pigment does not exist within the *hepatic* cells. These cells, however, usually contain a considerable amount of *yellowish-brown* pigment derived from the biliary coloring matters. According to Kelsch, there is an increased number of lymphoid cells in the *interlobular* tissue. This writer also maintains that a form of cirrhosis may be produced by malarial affection of the liver.

Pigment is found in the marrow of the bones, both outside of and *within* the blood-vessels. It is contained in lymphoid cells. Pigmentation of *the* brain forms a marked lesion in some cases of melanæmia. The change *in* color is most evident in the gray matter, which acquires a dark-gray or *slate* color contrasting markedly with the white matter. When the change *is* intense the white matter also has a dirty grayish tint and presents *many* puncta vasculosa. In some severe cases capillary hemorrhages have been found in large number. These extravasations have been attributed to *plugging* up of the small cerebral blood-vessels with pigment. In melanæmic brains the pigment is present chiefly within the small blood-vessels. It *is* also found in the walls of the vessels and in the perivascular spaces. *The* pigment does not exist in large amount in the brain unless it be also present in the circulating blood. If pigment be present in the kidney, it is met *with* chiefly in the glomeruli. The accumulation of pigment in other organs *than* those named is not great. It may be found in lymphatic glands, in *the* spinal cord, in the lungs, in the pancreas, in the skin, in mucous membranes, etc. In these situations it is contained within the blood-vessels.

After death from remittent fever more or less congestion and inflammation of the stomach and of the intestine are frequently found. The mucous membrane of these parts may present ecchymoses. The solitary glands and Peyer's patches may be swollen. The latter often present the shaven-beard appearance.

The same parenchymatous and hyaline degenerations which have been described under the head of Typhoid Fever have also been found *after* death from severe malarial fevers.

Acute nephritis, dysentery, and pneumonia are rare complications of *this* disease.

In typho-malarial fever, in addition to appearances characteristic of *malarial* disease, the abdominal lesions which are essentially those characteristic of typhoid fever are found after death.¹

CLINICAL HISTORY.—Under this head I shall present a brief sketch of simple remittent fever as regards especially its distinctive features, and afterward of typho-malarial fever.

Simple remittent fever often begins abruptly, but in a certain proportion of cases it has a brief forming stage, the prodromes being the *same* as those attending the development of other fevers. The febrile *career* begins with a chill more or less pronounced, either with or without rigor. During the chill, as in the cold stage of an intermittent *paroxysm*, the temperature of the body is actually raised, as shown by the thermometer in the axilla. The attack is oftener before than after mid-day. Febrile movement follows, varying in intensity in different cases, accompanied with cephalalgia, pain in the loins, etc. The thermometer in the axilla shows an increase of temperature of between 2° and 10° above the range of health. The febrile movement continues unabated for six, twelve, eighteen, twenty-four, and even

¹ Woodward at first believed that the intestinal ulcers of typho-malarial fever present certain peculiarities which distinguish them from those of ordinary typhoid fever. Extended studies led him to abandon this view.

fever, and in place of these are the gastric symptoms distinctive of the latter—namely, nausea and vomiting, with tenderness over the epigastrium. The ataxic symptoms of the typhoid state are either wanting in simple remittent fever or they occur at a later period. The typhoid eruption is wanting. The access is much oftener abrupt and accompanied by a more pronounced chill. Paroxysms of intermittent fever are liable to occur at the close of a remittent fever. Finally, remittent fever is developed only in malarial districts or in persons who have been exposed to malaria. There can be no question as to this differential diagnosis in cases of disease occurring in a situation where malaria is known not to exist and when the patient is known not to have been within a malarial influence.

Typho-malarial fever is discriminated, on the one hand, from simple remittent fever by the characteristic events of typhoid fever—namely, the abdominal symptoms, the eruption in some cases, the earlier occurrence of ataxic phenomena, epistaxis, and occasionally intestinal perforation. It is discriminated, on the other hand, from unmixed typhoid fever by the characteristic events of periodical fever—namely, remissions, gastric symptoms, jaundice, and the termination in some cases in intermittent fever. The diagnosis of typho-malarial fever by means of positive symptoms may be difficult, especially if the abdominal symptoms and the eruption of typhoid be absent, as is frequently the case. The diagnosis is to be based on the presence of more or less of the symptoms belonging to malarial and to typhoid fever, and on negative facts which serve to exclude other fevers.

PROGNOSIS.—Simple remittent fever in itself does not involve danger to life. In fatal cases the termination is due to coexisting affections. Of course it is to be understood that cases of pernicious remittent fever are not included under the head of simple remittent fever. An attack of remittent fever leaves behind it a liability to subsequent attacks of intermittent fever, and is liable to be followed by the sequels of the latter disease—namely, enlarged spleen, anæmia, and general dropsy. This disease differs much in severity at different times and places and in different cases at the same time and place. As a rule, it is likely to be more severe in tropical than in temperate climates.

Typho-malarial fever is a much graver affection than simple remittent fever, and it is certainly not less grave than typhoid disconnected from malarial fever. Like the latter, the rate of mortality differs at different times and places, owing to differences as regards the intrinsic tendency of the disease and a variety of circumstances. Data for determining the average death-rate are not available, as it has not been customary to separate cases of this disease from cases, on the one hand, of simple remittent fever in which the typhoid state occurs, and on the other hand of typhoid fever without the combined action of malaria.

TREATMENT.—The first and leading object in the treatment of simple remittent fever is the arrest of the disease by antiperiodic remedies, of which the preparations of cinchona are by far the most reliable, the sulphate, the bisulphate, and the muriate of quinia being the preparations to be preferred. As soon as the character of the disease is determined by the occurrence of a remission, one of these salts of quinia should be given in a full dose—namely, 10 or 20 grains to an adult. The remedy should be continued in doses of 5 or 10 grains after intervals of from two to four hours until it produces slight deafness or ringing in the ears, suspending the remedy when these manifestations of cinchonism appear. If other preparations of cinchona be used, they are to be given in equivalent doses in the same manner. If the remedy be not tolerated by the stomach, it should be given *per enema*.

ver, and in place of these are the gastric symptoms distinctive of the latter—namely, nausea and vomiting, with tenderness over the epigastrium. The ataxic symptoms of the typhoid state are either wanting in simple remittent fever or they occur at a later period. The typhoid eruption is wanting. The access is much oftener abrupt and accompanied by a more pronounced chill. Paroxysms of intermittent fever are liable to occur at the close of a remittent fever. Finally, remittent fever is developed only in malarial districts or in persons who have been exposed to malaria. There can be no question as to its differential diagnosis in cases of disease occurring in a situation where malaria is known not to exist and when the patient is known not to have been within a malarial influence.

Typho-malarial fever is discriminated, on the one hand, from simple remittent fever by the characteristic events of typhoid fever—namely, the abdominal symptoms, the eruption in some cases, the earlier occurrence of ataxic phenomena, epistaxis, and occasionally intestinal perforation. It is discriminated, on the other hand, from unmixed typhoid fever by the characteristic events of periodical fever—namely, remissions, gastric symptoms, jaundice, and the termination in some cases in intermittent fever. The diagnosis of typho-malarial fever by means of positive symptoms may be difficult, especially if the abdominal symptoms and the eruption of typhoid be absent, as frequently the case. The diagnosis is to be based on the presence of more or less of the symptoms belonging to malarial and to typhoid fever, and on negative facts which serve to exclude other fevers.

PROGNOSIS.—Simple remittent fever in itself does not involve danger to life. In fatal cases the termination is due to coexisting affections. Of course it is to be understood that cases of pernicious remittent fever are not included under the head of simple remittent fever. An attack of remittent fever leaves behind it a liability to subsequent attacks of intermittent fever, and is liable to be followed by the sequels of the latter disease—namely, enlarged spleen, anæmia, and general dropsy. This disease differs much in severity at different times and places and in different cases at the same time and place. As a rule, it is likely to be more severe in tropical than in temperate climates. Typho-malarial fever is a much graver affection than simple remittent fever, and it is certainly not less grave than typhoid disconnected from malarial fever. Like the latter, the rate of mortality differs at different times and places, owing to differences as regards the intrinsic tendency of the disease and a variety of circumstances. Data for determining the average death-rate are not available, as it has not been customary to separate cases of this disease from cases, on the one hand, of simple remittent fever in which the typhoid state occurs, and on the other hand of typhoid fever without the combined action of malaria.

TREATMENT.—The first and leading object in the treatment of simple remittent fever is the arrest of the disease by antiperiodic remedies, of which the preparations of cinchona are by far the most reliable, the sulphate, the sulphonate, and the muriate of quinia being the preparations to be preferred. As soon as the character of the disease is determined by the occurrence of paroxysms, one of these salts of quinia should be given in a full dose—namely, 10 or 20 grains to an adult. The remedy should be continued in doses of 5 or 10 grains after intervals of from two to four hours until it produces slight deafness or ringing in the ears, suspending the remedy when these manifestations of cinchonism appear. If other preparations of cinchona are used, they are to be given in equivalent doses in the same manner. If the remedy be not tolerated by the stomach, it should be given *per enema*.

If cinchonism be not produced during the remission, the remedy may be continued during the exacerbation of fever. This is preferable to waiting for another remission. In a case in which the practitioner is satisfied that a remission has already occurred—in other words, whenever the diagnosis is clear—the remedy should be given at once, notwithstanding the intensity of the febrile movement, without waiting for a remission. Time need not in any case be lost in resorting to cathartics or other measures preparatory to the administration of an antiperiodic remedy. In short, the treatment is essentially the same as in cases of intermittent fever. This plan of treatment will succeed in a large proportion of cases in promptly arresting the disease.

Aside from the treatment just stated, palliative measures are to be employed according to the indications in individual cases. The indications will relate to pain in the head, nausea and vomiting, vigilance and restlessness, heat and dryness of the skin, etc. The same measures are to be addressed to these symptoms as when they are present in other fevers. It is unnecessary to consider these measures in this connection. The treatment during convalescence is the same as after other fevers, except that a preparation of cinchona should be employed for some time in conjunction with a chalybeate, as after an attack of intermittent fever.

The plan of treatment which has been sketched does not embrace measures heretofore considered important in this disease—namely, emetics, cathartics, bleeding, and the use of mercury. Emetics are contraindicated by the condition of the stomach. Cathartics are not indicated by the disease *per se*. They are required only to overcome constipation, and generally simple enemata or mild laxatives will suffice for this object. Bleeding is called for only by active cerebral congestion or intense febrile movement with augmented power of the heart's action, the patient being robust and plethoric. Under the latter circumstances sedative remedies, saline laxatives, and cold to the surface will generally be sufficient without the abstraction of blood. The external use of cold water is highly useful when the skin is notably hot and dry. The wet sheet may be employed, as in cases of typhoid fever. Opium, given in pretty full doses early in the disease, appears sometimes to exert an effect beyond that of a palliative by inducing a more marked remission. The pathological views which formerly led practitioners to employ mercury freely in this disease are not tenable, and clinical observation affords no ground for regarding this remedy as specially indicated.

In typho-malarial fever the periodic element claims the treatment indicated in simple remittent fever. The object is to eliminate this element by means of antiperiodic remedies. Aside from this object, the hygienic and medicinal measures indicated are the same as in cases of unmixed typhoid fever. To discuss these measures here would be to repeat what has been presented in the chapter in which the treatment of typhoid fever is considered. The reader is therefore referred to that chapter.

It is highly important to recognize the existence of the malarial element in cases of typho-malarial fever with reference to continuing antiperiodic remedies throughout the course of the disease. I have known death to occur from a paroxysm of intermittent fever when the symptoms had denoted convalescence from the typhoid fever, the autopsy also showing that restorative processes were taking place in the intestinal ulcers. Probably in this case quinia in antiperiodic doses, continued throughout the course of the fever, would have prevented the fatal paroxysm.

Pernicious Remittent Fever.

A brief notice of pernicious remittent fever will suffice. This fever is distinguished as pernicious under circumstances similar to those which constitute

ounds for the application of the same term to intermittent fever—namely, circumstances giving to the disease unusual gravity and danger. This variety of the disease is also called malignant and congestive. Pernicious remittent fever presents the same diversities as regards symptomatic phenomena as pernicious intermittent fever. In cases in which death takes place quickly it is possible to determine whether the disease be intermittent or remittent; and a fatal result may take place before either a remission or an intermission occurs. The occurrence of an intermission or of a remission is the chief differential point. The two forms of disease, in a pathological view, are essentially the same, and they claim the same treatment. The importance of pernicious intermittent fever is by no means to be measured by this brief notice of it; but inasmuch as all that is of practical importance in relation to this disease is embraced in the consideration of pernicious intermittent fever, the reader is referred to that portion of the preceding chapter which treats of the latter. Remittent fever, especially the pernicious variety, has received in different parts of the world a variety of names denoting its geographical relations, such as Walcheren fever, African fever, Hungarian fever, jungle fever, lake fever, etc.

Yellow Fever.

The fever to be now considered has received a great variety of names, but is at this time everywhere known as yellow fever—a name the significance of which is derived from the frequent occurrence of yellowness of the surface of the body. Although the name relates to a symptom not constantly present, and occurring occasionally in other fevers, it has the merit of not involving any hypothesis concerning the nature or causation of the disease.

ANATOMICAL CHARACTERS.—The morbid appearances which are most frequent are situated in the liver, in the stomach and intestine, and in the kidneys. The liver may be somewhat enlarged, but it generally presents no marked change as regards size. It is pale in color rather than congested. Its resistance is often diminished. The most characteristic change is the yellow color which the organ presents in most (although not in all) cases. The change in color may affect the whole liver or may exist in a larger or smaller number of scattered patches. The abnormal coloration is due to the presence of fat, as was proven by Alonzo Clark in 1853. The fat is in the form of large and small drops in the liver-cells. According to some observers, fat is found also in the interstitial tissue. The process is to be regarded as an acute fatty degeneration of the liver.¹ Some writers describe an actual disintegration of some of the hepatic cells in yellow fever. The yellow color may be due in part to jaundice of the liver. The combination of bile-staining; and of fatty metamorphosis produces the so-called saffron-colored liver. Small ecchymoses are often found upon the surface of the liver. Schmidt describes the occasional presence in the liver, as well as elsewhere, of reddish-brown stains which he attributes to extravasations of hæmoglobin.² The mucous membrane of the stomach is usually swollen, softened, and congested. Small hemorrhages are found in the mucous and submucous tis-

The presence of large oil-drops is not a sufficient criterion of fatty infiltration in distinction from fatty degeneration. (Consult the article on Fatty Liver, p. 550.) It is incorrect to regard the hepatic changes in yellow fever as comparable in degree or extent with those in acute yellow atrophy of the liver. There is still less ground for the assumption that the essential symptoms of yellow fever are referable to an acute parenchymatous or fatty degeneration of the liver (Liebermeister, *Middleton*).

Schmidt, "The Pathology of Yellow Fever," *New York Medical Journal*, 1879, vol. x. p. 128.

sues. The stomach often contains a dark, bloody fluid, which is of the same nature as the black vomit to be described under the head of the Clinical History. The cells of the gastric tubules undergo parenchymatous degeneration. There may be an extensive accumulation of lymphoid cells in the submucosa and other coats of the stomach. Changes similar to those of the stomach are found in the upper part of the small intestine, and they may extend downward to a variable degree. The upper part of the intestine contains in some cases black matter similar to that found in the stomach. The Peyerian and solitary glands of the intestine present no morbid alteration.

The kidneys usually are enlarged and the seat of parenchymatous degeneration. They often contain small extravasations of blood. Acute diffuse nephritis is a frequent accompaniment of yellow fever. In this condition the cortex is swollen and presents a yellowish-white color mingled with congested and hemorrhagic portions. The epithelial cells of the convoluted tubes contain fatty molecules. Red blood-corpuscles are found in the tubes as well as in the intertubular tissue. Collections of emigrated white corpuscles are met with between the tubes. Miliary abscesses have been seen exceptionally in the kidneys of those who have died of yellow fever.

It is a remarkable fact that in a disease so acutely infectious as yellow fever the spleen as a rule undergoes no enlargement. The lungs are often the seat of hypostatic congestion. In many cases hemorrhagic infarctions have been found in the lungs. The pleura as well as the pericardium and other serous membranes frequently presents small ecchymoses. Parenchymatous and fatty degeneration of the myocardium has been frequently seen in some epidemics. The brain and its membranes present nothing distinctive. No changes have been discovered in the blood other than those belonging to most of the essential fevers. The attempts to discover a specific organism in the blood and tissues have thus far met with no success.¹

CLINICAL HISTORY.—An attack of yellow fever usually is abrupt. In a minority of cases it is preceded for one, two, or three days by languor, lassitude, loss of appetite, pain in the head, and chilly sensations. The attack is generally denoted by a chill, with or without rigor, the chill in most cases being of moderate intensity. Fever follows, differing in intensity in different cases. The temperature quickly reaches its maximum, which varies between 102° and 110° F. The pulse seldom exceeds 100. The tongue is moist and more or less coated. Vomiting occurs in a certain proportion of cases early, but it rarely is a prominent symptom until a later period. Tenderness on pressure over the epigastrium is more or less marked. The bowels, as a rule, are constipated. Cephalalgia, the pain referred especially to the supraorbital region, is usually present, and is sometimes intense. Frequently pain in the loins and pain in the lower limbs, especially in the calves of the legs, is a prominent symptom. This fever bears an analogy to smallpox in the frequent prominence of lumbar pain. The mind usually is clear, but occasionally delirium is manifested, rarely violent and active, and sometimes mirthful. The eyes are reddened, irritable, watery, or tearful. This is quite constant, and so marked as to constitute a diagnostic feature. Otherwise, the organs of sense are not disturbed. Generally there are no pulmonary symptoms.

The pyrexia continues for a period varying between a few hours and three days. Then follows either a marked abatement or entire cessation of fever. A remission is said to take place; but this term is not always accurate, inasmuch as there may be complete apyrexia, and in a certain proportion of cases there is no return of fever. The condition following the febrile paroxysm

¹ The published observations of Freire and of Cremona upon this point are not of a nature to inspire confidence in their conclusions.

been called "the state of calm." This is reckoned as the second stage of the disease, the first stage embracing the period of fever, the latter being called the "febrile period," the "stage of excitement," or the "paroxysm." The first stage may be regarded as constituting the disease proper, and what may follow as sequels of the disease. The disease is then a fever with single paroxysm. In mild cases convalescence takes place immediately after the stage.

In grave cases the cessation of fever is often deceptive. The pains, etc., cease, and the patient may feel as if convalescence had begun; but after a period varying between a few hours and twenty-four or longer there are new symptoms more distinctive of the affection than those during the febrile paroxysm. The pulse sometimes falls below the normal frequency, and it has been observed to fall as low as 40, and even 30, per minute. It is sometimes small and weak, and sometimes vibratory. It is always notably compressible, and has been called a "gaseous pulse." The surface is usually cool, especially the parts of the body which are exposed. In the few cases which I have observed capillary congestion of the skin existed in a marked degree. Lividity of the back, attributable to hypostatic congestion, is sometimes observed.

If the symptoms referable to the digestive system, those most characteristic pertain to the stomach. Vomiting occurs, if not already present, and if present it becomes more prominent. In a large proportion of fatal cases and a few of the cases ending in recovery the black vomit occurs. This, taken in connection with other symptoms, is pathognomonic of the disease. Heretofore there has been much discussion respecting the nature of the vomited matter, but it is settled that the appearances are due to blood changed by the action of the gastric fluids. As regards the gross appearances, the matter vomited is a thin liquid of a reddish, brown, claret, or blackish color, with a liment resembling coffee-grounds. Occasionally the liquid is bright red, the blood having undergone but little change. Rarely it has a greenish or yellowish tinge, from the presence of bile. The secretion is acid, and it has an acid taste without bitterness. It is sometimes acrid, excoriating the throat, tongue, and lips. The microscope shows the sediment to contain integrated particles of food, mucus, epithelium, blood-pigment, and deformed blood-discs, often decolorized. Fungus-spores are often found. A liquid resembling the black vomit may be produced artificially by adding acid to blood out of the body. The bilious matter vomited in some cases of remittent fever presents somewhat similar gross characters, but chemical, microscopical, and spectroscopical examination shows the presence of bile and the absence of blood-constituents. The black vomit in different cases of yellow fever is more or less abundant. It is sometimes ejected with force, and sometimes by an act of regurgitation rather than of vomiting. It generally ceases for a period of from twelve to twenty-four hours before death. The black vomit rarely occurs until after the febrile paroxysm. It occurs at various periods afterward, but generally not until toward the close of the disease. Blair described a matter vomited prior to the black vomit, limpid or slightly opalescent, which he termed the "white vomit." Tenderness over the epigastrium is more or less marked, and the tenderness is sometimes severe. The tongue is frequently reddened, dry, and cracked; in some cases it is moist and covered with a creamy coating, and sometimes it presents its natural appearance.

During the second stage the evacuations from the bowels are frequently brownish, approaching to a black, appearance. They resemble sometimes molasses. This appearance is due to the presence of blood, so altered, however, in its passage through the intestinal canal that its morphological characters are not demonstrable. Uric acid and the triple phosphates may be

found in the evacuations from the bowels. Sometimes blood but little altered is passed from the bowels. Diarrhœa in this as in the first stage is rare. The abdomen is soft and seldom meteorized. The melænic discharges generally precede the occurrence of black vomit, and they have been called the "black vomit stools."

Albuminuria is of frequent occurrence in grave or fatal cases. Hyaline and granular casts, red blood-corpuscles, renal epithelium, and epithelium from the bladder are found in the sediment of the urine.¹ A scanty secretion of urine or suppression not infrequently precedes a fatal ending. Uræmia occurs in a certain proportion of cases. The urine in certain cases becomes of a yellow or orange color from bile-staining, and it is sometimes bloody.

Yellowness of the surface of the body—whence the disease derives its name—occurs after the febrile paroxysm. The conjunctiva becomes yellow, and this with the redness gives to the eye a striking and peculiar appearance. The yellowness of the skin is especially marked on the chest and upper extremities. The jaundice is probably hepatogenous, but it is considered by some as hæmatogenous. It exists in only a certain proportion of cases. It occurs in a much larger proportion of fatal than of non-fatal cases, and, in fact, it occurs in a small proportion of the latter. The yellowness continues after death and into convalescence.

Hæmorrhage in various situations other than the stomach, intestine, and the kidneys or bladder, to which reference has been already made, is often a striking feature of the disease. It occurs from the nostrils, gums, uterus, wounds or abrasions of the skin, and sometimes from the eyes, meatus auditorius, finger-nails, holes bored in the ears for ear-rings, etc. Petechiæ and vibices are sometimes observed.

As regards symptoms referable to the nervous and the muscular system, coma and convulsions are of occasional occurrence. They are probably dependent on uræmia. Delirium is observed, but frequently the mind remains clear. Delirium may exist during the fever, and disappear afterward. Generally there is notable muscular prostration, but to this rule there are remarkable exceptions. Patients sometimes do not take to the bed, but keep about their usual avocations, not thinking themselves much ill, often a few hours before death. These have been called "walking cases." Rush relates a case in which the patient stood up before a glass and shaved himself on the day of his death. In a case cited by Bartlett the patient, a soldier, continued to do duty until black vomit took place. In another case the patient dictated and signed a letter a quarter of an hour before death. Cartwright cited an instance of a shoemaker who nearly finished a shoe the day before his death. Fenner saw a patient quietly reading a book after the black vomit had occurred. These cases exemplify a kind of cheerful delirium, as it was called by La Roche, in which the patient fancies himself well or but little ill.

The physiognomy of patients is described by different writers with a good deal of metaphor, but nearly all state that it is characteristic. The face is flushed. The appearance of the eyes is described by different writers as injected, brilliant, transparent, fiery, and glassy. To the facies are applied the following terms: suffering, dejection, anxiety, anguish, despair, terror, stupidity, vacancy, astonishment, sullenness, etc. The diversity of these terms raises a suspicion that the peculiarity of the physiognomy is less distinctive than observers have generally supposed; at all events, it appears to be difficult to convey by language a clear idea of the characteristic appearance.

The duration of the disease after the febrile paroxysm varies between

¹ Vide "The Urine in Yellow Fever," by Prof. J. W. Holland, in the *London Practitioner*, July, 1879, and the *American Practitioner*, Sept., 1879.

twelve hours and three or four days. In cases of great gravity the duration is brief, the disease running rapidly to a fatal termination.

Writers recognize a third stage in fatal cases, called the stage of collapse or the stage of exhaustion. The collapsed condition is denoted by prostration, feebleness and irregularity of the pulse, coldness of the extremities, low delirium in some cases, the intellect remaining clear in other cases, and mental indifference or apathy generally existing as in cases of epidemic cholera,—these symptoms showing tendency to death by asthenia. Coma and convulsions sometimes occur in this stage, attributable, probably, to uræmia. In some cases this period is characterized by great restlessness, jactitation, and general distress; but in other cases the patient remains quiet and seems free from suffering.

If death do not take place, the third stage is the stage of convalescence. When the disease passes to the second stage, and presents the grave symptoms belonging to this stage—namely, black vomit, hemorrhage, etc.—the recovery is always slow, and is frequently preceded by fever having more or less of the phenomena of the typhoid state. Relapses sometimes occur after convalescence appears to be declared.

In mild cases the disease ends in convalescence immediately following the paroxysm of fever. Whenever an epidemic prevails there is a certain proportion of cases devoid of any gravity. In these cases a slight chill occurs, followed by moderate pyrexia continuing for one or two days, and recovery quickly takes place. These cases would not be recognized as cases of yellow fever except from the fact of their occurrence during the prevalence of an epidemic. When this mild form of the disease occurs it is not infrequently a matter of doubt whether patients have had the disease or not.

More severe cases are distinguished by the intensity of the pyrexia. The term inflammatory, often applied to these cases, is not correct, inasmuch as the intensity of the febrile movement is not due to inflammation, but to the fever *per se*. Malignant cases are those characterized by black vomit or profuse hemorrhage in other situations, followed by collapse or exhaustion, and also cases in which coma or convulsions occur with suppression of urine.

The duration of the disease is variable. Shortness of its career is a distinguishing feature. In the shortest cases death or convalescence takes place in two or three days. According to La Roche, the duration varies between three and nine days. The average duration is less than a week.

CAUSATION.—The peculiar features of this disease, its limitation within certain geographical boundaries, and its occurrence as an epidemic, warrant the inference that it requires for its production a special cause. Does the special cause emanate from the bodies of those affected with the disease? in other words, is the disease contagious? This question has given rise to much discussion. Volumes have been written by contagionists and non-contagionists in defence of the two opposing doctrines. It is evident that the question is one of great importance in its bearing on commerce and quarantine laws, as well as on precautionary measures respecting exposure in visiting or attending upon those affected with the disease. (For a full consideration of this topic the reader is referred to works treating *in extenso* of yellow fever, and especially to the elaborate treatise by La Roche.) I shall simply state the grounds which substantiate the non-contagiousness of the disease:

1. The disease is confined within certain territorial limits. In this respect it differs from most diseases the contagiousness of which is established. Even in localities in which it is prevailing as an epidemic it is sometimes restricted to a circumscribed area.
2. The rise and progress of epidemics are not consistent with its diffusion

by contagion. For example, Fenner, with great zeal and fidelity, traced the first 30 or 40 cases in the epidemic at New Orleans in 1853, and ascertained that the disease broke out in different places among persons who could have had no communication with each other. Fenner investigated the origin and spread of the disease in New Orleans for twelve years, and stated that he never found the least proof of personal communicability. This is alike true of epidemics in other places.¹

3. In certain places within the yellow-fever zone sporadic cases occur almost every year. According to Fenner, a summer never passes in which there is not a greater or less number of sporadic cases in New Orleans, but the disease prevails as an epidemic only in certain years. Were the disease contagious it should be diffused more or less whenever there are any cases of it.

4. When it prevails as an epidemic it spreads too rapidly to be diffused by contagion.

5. Persons going from a district where it prevails into a district where it does not exist, and becoming attacked in the latter, do not communicate the disease. There is abundant evidence that this is the rule, and the apparent exceptions are so few and of such a character that it is most logical to explain them otherwise than by the supposition of contagion.

6. Persons brought into close contact with yellow-fever patients—physicians, nurses, or other hospital patients—do not contract the disease.

7. Epidemics run a certain course as respects duration, and abruptly end, in this respect resembling epidemics of cholera. The disease should prevail longer and disappear more slowly if propagated by contagion. Like other epidemics, the disease, as a rule, becomes milder by continuance. It appears to absorb other diseases while it continues, in this respect resembling epidemic cholera, and its prevalence is arrested by cold. These facts, especially the two latter, are not consistent with the doctrine of contagion.

8. The great majority of those who have had an extensive practical acquaintance with the disease believe it to be non-contagious.

9. Experiments to test the question of communicability, by inoculation, by swallowing the black vomit, and by the utmost possible exposure, have led to negative results. To cite one among many experimental observations, Dowling gives the following account: In 1805, Don Cabanellos, a Spaniard, slept at night with his children in beds in the lazaretto in which yellow-fever victims had died. For submitting the question of contagion to this personal test he was made physician to the royal household, with an annuity of twelve hundred dollars. A number of galley-slaves who accompanied him had one year's imprisonment remitted. The whole party amounted to fifty, and no one suffered any harm.

10. Complete seclusion has proved ineffectual to prevent the disease.

In view of the foregoing considerations, to which others might be added, it seems certain that yellow fever is not produced by means of a contagium.

Yellow fever, therefore, is a purely infectious miasmatic disease. Another question arises in connection with that of contagion—namely, May not the infection be transported in clothing, merchandise, etc., and the disease be in this way imported? Facts have established an affirmative answer to this question. The special cause can in this way be distributed by vessels, railroads, and other conveyances. The fact of the disease being portable renders judicious quarantine restrictions of vital importance, but in view of its non-contagiousness the restrictions need not include the detention of persons.

¹ Vide article on "Epidemiological Conclusions and Suggestions," in *Brit. and For. Medico-Chirurg. Review*, Oct., 1870, p. 484.

Of the nature of the infection we have not, as yet, demonstrative proof. Something, however, is known of the conditions under which it is produced. It is indigenous in warm climates. Yellow fever is rarely developed south of 20° south or north of 40° north latitude. It prevails more in the Eastern than in the Western Hemisphere, and in certain parts of Europe and America than in Africa. In the Western World it prevails especially in the commercial towns on the Atlantic coast south of Charleston, S. C., on the Gulf of Mexico, and in the West India islands. It rarely prevails in rural situations. It prevails only in the summer season in other than tropical climates, and in the latter chiefly during the hottest months. A high temperature is essential to its causation, but in yellow-fever localities epidemics do not always occur in the years in which the temperature is highest. Humidity has been supposed to favor the development of the disease, but this is not conclusively established. There does not seem to be ground for connecting the causation with any known meteorological conditions other than a high temperature. As stated by Nott, the special cause is most active near the ground, persons on a ground-floor being more likely to be attacked than those in stories above. The miasm is more active at night than in the daytime.

In localities where the disease prevails often the conditions for its development do not uniformly exist during the hot seasons. Epidemics occur only in certain years. It seems that the efficiency of the special cause is favored by the co-operation of other causes, and hence sanitary measures—drainage, sewerage, removal of filth, avoidance of overcrowding, etc.—contribute to the prevention of yellow-fever epidemics.

Unacclimation is a condition pertaining to individual susceptibility. Natives of yellow-fever localities are rarely attacked. Particular epidemics, however, have been characterized by a considerable number of cases among the native population. Not having experienced the disease is another personal condition. The disease having been once experienced, the susceptibility to the special cause, as a rule, is extinguished. The number of persons who have the disease more than once is probably not greater than the number of exceptions to the rule that smallpox and typhus render the system insusceptible ever afterward to the special causes of these diseases. Acclimation, as regards this disease, is complete only when the disease has been experienced.

The negro race seems to be singularly exempt from a liability to this disease. Statistics show the mortality among negroes to be insignificant. It is stated, however, by Fenner that the insusceptibility is not nearly so great as mortuary statistics seem to show, in consequence of the fact that the disease in the negro is almost invariably mild and not likely to prove fatal. The susceptibility is not affected by age, persons of different ages, inclusive of infancy, being liable to the disease. Statistics show a larger proportion of cases among males than among females.

The special cause is destroyed by cold. It is a matter of common observation that an epidemic is arrested by one or two hard frosts. Epidemics, however, have a self-limited duration. Fenner noted that at New Orleans repeatedly the disease disappeared before the occurrence of frost. An epidemic rarely continues longer than 60 or 70 days. Barlow calculated the average duration of yellow-fever epidemics, and finds it to be 58.33 days, being somewhat longer than the mean duration of epidemics of cholera.

Of the nature of the special cause or infection, as already stated, positive proof has not as yet been obtained; but that the disease is produced by specific germs or organisms is as logically established as with respect to any of the infectious diseases the causes of which have not been demonstrated. Assuming the existence of yellow-fever germs, the production of the disease

by filth or any local conditions without the presence of these germs can only be considered as possible by those who hold to the doctrine of spontaneous generation. While, as already stated, certain obvious local conditions may have an auxiliary agency, that these conditions are essential is disproved by instances in which the disease is developed in situations as healthy as possible in a sanitary point of view. The multiplication of germs without the body, therefore, may take place irrespective of any apparent local causes. The organisms which furnish the yellow-fever germs are exotic as regards most if not all parts of this country. The sporadic cases which appear in New Orleans in seasons when the disease is not epidemic are probably due to germs which have escaped destruction having been placed under circumstances favorable for retaining their vitality. This has been called the "laying over" or the "hibernation" of germs. Germs attached to clothing or other articles under favorable circumstances may probably retain their vitality and infective capability for a long period.

The period of incubation is variable. It varies between two and fifteen days, and in the majority of cases it is nearer the first than the second of these numbers. Campbell has reported an instance in which the period was nearly six weeks.¹

DIAGNOSIS.—The access of the disease and the symptoms during the febrile or first stage present nothing very distinctive. All observers agree that it is often difficult to arrive at a positive diagnosis during this stage. In a considerable proportion of cases the disease at the end of this stage terminates in convalescence. These cases would not be considered as cases of yellow fever except during an epidemic. The disease in these cases presents the characters of a febricula. The symptoms which have diagnostic significance are—the abruptness of the attack, pains in the back and limbs, and suffusion or redness of the eyes.

In cases progressing beyond the febrile paroxysm and presenting the grave events which are liable to follow, the diagnostic features are sufficiently distinctive. They are—yellowness of the conjunctiva and skin, black vomit, hemorrhages elsewhere than from the stomach, epigastric tenderness, slowness of the pulse in certain cases, coldness of the extremities, suppression or a scanty secretion of urine, and the phenomena denoting collapse. All these events are not present in every case, but generally enough of them exist to render the diagnosis positive. The march of the disease to a fatal issue from the end of the febrile paroxysm or the first stage in well-marked cases is peculiar, and it can hardly be confounded with any other affection.

PROGNOSIS.—The mortality from yellow fever varies much in different epidemics. The range of variation is between 10 and 75 per cent.² The average mortality, according to calculations by La Roche, is 1 in 2.32. The rate of mortality differs in different periods of the same epidemics, the rule being a decrease in the rate as the epidemic approaches its termination. Bemis gives the rate of mortality in private practice during the epidemic of 1878 in New Orleans as 10 per cent. among white patients and 3 per cent. among colored patients. The mortality during the same epidemic among hospital patients was 51.7 per cent. for white and 21 per cent. for colored patients.³

Unfavorable prognostics are—yellowness of the surface, black vomit, great

¹ "The Yellow-Fever Germ on Coast and Inland," by Henry F. Campbell, M.D., *Trans. of the Med. Association of Georgia*, 1879.

² DuCosta, *Medical Diagnosis*, Philadelphia, 1881, p. 828.

³ S. M. Bemis, article on "Yellow Fever" in *Pepper's System of Practical Medicine*, by American Authors, Philadelphia, 1885, vol. i.

diminution or suppression of urine, abundant hemorrhage in any situation, coldness of the extremities, jactitation, hiccough, delirium, convulsions, and coma. Of these symptoms, black vomit and suppression of urine are almost invariably forerunners of death. Coma and convulsions are fatal symptoms dependent on uræmia.

A favorable prognosis cannot be confidently entertained in any case of this disease. Unfavorable events are liable to occur when up to the time of their occurrence the symptoms appeared to be favorable. Black vomit, hemorrhage elsewhere, and uræmic convulsions or coma are liable to occur unexpectedly in cases which appear to be progressing favorably.

Exclusive of cases in which the immediate cause of death is uræmic coma, the mode of dying is by asthenia.

TREATMENT.—With reference to the treatment of yellow fever, it is to be premised that no specific remedy has been discovered. There is no known plan of treatment on which reliance can be placed to cut short the disease. Another consideration to be premised is that the disease, exclusive of malignant cases, tends to recovery. Mild yellow fever is a very mild disease, not tending to destructive lesions of either the solids or fluids, nor does it tend to continue indefinitely if not arrested, like intermittent fever.

A third preliminary consideration is that in a considerable proportion of malignant cases the disease is necessarily fatal. Hence, a large proportion of fatal cases is by no means proof of injudicious treatment. A fourth consideration is that different epidemics differ as regards the relative proportion of mild and malignant cases. In some epidemics most of the cases are mild, and in others malignant. It follows that the ratio of recoveries under a certain plan of treatment may be no test of the superiority of that plan. Measures which appear to be eminently successful in one epidemic may appear to fail in another epidemic, the difference being due to variations as regards the tendency of the disease to a fatal issue.

In cases of mild yellow fever no active interference is required. Quietude, restricted diet, ventilation, and other hygienic regulations, together with such palliative measures as particular symptoms in individual cases may indicate, suffice for the treatment. The palliative measures embrace anodyne and refrigerant remedies, cold applications to the head, sponging of the body, laxatives in some cases, etc. It is, however, to be borne in mind that the disease may become malignant in cases which are at first mild in appearance. It is impossible always to distinguish at the outset the cases which will prove to be mild, and hence it is of vast importance to take every precaution to prevent the development of grave symptoms. For this end hygienic measures are especially or chiefly important. Patients should at once give up to the disease and take to the bed. As complete rest of body and mind as practicable is to be enforced. The services of a faithful and experienced nurse are of more importance than medication. Free ventilation, cleanliness, and other sanitary measures are not less important in this than in other forms of fever.

In cases characterized by intensity of fever during the febrile paroxysm no one entertains at the present time the propriety of bloodletting. Antipyretic measures of treatment—namely, cold sponging and the wet sheet—are rationally indicated. Data are not as yet available for forming an opinion as to the efficacy of these measures in preventing the grave events of the disease and in lessening its mortality.

Purgatives have been much employed in this as in most other diseases. Drastic or active purgatives do harm by increasing the gastro-intestinal irritation and producing exhaustion. Even if well borne, it is difficult to see what indication they fulfil which may not be equally met by mild laxatives.

or simple enemas. The latter are indicated by constipation. Purgation, except in some cases for the purpose of eliminating urea, is to be avoided. Emetics, which have also been much used, are contraindicated by the gastric symptoms which belong to the history of yellow fever.

Mercury has been considered as important in this disease. Calomel in large doses has been much used, and it has been thought to be desirable to produce ptyalism. This practice has now but few advocates. Facts do not warrant the opinion that mercurialization is in any sense curative, and the testimony of most physicians who have had practical acquaintance with this disease is adverse to the use of mercury in any form.

Measures to relieve gastric irritability are often indicated. For this end counter-irritation over the epigastrium may be employed by means of small blisters, dry cupping, sinapisms, and stimulating liniments. Anodynes, given either by the mouth or by the hypodermic method, are indicated for this end. Other remedies are chloroform in small doses, prussic acid, and creasote. Ice swallowed in small pieces has been found useful in allaying irritability of the stomach. To prevent black vomit, and with a view to arrest gastric hemorrhage when it has occurred, the acetate of lead with opium has been much extolled. With reference to this event careful attention should be given to the ingesta. Milk with lime-water, not given in large quantity, is probably the best article of diet. If sustaining measures be not indicated, bland liquids only should be taken into the stomach.

Hemorrhages elsewhere call for local styptics if the source of the hemorrhage be accessible, and for ergot or other hæmostatics. In a case related to me by a former colleague life was apparently saved by the transfusion of blood.

Great restlessness and vigilance call for opium or other anodyne remedies. Deficiency of the urinary secretion is an indication for diuretic remedies if they be tolerated by the stomach, and for measures to produce diaphoresis if diuretics be not borne or if they prove inoperative. If symptoms be present denoting uræmia, the hot-air bath should be employed. Under these circumstances elaterium or some other hydragogue may be advisable if relief be not procured by diaphoresis.

Sustaining measures are indicated in proportion as a tendency to collapse or death by asthenia is denoted by the symptoms. The irritability of the stomach may interfere with the sustaining treatment. The forms of stimulus and nourishment are to be selected which on trial are found to be best borne. Alcoholic stimulants may be given *per enema* if not retained by the stomach. Two of my colleagues in the New Orleans School of Medicine, who had experienced this disease in its severe or malignant form, attributed their recovery to the free use of alcoholic stimulants. In one of these cases, when a fatal termination was regarded as imminent, a favorable change occurred immediately after champagne had been given freely.

PREVENTION.—Measures for the prevention of yellow fever relate—1st, to the removal of local conditions which favor the multiplication of the disease-germs; 2d, to quarantine regulations; and 3d, to disinfection. The first of these three divisions embraces all that pertains to public and private hygiene. The local conditions which are especially important as auxiliary causes are unknown, and therefore it can only be hoped that they will be reached by rendering sanitary measures as complete as practicable; but, be these measures never so complete, they do not make superfluous those of quarantine and disinfection. The object of quarantine regulations is that the disease-germs shall not be imported. To effect this object either there must be non-intercourse with places in which the

disease prevails, or all articles of merchandise, clothing, etc. brought therefrom must be thoroughly disinfected. To be efficient, quarantine regulations must include not only vessels from infected parts, but inland transportation by railroads and other conveyances. There is no danger of the disease being carried by the living body after disinfection of the wearing apparel, or by the bodies of the dead. Detention of the well or the sick is therefore a needless precaution, except to prevent groundless popular apprehensions. If importation of the germs have taken place, the houses with their surroundings in which cases occur should be instantly and completely disinfected. The object now is to "stamp out" the disease. There is ground for the belief that this object may be effected if measures of disinfection be promptly and thoroughly carried out.

During the prevalence of an epidemic unacclimated persons should avoid going within the infected area except under a sense of duty, and they who are already within this area should leave it unless there be motives for remaining which render the risk of life justifiable and praiseworthy.

CHAPTER VI.

ERUPTIVE FEVERS.

Variola, or Smallpox: Anatomical Characters; Clinical History; Causation; Diagnosis; Prognosis; Treatment.—**Varioloid, or Modified Smallpox.**—**Vaccinia, or Cowpox.**—**Varicella, or Chicken-pox.**

THE fevers which remain to be considered are characterized by an eruption or exanthem, and hence they are called eruptive or exanthematous fevers. The continued fevers, typhus and typhoid, have also an eruption, but the eruption is less constant and less prominent than in the eruptive fevers. The eruptive fevers are *variola*, or smallpox, including the modified form known as *varioloid*; *varicella*, commonly called chicken-pox; *scarlatina*, or scarlet fever; *rubeola*, or measles; *roseola*, or rose-rash; and *rötheln*, or German measles. The eruption in two of these fevers is moist; that is, vesicular or pustular. This is true of *variola* and *varicella*. In the remainder the eruption is dry, and is properly an efflorescence or rash. To the latter kind of eruption the term exanthem is, strictly speaking, restricted.

The eruptive fevers were formerly considered as varieties of one disease, and the individuality of each was not fully settled much before the present century. Each is a distinct species of fever, having phenomena and laws peculiar to it and its own special cause. All, with the exception of *roseola*, are propagated by special causes reproduced within the body; that is, they are communicable diseases.

The division of the career of the disease into stages is the same in all the eruptive fevers. The first stage is the stage of invasion or the access. This stage begins with the first manifestations of disease and ends with the first appearance of the eruption. The second stage is the stage of the eruption, and extends from the time when the eruption first appears to its disappearance. This stage is subdivided in *variola*. The stage of desquamation or desiccation follows the eruptive stage, and this either constitutes or is fol-

lowed by the stage of convalescence. The consideration of these fevers will also embrace the periods of incubation and certain events liable to occur after the disease, or sequels.

Variola, or Smallpox.

The discovery of vaccination by the immortal Jenner toward the close of the eighteenth century has divested this disease of much of the importance which it had in the two previous centuries, when it ranked first among the acute affections destructive of human life. It is not, however, so rare, even in its unmodified form, at the present day but that cases are liable to come under the observation of every practitioner. The gravity and loathsomeness of the disease, together with its contagiousness, render highly important an early diagnosis and judicious management. I shall consider first unmodified variola, and afterward, under a separate head, the modified form of the disease known as *varioid*. The latter head will embrace the consideration of variola produced by inoculation.

ANATOMICAL CHARACTERS.—The characteristic lesion of smallpox is the eruption. The successive stages of the eruption are the macule, the papule, the vesicle, and the pustule. The pustule undergoes desiccation. The macule is a reddish, slightly-elevated spot due to congestion of a circumscribed portion of the skin. The microscope shows that in this stage the capillaries of the papillæ of the corium are dilated, tortuous, and elongated. The connective tissue of the papillæ is slightly œdematous. The *papule* is due chiefly to swelling of the epithelial cells of the rete Malpighii, and to the appearance in the same situation of little cavities containing a clear fluid. It is to be noted that cavities holding fluid are present in the papule as well as in the vesicle; but in the former they are so small that the vesicular structure is not evident to the naked eye. The swelling of the epithelium and the small cavities are present chiefly in the middle layers of the rete Malpighii. Weigert¹ has shown that in the centre of the pock the lowest cells of the rete Malpighii have undergone a peculiar metamorphosis, by which they are transformed into irregularly-shaped opaque masses devoid of nuclei. To this change he has given the name *diphtheroid metamorphosis*, as it resembles the change described by Wagner as occurring in the epithelium of mucous membranes in diphtheria. The metamorphosis belongs to the group of the coagulation necroses. Weigert regards this necrosis of cells in the rete Malpighii as the first and the characteristic effect of the smallpox poison upon the skin. The diphtheroid metamorphosis affects only a certain number of cells in the base of the pock.

Another alteration which many of the epithelial cells undergo is the formation in their protoplasm of spaces or cavities containing a clear, serous fluid. This alteration has been called *serous infiltration* and *vesicular or dropical transformation* of the cells. The cells in the upper and the middle layers of the rete Malpighii are those chiefly affected. At first a clear ring forms around the nucleus; and this transparent zone increases in size until nearly the whole cell is converted into a cavity, the wall of which is formed by the outer border of the cell. In this vesicular transformation the cell becomes swollen, so that the cavity may be larger than the original cell. The boundaries separating adjacent cell-cavities may become ruptured, so that by the coalescence of several cavities larger spaces with irregular walls are formed. In this way many explain the formation of the *vesicle* out of the *papule*. According to this view, in the *papule* a large number of the epithelial cells in the upper Malpighian layers become swollen and transformed into cavities, the

¹ *Anatomische Beiträge zur Lehre von den Pocken*, Breslau, 1874, Theil i.

walls of which are represented by the condensed peripheral layers of the cell. These cavities by rupture of their walls open into each other, and when large spaces containing a clear fluid have thus been formed the appearance is that of the characteristic smallpox *vesicle*. The interior of the vesicle is subdivided by a network or reticulum composed of altered epithelial cells; but the vesicular transformation of cells is not the sole origin of the small cavities of the papule or of the larger spaces of the vesicle. The serum which transudes from the capillaries of the corium penetrates the epidermis, and not only enters the cells, but also makes its way between the cells, which are thereby pushed apart. Thus, spaces containing serum exist between the cells as well as within the cells. The extracellular accumulation of serum and the coalescence of intracellular cavities combine to form the spaces of the smallpox vesicle.

The manner in which the *reticulum* of the smallpox vesicle is formed has been, and is still, a matter of controversy. The reticulum consists of coarse and of fine bands which stretch from the floor to the roof of the vesicle, and which interlace in its interior. It is generally admitted that these bands are composed of more or less altered epithelial cells. Weigert believes that the reticulum is formed in great part of irregular and branching masses which represent cells that have undergone the diphtheroid metamorphosis or coagulation necrosis. Cornil and Leloir are of the opinion that the reticulum is formed mainly by the borders of cells in whose substance cavities have appeared, these borders representing the partitions between the intracellular cavities. All, however, admit that at least some of the bands are composed simply of epithelial cells which have been compressed, elongated, and displaced by the accumulation of fluid between them.

The roof of the smallpox vesicle is composed of the stratum corneum, the stratum lucidum, and often some of the upper cells of the rete Malpighii. The sides of the vesicle are formed of cells in the middle layers of the rete Malpighii, and the floor of the vesicle is composed of the lowest cells of the rete Malpighii, some of which have undergone the diphtheroid metamorphosis. Some of the epithelial cells in the sides and in the base of the vesicle are enlarged, and these often contain two or more nuclei. There is reason to believe that in these situations there is an active proliferation of epithelial cells.

A characteristic appearance of the smallpox vesicle is produced by a central depression in its roof. This depression constitutes the so-called *umbilication of the vesicle*. Not every smallpox vesicle is umbilicated. Vesicles in the palm of the hand and in the sole of the foot are not umbilicated. There have been various theories as to the cause of the umbilication. Some have attributed it to the existence of a sweat-gland or of a hair-follicle in the centre of the vesicle. The umbilication may, however, be present in vesicles which are not formed around hair-follicles or sudoriparous glands. The most plausible explanation is that which attributes the central depression to swelling and proliferation of the epithelial cells in the sides of the vesicles. The influence of this cause is aided by the presence of bands which pass from the centre of the roof to the floor of the vesicle. These bands, the existence of which has already been noticed, act as retinacula which hold down the central part of the roof, while the sides of the vesicle are swollen by the enlargement and proliferation of cells and by the accumulation of serum.

The smallpox vesicle is filled with serum, called, in this situation, lymph. The serum may be perfectly clear, but it usually contains a few pus-cells and some granular material and micrococci. The pus-cells are probably emigrated white blood-corpuscles. A delicate network of fibrillated fibrin is sometimes found in the lymph of the vesicle. The lymph in the vesicles becomes more

and more clouded by the presence of pus-cells. By the accumulation of these cells the vesicle is gradually transformed into a *pustule*. As the pus-cells increase in number the reticulum within the vesicle is destroyed, so that the fully-formed pustule consists of a single cavity. The destruction of the reticulum causes the umbilication to disappear.

In hemorrhagic variola the vesicle becomes filled with red blood-corpuscles instead of emigrated white corpuscles. Between the corpuscles is a network of fibrin.

Pus-cells are found in the connective tissue of the corium, especially around the vessels of the papillæ. These pus-cells, which are undoubtedly emigrated white blood-corpuscles, are present in large number during the pustular stage. The pustule may extend in depth in consequence of suppuration of the upper layers of the corium. The cicatrices or pock-marks which follow an attack of variola are extensive and deep in proportion to the extent to which the corium is involved in the suppurative process during the pustular stage.

During the stage of desiccation the contents of the pustule disintegrate and dry up. After the pustule ruptures and discharges its contents brownish scabs are formed by the desiccation of the pustular contents. Beneath these scabs the epithelium is regenerated, the new cells being produced by proliferation from the intact epithelial cells.

In a number of cases of smallpox Weigert observed colonies of micrococci in blood-vessels and lymph-spaces in the corium, as well as similar colonies in the vesicles. These micrococci are to be regarded as a complication, and not as concerned in the causation of the disease.

The occurrence of the variolous eruption upon the mucous membranes of various parts of the body will be described in connection with the Clinical History. Parenchymatous degeneration of the liver, heart, and kidneys has been observed in cases of smallpox. Colonies of micrococci are often found in internal organs. The formation of abscesses is rare. The spleen is sometimes swollen. Ecchymoses are very frequently found in the mucous membrane of the renal pelvis and of the ureters. In variola hemorrhagica, hemorrhages are present in the interior of the body as well as upon the surface. They are found in the mucous membrane of the air-passages, in the lungs, in the mucous membrane of the alimentary tract, especially of the stomach and rectum, in the uterus, and rarely in the Fallopian tubes and ovaries or in the testicles. Punctate hemorrhages are present in the serous membranes and in the pia mater. The complications of smallpox, which are many, will be noticed under the head of Clinical History.

CLINICAL HISTORY.—Differences pertaining to the eruption and other events embraced in the clinical history in different cases are so great that writers have made several varieties of the disease. The division into *confluent* and *discrete* or *distinct variola* is generally adopted. In the latter variety the vesicles and pustules are separate or distinct from each other. In the former variety coalescence of the vesicles or pustules takes place. In cases in which coalescence exists to a greater or less extent, but not over the whole or the greater part of the surface of the body, the disease is said to be *semi-confluent*. When the eruption has a hemorrhagic character the disease is called *hemorrhagic variola*. Without considering these varieties under separate heads, I shall notice their distinctive features in connection with the symptomatology of the several stages of the disease.

Stage of Invasion.—The disease is ushered in by a chill in the great majority of cases, and the chill is usually more marked than in the other eruptive fevers. In some cases a series of chills occurs, alternating with flushes of heat. Febrile movement follows, accompanied generally by more or less perspira-

tion. The latter is likely to continue or to recur more or less frequently up to the time of maturity of the eruption—a feature distinctive of this as compared with the other eruptive fevers. The febrile movement is known as the primary fever. It is often intense, the thermometer sometimes showing a rise to 104° or 105°. Nausea and vomiting are often prominent symptoms in this stage. The tongue becomes coated. Pain is referred to the epigastrium, accompanied by tenderness on pressure, either with or without notable nausea and vomiting. Generally, the bowels are constipated, but diarrhoea is sometimes present, especially in children. Cephalalgia, pain in the limbs, and general debility are more or less marked, as in the early part of other essential fevers; but in this fever pain in the loins is usually a marked symptom and possesses diagnostic importance. Incomplete paraplegia is occasionally observed, generally disappearing with the development of the eruption. Paralysis of the bladder, giving rise to retention of the urine, sometimes exists without paraplegia. Convulsions often attend the development of this disease in children, and sometimes occur in adults. Delirium is an occasional symptom.

If the symptoms in this stage be mild, the eruption will probably be discrete; but if the chill be notably marked, the pyrexia intense, the lumbar pain severe, etc., it may be expected that the disease will prove to be of the confluent variety.

The duration of this stage, as a rule, is two days. The eruption begins to appear on the third day after the attack. There are, however, exceptions to this rule. In some cases the eruption appears on the second or on the fourth day. The duration is sometimes extended to the fifth or sixth day, and occasionally even longer. The eruption, if it appear on the second day, may be expected to be confluent, and on the other hand in proportion as the appearance of the eruption is protracted beyond the third day mildness of the disease is to be expected. Two events relating to the skin are of occasional occurrence in this stage. One of these is a cutaneous efflorescence or rash. The whole or the greater part of the surface of the body may be covered with this erythematic redness, resembling the appearance in scarlatina. The disease is liable to be mistaken for scarlatina when this occurs. In other cases the rash is in isolated patches, and it may then bear a resemblance to measles. The patches, however, are not elevated; that is, they are not papular. Small vesicles or sudamina are sometimes observed. The efflorescence appears on the second day and continues only eighteen or twenty-four hours, giving place to the eruption peculiar to the disease.

The other event is the appearance of petechiæ and ecchymoses. These may be more or less abundant. They are sometimes very abundant, covering both the trunk and the extremities. In some cases these foreshadow subsequent hemorrhages, but they by no means always have this significance. They do not always denote severity of the disease, and they are sometimes observed in mild cases. They continue during the greater part of the stage of the eruption.

Stage of Eruption.—The histological structure of the different forms of the eruption has already been considered. It remains to notice the clinical characters of the eruption. The eruption, as a rule, appears first on the face, especially about the lips and chin, and nearly at the same time on the neck and wrists; next on the chest and arms; then over the body; and last on the lower extremities. Its diffusion over the whole cutaneous surface occupies between one and three days. Exceptionally it is first observed on the genital organs, chiefly in young children, and on the loins or nates. It may appear first in the neighborhood of a blister or sore existing in any part of the body. Successive changes take place in the physical characters of the

eruption which in different stages of its progress represent nearly all of the cutanei. At first the eruption appears in the form of small red spots or specks, sometimes having a purplish or livid color. It is now a maculated eruption. The central part of the *maculæ* becomes hard, slightly elevated, and pointed. A change has taken place from a maculated to a papular eruption. In this stage of its progress the eruption is not unlike that of measles, and the disease is liable to be mistaken for the latter. The *papulæ* are smaller, rounder, and harder, and lack the crescentic or curvilinear arrangement which characterizes the eruption of measles. They feel like small shot under the skin. Next, a clear liquid becomes visible in the *papulæ*, which now become *vesiculæ*. This change is observed twenty-four hours after the first appearance of the eruption. After twenty-four hours more—i. e. forty-eight hours from the first appearance of the eruption—the vesicles have acquired considerable size. On the fifth day of the stage of the eruption the vesicles have attained to nearly or quite their full development, measuring from one-quarter to one-third of an inch in diameter, and are raised two-tenths to four-tenths of an inch above the level of the skin. More or less of the vesicles present a depression in the centre. They are said to be *umbilicated*. This appearance is highly characteristic, indeed almost pathognomonic. It is observed in no eruption other than that of variola, except in the vaccine vesicle, and sometimes in ecthyma. This umbilicated appearance may be detected in some of the vesicles, often as soon as the latter are discoverable. The vesicles are multilocular, as has already been described. They contain an opalescent serum.

This is the history of the eruption up to the period when the vesicles reach the maximum of their development if the eruption be discrete. In the confluent variety a diffused redness of the surface precedes the appearance of papules and vesicles. This diffused redness is likely to lead to the error of supposing this disease to be measles. The vesicles when they first appear have not the determinate form of those in discrete smallpox, but run together or coalesce to a greater or less extent. At the end of the period for the full development of the vesicles the face and other parts are covered with patches of greater or less size, in which the cuticle is uniformly raised by opalescent serum, resembling a blister. The whole of the face and the greater part of the cutaneous surface may be covered with coalescent vesicles.

After the full development of the vesicles there is another important change in the eruption. The vesicles become pustules. In other words, suppuration takes place. With this change the external characters are altered. The pocks are more distended. The reticulum is broken up. The central depression is lost, and the pustules become pointed. This change from vesicles to pustules is accompanied by general symptoms which show it to be an important epoch in the clinical history of the disease. Hence with this change begins another stage—namely, the *suppurative stage*, or the stage of *maturation*. This will claim consideration under a distinct head. It will be observed that of the different forms of cutaneous eruption, all except the *squamæ* and *tuberculæ* are represented in the successive changes in the eruption of smallpox—namely, enumerating them in the order of their sequence, *maculæ*, *papulæ*, *vesiculæ*, *pustulæ*, and in the confluent eruption *bullæ*.

The eruption is not limited to the skin. Simultaneously with its appearance on the cutaneous surface it may be observed to a greater or less extent on the mucous membrane of the mouth and throat. It appears here in the form of round opaque spots. As no stratum corneum exists upon the mucous membrane, the formation of typical vesicles and of pustules does not take place. Little erosions and ulcers rapidly form in the site of the eruption. The membrane surrounding the spots is swollen and inflamed. The spots

are observed especially on the tongue and soft palate. They are liable to occur in the larynx, trachea, and bronchi; on the conjunctiva, leading sometimes to ulcers and destruction of the eye; within the nostrils, in the external meatus auditorius, and on the prepuce or vulva. The eruption does not occur upon serous membranes, and probably not on the mucous membrane of the stomach or intestine. In the larynx the eruption may cause laryngitis, which may prove fatal. An instance of this kind has fallen under my observation.

A striking feature of the primary fever pertaining to this disease is either a notable remission or complete apyrexia on the appearance of the eruption. The pulse falls to nearly or quite the normal frequency, and the heat of the skin is but little or not at all above that of health; and the thermometer in the axilla shows a reduction to 100° F. or lower. This is a highly diagnostic feature of smallpox, provided the eruption be not confluent. In the confluent variety this feature is either wanting or is much less marked. As the eruption progresses the febrile movement is gradually developed or increased.

Stage of Suppuration.—With the change of the eruption to pustules, usually on the sixth day after the first appearance of the eruption, there is a recurrence of notable increase of pyrexia, constituting what is known as the *suppurative fever* or the *secondary fever*. The pulse becomes more or less frequent, the heat of the skin is sensibly raised, and the thermometer denotes increase of temperature, especially in the evening as compared with the morning. The perspirations, which up to this epoch are likely to occur, now cease. In mild cases of discrete smallpox the secondary fever continues only for three or four days; but it continues longer in the confluent variety irrespective of any complication. The pyrexia is symptomatic of the affection of the skin, and its intensity, other things being equal, is proportionate to the degree of cutaneous inflammation. More or less redness and œdema of the skin are apparent in the spaces between the pustules. Tumefaction of the face occurs, and is often considerable. The swelling of the eyelids is often sufficient to close the eyes, as in cases of erysipelas. Swelling of the hands and feet occurs in severe cases, especially if the eruption be confluent. The redness and swelling are accompanied by a burning pain, as in erysipelas. Salivation is a frequent symptom. In severe cases of the confluent variety it is often very profuse, and accompanied with more or less swelling of the salivary glands. It is measurably or chiefly dependent on the eruption in the mouth and fauces. It is rarely observed in children. In severe cases delirium is likely to occur in this stage. The delirium is generally passive, like that in most cases of typhoid fever, but it is sometimes active or maniacal. Other ataxic symptoms—namely, subsultus, carphologia, and coma-vigil—may also occur, denoting always a condition of gravity. Coma occurs in a certain proportion of fatal cases. Other symptoms are due either to complications or to anomalous occurrences which will presently be noticed. Diarrhoea is an occasional symptom, and is always an unfavorable omen. The duration of the stage of suppuration is four or five days.

Stage of Desiccation.—This stage begins on about the twelfth day of the disease. The exceptional cases in which it begins much earlier or later are very few. The tumefaction and redness of the skin diminish. The pustules, for the greatest part, break, and the pus concretes into a thick scab. Over patches in which the eruption is confluent there is a continuous scabby crust. The whole face in severe cases is covered as if by a mask, presenting a hideous appearance, and the greater portion of the surface of the body may present a similar aspect. The diminution of the inflammation and the formation of scabs are first observed on the face, afterward on the trunk and upper extremities, and at last on the lower extremities. During

this stage the skin exhales a sickening characteristic odor. In cases in which the eruption is confluent the stench is extremely offensive and may be perceived at a considerable distance. The spectacle in this and the preceding stage, and the fetor, render smallpox the most repulsive and loathsome of diseases. In mild cases the stage of desiccation is the stage of convalescence. The scabs fall off, leaving the skin beneath unbroken, but presenting a discoloration continuing for a long time, and especially apparent when the surface is exposed to cold; but in severe cases the skin beneath the scabs is excoriated or ulcerated, the scabs are liable to be renewed, and troublesome ulcerations sometimes follow. More or less pyrexia in severe cases continues into the stage of desiccation. In mild cases there may remain no permanent traces of the eruption, but in the great majority of cases there are left cicatrices, either circular or linear, which are known as "pitting" or "pock-marks." The amount of pitting will depend on the abundance of the eruption, the size of the pocks, and the depth of the ulcerations. Some of the pocks do not break, but harden, and their contents are absorbed. It is probable that in these the corium is not involved in the suppuration or that the vesicles are not converted into pustules.

To recapitulate the relative duration of the several stages in the majority of cases: The duration of the stage of invasion is between two and four days; of the stage of eruption, about five days; of the stage of suppuration, four or five days; and of the stage of desiccation, between six and ten days—making the duration of the disease in cases ending in recovery between seventeen and twenty-four days. In mild, uncomplicated cases the recovery is usually rapid, but convalescence may be indefinitely prolonged by ulcerations of the skin and other complications.

Various complications and anomalous events are liable to occur in the several stages of the disease. Pharyngitis, dependent on the eruption within the pharynx, is sometimes sufficient to occasion much pain and difficulty of deglutition. Laryngitis, dependent on the eruption within the larynx, is of not infrequent occurrence. It is denoted by huskiness of voice, or aphonia, with, in some cases, more or less difficulty of respiration. The laryngeal inflammation is sometimes diphtheritic. Edema of the glottis is an occasional accident. Bronchitis, also from the eruption, occurs in a certain proportion of cases. Sometimes there is inflammation of the gastric or of the intestinal mucous membrane. This is rarely of the diphtheritic variety. Pneumonitis, pleuritis, and pericarditis are rare complications. Endocarditis, including the acute ulcerative form, has been observed as a complication. Furunculi, or boils, and subcutaneous abscesses are not uncommon, both as concomitants and sequels. Phlegmonous tonsillitis and suppurative inflammation of the cervical lymphatic glands and of the salivary glands occasionally occur. Erysipelas on the face, neck, limbs, or body is not very infrequent. Gangrene may occur on parts exposed to pressure, and sometimes in other parts. Ophthalmia is an important complication, sometimes leading to permanent blindness from opacity or perforation of the cornea. The inflammation in the throat sometimes extends through the Eustachian tube and gives rise to median otitis, which is liable to eventuate in deafness.

Hemorrhage in various situations occurs in a certain proportion of cases. Epistaxis is an occasional early symptom, but does not betoken unusual gravity of the disease. Hæmaturia is sometimes an early and always a grave symptom. Hemorrhage occurring at any period of the disease from the mouth, throat, air-tubes, or bowels, accompanied by petechiæ or vibices, and sometimes by an extravasation of blood into the pocks, characterizes certain malignant cases. Hemorrhagic, scorbutic, and black variola are names applied to the disease as exhibited in these cases. The most dangerous form of

hemorrhagic smallpox is that in which an acute hemorrhagic diathesis develops in an early stage of the disease. The disease has then been called *purpura variolosa*. Death may take place in these cases before any eruption characteristic of smallpox has appeared, and then a diagnosis is possible only from a knowledge of the etiology of the case. In females menstruation may occur, and if not irregular or profuse it is not an untoward event. Metrorrhagia often occurs in hemorrhagic cases.

Albuminuria is a symptom of not infrequent occurrence in severe cases. It is probable that the coma which occasionally occurs is sometimes due to uræmic poisoning dependent on acute nephritis. Orchitis and ovaritis are rare complications. Inflammation of the synovial membranes of the joints, sometimes with serous and sometimes with purulent exudation, is also an infrequent complication. Paralysis of the lower extremities and of the bladder has been known to be a sequel of smallpox. This is due, according to Westphal, to an acute disseminated myelitis.

CAUSATION.—Smallpox is a highly contagious disease. It may be communicated by means of a virus—that is, by inoculation—and by means of inappreciable emanations from the body. The disease is readily transported by means of fomites, which may retain the contagium in an effective condition for months and even years. A very transient and slight exposure often suffices for the production of the disease. Thus, it is not infrequently taken by passing in the street or meeting in public conveyances persons who either are affected or have recently been affected with it. It may be contracted in hackney-coaches which have been used for carrying patients to hospitals. The disease is generally supposed to be communicable in all its stages, but undoubtedly it is most highly so during the stages of suppuration and desiccation. The contents of the vesicles and pustules and the crusts and scabs formed by desiccation contain the contagium; and it is probably contained not only in the emanations from the cutaneous surface, but in the expired breath and perhaps in the intestinal excreta. The disease may be communicated from the dead body by means not only of a virus, but by inappreciable emanations. Thus it has been contracted in the dissecting-room from subjects dead with the disease. It is stated that a cadaver may retain the virus in a condition to communicate the disease for an indefinite period—even for several years.¹ The following instance is interesting as showing the communication of the disease from the dead body, death having taken place before the development of the eruption: “During the winter of 1848–49 a young man, a member of the medical class of the New York University, died suddenly and unexpectedly in the night under the care of a physician who had not thought him seriously ill. I was invited to the autopsy, and observed, when the corpse was uncovered, a few dark-red spots on the surface which were supposed to be petechial, the principal symptoms of his attack having been gastric with great debility, as we were informed. The coffin was taken home to a New England village for burial, where, at the funeral, some of the relatives approached and opened it to see the face of the deceased before it was inhumed. Of this number, eight were attacked with smallpox, no other persons in the neighborhood being assailed.”² Whether the disease be ever produced otherwise than by means of a contagium is, and must always remain, an open question; for with regard to reported cases in which the disease has appeared to originate spontaneously it can always be said that there may have been some unsuspected and untraceable exposure.

¹ Vide *Nouveau Dict.*, art. “Contagion.”

² Vide article by Dickson in the *American Journal of the Medical Sciences*, for July, 1862.

This explanation is more rational than the supposition that the special cause is produced *de novo*.

The susceptibility to the disease exists at all ages, but it is greatest in children. Some persons are wholly insusceptible to it, exposing themselves as fully as possible with impunity. Cases have been observed in which persons have become susceptible after having been insusceptible for many years. Unknown causes peculiar to certain times and places co-operate with the contagium in the diffusion of the disease, so that it prevails as an epidemic. Reference in these statements is had to the production of the disease in the natural way; that is, exclusive of inoculation. The disease is thus produced is distinguished as *natural smallpox*. The negro and Indian races are particularly susceptible to the disease. As a rule, the occurrence of the disease once extinguishes the susceptibility ever afterward. Instances, however, are not extremely infrequent of the disease having been experienced twice, and it has been known to occur thrice.

Certain interesting facts relate to the susceptibility of the *fœtus in utero*. A pregnant woman affected with the disease may or may not communicate it to the *fœtus*. The development of the disease before birth generally causes the death of the child, and cases have been reported of stillborn children presenting the different stages of the eruption. The death of the *fœtus*, however, does not always occur. Healthy children have been born presenting the evidence of having passed safely through the disease in the uterus. In some instances the disease has been contracted before birth, but not developed until several days after birth. Recovery has taken place under these circumstances. The disease may be communicated to the unborn child by the mother after the fourth month of pregnancy, and perhaps before. Finally, the special cause may be received into the system of the mother and the *fœtus* become affected without the mother experiencing the disease. This fact has been observed in cases in which the susceptibility of the mother had been extinguished, either by the disease having been experienced or by vaccination.

The special cause of this disease remains for a certain period latent; that is, there is a period of incubation. The duration of this period varies between five days and nearly three weeks, the average duration probably being between twelve and fourteen days. Facts appear to show that the special cause of rubecula or of scarlatina may be in operation simultaneously with the operation of the special cause of variola; in other words, smallpox may be combined with either measles or scarlet fever. Cases, however, exemplifying these combinations are extremely rare.

During an epidemic prevalence of smallpox cases are sometimes observed in which all the symptoms of the stage of invasion occur without being followed by an eruption. The disease appears to abort spontaneously at the end of the stage of invasion. These attacks resemble febricula, but it has been observed that persons who have had these attacks during the prevalence of smallpox are thereafter insusceptible to the disease, although not protected by vaccination. Hence it has been considered that the disease sometimes occurs without an eruption; and writers have been accustomed to recognize as a variety of the disease *variola sine variolis*.

The question as to what is the essential causative principle, or the contagium, is one of great pathological interest. It was at first thought by Weigert and by Cohn that the round bacteria or micrococci which they have observed in lymph from the vesicles, as well as in other parts, represent the contagious germs of smallpox. This view is now abandoned.

DIAGNOSIS.—The diagnosis of smallpox presents no difficulty after the characters of the eruption are fully manifested; but it is not so easy at an early

period of the stage of the eruption before the vesicles are distinct. In seeking to determine the character of the eruption vesicles should be looked for, and next their umbilicated appearance. This appearance, it is to be borne in mind, is almost pathognomonic. The distinctive characters of the papules, as determined by the touch, are also to be borne in mind—namely, they are granular, hard, and deep-seated. The duration of the stage of invasion is to be considered—namely, from two to three days. The prominence of lumbar pain and vomiting, and especially either a remission or a cessation of febrile movement at the time of the appearance of the eruption, are important diagnostic features. It is to be remarked that lumbar pain is not in all cases a prominent symptom, so that its absence is not entitled to much weight in the exclusion of smallpox. An examination of the throat and mouth should not be omitted. The round, whitish, or ashy spots which are characteristic of the eruption on a mucous surface are generally apparent here as soon as, or before, the eruption appears on the skin. The appearance of the cutaneous eruption successively on the face or neck, the trunk and upper extremities, and the lower extremities is to be recollected.

The diagnosis cannot be made with positiveness prior to the stage of the eruption. Pain in the loins with febrile temperature, taken in connection with the absence of the symptoms which attend the access of the other eruptive fevers and of typhoid fever, should excite a strong suspicion of smallpox, especially if the patient be not protected either by vaccination or by having once had the disease. The exclusion of rubeola and scarlatina by the absence of the symptoms characteristic of the stage of invasion in these diseases is an important step in the diagnosis prior to, and in the early part of, the stage of eruption. When the eruption first appears the differential diagnosis lies chiefly between these fevers. In rubeola the Schneiderian membrane and air-passages, and in scarlatina the fauces, are prominently and early affected, as will be seen in treating of these fevers. Moreover, in rubeola the stage of invasion is longer, and in scarlatina it is shorter, than in variola. In neither rubeola nor scarlatina does the pyrexia remit or cease when the eruption appears. Other affections liable to be confounded with smallpox are lichen accompanied with pyrexia and a secondary syphilitic eruption. The occasional occurrence of an efflorescence and of petechiæ preceding the eruption proper, to which reference has been made, is to be borne in mind. The difficulties attending the diagnosis of purpura variolosa have already been mentioned.¹

The diagnostic points should be fixed in the memory, as, in view of the danger of the diffusion of the disease by exposure before its character is ascertained, an early diagnosis is immensely important. As another inducement for being prepared to recognize the disease promptly it may be added that the ability of the physician is thereby strikingly shown, while, on the other hand, delay or failure to recognize it brings upon him popular censure.

The attempt has sometimes been made by criminals and impostors to simulate the eruption of smallpox by rubbing the skin with croton oil or tartar-emetic ointment.²

PROGNOSIS.—Unmodified or natural smallpox is attended with much danger to life, the ratio of fatal cases being as 1 to 3 or 4. The mortality is very great

¹ Prof. Janeway calls special attention to the danger of mistaking purpura variolosa for malignant measles, typhus fever, ulcerative endocarditis, and purpura hæmorrhagica. Other valuable suggestions are contained in his article on "The Diagnosis of Certain of the Infectious Diseases," *Medical News*, July 17, 1886.

² For an example vide *Report of the Proceedings of the Illinois State Board of Health*, Springfield, Ill., June 29, 1883.

in cases of the confluent, and considerably less in the discrete, variety, the ratio in the latter being as 1 to 10. The death-rate varies between wide limits in different epidemics. The disease is much more fatal to children than to adults, and is especially fatal in early infancy. It is also extremely fatal to aged persons. Death is sometimes attributable to the intensity of the disease *per se*. Life is then destroyed before the eruption is matured and without any important complication having taken place. Instances of this kind are rare. If death take place before the stage of suppuration, it is generally due to some important complication. Complications which are likely to prove fatal are—acute laryngitis, œdema glottidis, pneumonia, acute ulcerative endocarditis, and an affection of the kidneys involving uræmia. The latter is to be suspected in cases in which coma or convulsions occur.

Death not attributable to complications is generally due to inability of the powers of the system to support the cutaneous affection; hence the danger, other things being equal, is proportionate to the amount of the eruption. Confluent smallpox involves a very extensive suppurative inflammation which is likely to lead to a fatal result by exhaustion. Unfavorable prognostics are—great prostration, frequency and feebleness of the pulse, typhoid delirium and other ataxic symptoms, absence or subsidence of redness and tumefaction of the face and extremities, cessation of salivation, diarrhoea, hemorrhage from the mucous membranes, and extravasations on the cutaneous surface.

Death taking place during or after the stage of desiccation is attributable to ulcerations of the skin, boils, abscesses, erysipelatous inflammation, gangrene, continued diarrhoea, etc.

In pregnant women the disease in its severe form is likely to induce abortion or miscarriage, and under these circumstances the result is generally fatal.

TREATMENT.—The treatment of smallpox embraces measures having direct reference to the eruption, and those indicated by the phenomena of the disease irrespective of the eruption; in other words, the treatment is local and general.

The general treatment involves the same principles as do the continued fevers. There is no special treatment. The disease will run its course, and hence the expectant plan is to be pursued. During the stage of invasion the intensity of the febrile movement may be lessened by the use of cold drinks, ice-water, lemonade, carbonated water, allowed as freely as the condition of the stomach will permit, by refrigerant remedies and by sponging the surface of the body with cold or tepid water. If there be hyperpyrexia the wet sheet and sprinkling with cold water may be resorted to, as practised in cases of typhus and typhoid fever. Refrigeration is not objectionable on the score of interfering with the appearance of the eruption. Cathartics are not indicated, but constipation is to be removed by mild laxatives or simple enemata. Remedies to relieve nausea or vomiting and cephalalgia are frequently indicated in this stage. It has been claimed that the sulphites have a modifying effect upon the disease, lessening its severity and danger. Sanson advises the sulphite of sodium in doses of 20 or 30 grs., given every third or fourth hour. He also regards as a useful remedy the sulphocarbonate of sodium, given in the same doses and with the same intervals. I have met with practitioners of experience who from their observations attributed to the sulphites a favorable influence over the disease.

During the stage of the eruption prior to suppuration palliative measures are indicated by continued nausea or vomiting, vigilance, restlessness, diarrhoea in some cases, etc. The various complications which are liable to occur

will also furnish therapeutical indications. It is probable that the mineral acids are useful in this fever as well as in the continued fevers. Alimentation and supporting measures in some cases are important in this stage. These measures are important in the suppurative stage and the stage of desiccation in proportion as the eruption is copious and confluent and the general symptoms are indicative of asthenia. The principles which should govern the use of alcoholic stimulants and tonic remedies in conjunction with concentrated nutriment are the same as in all the essential fevers as well as in other diseases in which danger in the direction of asthenia is more or less imminent.

All the hygienic conditions which are so important in the treatment of typhus and typhoid fever are not less important in the treatment of smallpox; and of these conditions the freest possible ventilation is of especial importance.

The local treatment embraces measures to render the eruption abortive on the face or to prevent the disfiguration caused by pitting. The treatment for this end is called *ectrotic*, this term signifying to miscarry. The ectrotic treatment, extending more or less over the body, has been supposed to be useful by limiting the amount of cutaneous inflammation, and thereby the degree of secondary fever and danger from exhaustion. Of the various ectrotic measures which have been tried, the following have been found measurably successful:

1. The careful evacuation of the vesicles by means of a fine needle. This plan was advocated by Rayer. It calls for much patience on the part of the operator.

2. Evacuation of the vesicles and cauterization by means of a fine-pointed stick of the nitrate of silver. This also is a very tedious operation. It is highly recommended by Velpeau, Bretonneau, and others.

3. The application of the tincture of iodine once or twice daily by means of a brush while the eruption is papular. This plan was introduced by Crawford of Montreal and Samuel Jackson of Northumberland, Pa. The effect was observed by Sargeant in thirty cases, the treatment being limited to one side of the face. There was but little swelling on the side on which the iodine was applied; the vesicles were flattened; and the pitting, although not prevented, was evidently diminished.

4. The exclusion of light and air was recommended as an ectrotic measure by the late Dr. Picton of New Orleans. This is effected by covering the face with a plaster of some kind. Covering the face with gold-leaf, as practised by the Egyptians, according to Larrey, must be useful chiefly by excluding light and air.

5. The application of a mild mercurial ointment spread on cloth has been highly recommended by authors in different countries. The risk of producing the constitutional effects of mercury is an objection of considerable moment to this plan. Mercurialization is certainly not desirable in smallpox. In view of this risk Bennett was led to substitute for the mercurial ointment calamine saturated with olive oil, and this application he found to be usually effective. Skoda and Hebra recommend the application of compresses dipped in a solution of corrosive sublimate (grs. ij–iv to water ℥vj). Niemeyer preferred a weaker solution (gr. j to ℥vj).

6. The application of the subnitrate of bismuth and prepared chalk in equal parts twice daily, after smearing the surface with sweet oil, is stated to be an effective ectrotic measure by Hamilton of Illinois.¹

7. Stokes advised the application of poultices over the face as the surest method of preventing disfigurement. They should be applied at the earliest

¹ *American Journal of the Medical Sciences*, Oct., 1865.

agreeable to the patient.

A solution of gutta-percha in chloroform was used by Wallace. The *modus operandi* of the gutta-percha is solution, the effect being produced by the exclusion of air.

9. Carbolic acid has been used with success by Lemair. acid is to be liquefied by alcohol, and applied by means of oil brush as soon as the contents of the vesicles begin to

10. The application of cold wet cloths to the skin is an efficient ectrotic measure.

Aside from ectrotic measures, the local treatment consists of lotions to abate undue heat, a weak solution of the chloro-septic and to allay pruritus, soothing unguents in the sun-absorbent powders. If ulcerations follow the falling off require the same applications as ulcers occurring under

It should be an object of treatment to prevent the entry on the conjunctival membrane. The continued application with cold water is advisable for this object.

With a view to prevent diffusion of the disease patients charged from hospital, or if treated at home allowed to surface is completely free from scabs and repeated treatment been employed. All articles of clothing worn during to left at the hospital, or in cases in private practice destroyed as a means of destroying the contagium should not be worn by visitors, after visiting patients affected with this disease. Patients until after having been sufficiently in the open air to be dissipated by free ventilation. The hands should be washed after leaving the hospital or house, and change of dress to patients, especially young children, is to be recommended.

Modified Smallpox, or Variola

Thus far, smallpox has been considered as produced by contagion or the contagium in fomites—that is, natural smallpox unmodified by vaccination. Materially modified as vari-

China and Persia. Imported into Turkey, the practice was introduced thence into Great Britain by Lady Mary Wortley Montague in 1721. It was not adopted in France until 1764. In the same year of its introduction into Great Britain a large number of persons in Boston and the vicinity were inoculated by Zabdiel Boylston. Boylston was the first to note this important fact relating to variola produced by inoculation: namely, that the average period of incubation is shorter by several days than in cases of natural smallpox. Hence the production of natural smallpox may be anticipated and prevented by inoculation after known exposure to the miasm of the disease.

The eruption in cases of inoculated smallpox or after variolation is usually slight. The pocks rarely exceed one hundred. Many of them abort; that is, they do not proceed to suppuration. The secondary fever is slight or wanting. There is very little constitutional disturbance and the disease leaves little or no pitting. These statements are true in the main. Exceptionally, when inoculation was largely practised the disease was severe. The rate of mortality was exceedingly small, varying, according to Shattuck, in 23,000 cases in Boston between 5 and 30 deaths in 1000. Transferring the virus from persons successively inoculated, the disease becomes progressively more and more modified, until at length, as a rule to which there are exceptions, the eruption consists only of the pustule formed at the point of inoculation, with a few pustules developed around this mother-pustule.¹

As a rule, variolation affords complete protection ever thereafter against smallpox. For those who availed themselves of it, therefore, it was a great blessing prior to the discovery of vaccination; but it contributed to the diffusion of the disease by multiplying the foci of contagion, and since the discovery of vaccination it has ceased to be resorted to as a means of avoiding the danger and disfigurement of natural smallpox. Under certain circumstances, however, the physician is not only justified but it is his duty to practise inoculation. These circumstances are the known exposure of persons who have never had the disease and who are unprotected by vaccination, and an inability to obtain the vaccine virus. Inoculation should then be resorted to in order to secure the great advantages of modified smallpox. The late Prof. Dickson advocated a restoration of the practice of inoculation, in addition to vaccination, with a view to test the protective power of the latter, and to destroy as completely as possible all susceptibility to the disease.²

At the present day in most cases of varioloid the modification is due to vaccination. Vaccination does not always afford complete protection against smallpox, but in general the disease is materially modified.

In varioloid the primary or eruptive fever in the stage of invasion is often as marked as in cases of natural smallpox. The duration of this stage may be longer than the average duration in ordinary variola. The eruption is usually far less copious; a few pocks only may appear, and the eruption may even be limited to a single pock. The eruption passes more rapidly through the successive changes, the maturation being completed in five or six days. Frequently the eruption aborts to a greater or less extent. It may stop at the vesicular, and even at the papular, period. More or less of the vesicles dry up without breaking. The general symptoms, as a rule, are much milder than in most of the benign cases of natural smallpox. The secondary fever is either slight or wanting, and the convalescence is speedy. Exceptionally, cases are severe, and the disease proves fatal in a ratio varying between 7 and 10 per cent.

² *Am. Journ. of Medical Sciences*, July, 1862.

Smallpox is modified in a certain proportion of cases spontaneously; this is, irrespective of inoculation or vaccination. Cases presenting the character of varioloid occurred prior to the practice of inoculation and the discovery of vaccination. They were, however, rare. Finally, modified smallpox varioloid is likely to be the form of the disease when it occurs in those who have before experienced it. In all cases of varioloid it is to be borne in mind that the disease is essentially variola or smallpox, and that, however mild may be the cases, they are capable of communicating to persons unprotected a severe and fatal form of the disease.

The DIAGNOSIS in cases of varioloid offers difficulties which do not obtain in cases of unmodified smallpox. The disease most likely to be confounded with varioloid is rubeola or measles. The different points will be stated in treating presently of the latter disease.

In cases of varioloid oftener than in ordinary variola the eruption is liable to be preceded and accompanied by an efflorescence bearing considerable resemblance to scarlatina. Until the variolous eruption is developed the disease may be supposed to be scarlatina. The occurrence of papules in the midst of the efflorescence and the remission or cessation of pyrexia are the differential points. Moreover, an examination of the mouth and throat may show the characteristic eruption here before its distinctive characters on the skin are apparent. The occurrence of a scarlatiniform eruption explains in some cases the supposed coexistence of variola or varioloid and scarlatina. An eruption resembling that of varicella has been observed in some cases of varioloid (*variola varicelloides*).

The TREATMENT of varioloid does not claim separate consideration. The same principles are involved as in the treatment of ordinary smallpox. The comparative mildness in the great majority of cases renders active treatment unnecessary. Usually little is required except hygienic measures.

Vaccinia, or Cowpox.

Vaccinia and cowpox are names of a disease of the cow which, communicated to man, destroys in the great majority of cases for a certain period the susceptibility to smallpox, and in the cases in which it does not offer complete protection against the latter disease renders it, as a rule, mild and devoid of danger. Cowpox is transferred to man and from one person to another by the introduction of a virus, and never at a distance by infection. The operation for its communication is called *vaccination*. For the employment of vaccination as a means of preventing smallpox the world is indebted to the immortal Jenner. The discovery was promulgated by Jenner in 1798, after a series of observations and experiments which had occupied his attention for twenty years. The fruits of this transcendently important discovery have been the saving of an incalculable number of lives which would otherwise have been destroyed by one of the most loathsome of diseases, and the prevention, to an extent which cannot be computed, of the disfigurement and other distressing effects which smallpox is liable to produce when it does not prove fatal. Of all the benefactors who have ever lived, no one has conferred on mankind such immense, palpable, and time-lasting benefits. Yet outside of the ranks of the medical profession how many are ignorant of the name of the discoverer of vaccination! The practice of vaccination met at the outset with much hostility, but Jenner lived to see it triumph over all opposition, and to witness the beginning of beneficent results which will accumulate from age to age until the end of the world. The practice was introduced into this country in 1799, notwithstanding a bitter popular prejudice, by Benjamin Waterhouse of Boston, the first professor of medicine in Harvard University.

Connected with vaccinia and vaccination are questions of great interest and importance which have given rise to extended experimental and statistical researches, as well as much discussion. They have occupied a considerable share of medical literature since the time of Jenner. Certain points are still unsettled and claim further investigation. The scope and character of this work allow of only a brief statement of facts and the opinions most consistent with existing knowledge, considered with direct reference to the practice of medicine.

Directing attention first to the descriptive history of vaccinia in man, on the third day after vaccination (the operation being usually performed on the arm near the insertion of the deltoid muscle) red points slightly elevated—that is, small papules—are apparent at the spots where the vaccine virus was inserted. On the fourth day the papules are more developed and reddened. On the fifth day vesicles are discoverable. The vesicles increase, presenting an umbilicated appearance, and on the eighth day they attain their full development, being elevated two to three lines and measuring one-third of an inch in diameter. The vesicles, like those of smallpox, are multilocular, flattened at the summits, and contain a transparent viscid liquid called the vaccine lymph. On the seventh or eighth day a red areola is apparent, extending one to three inches around the pocks, increasing in redness until the ninth or tenth day, and the contents of the vesicles become more or less purulent. At this time there usually is slight pyrexia with some local pain and pruritus. The lymphatics of the arm become swollen and the glands in the axilla may become enlarged and tender. On the tenth or eleventh day the pyrexia subsides and the redness around the pocks diminishes. A dark spot soon appears in the centre and gradually extends over the whole of the pocks. The pustules desiccate, and at about the fifteenth day they are converted into black hard scabs, which fall off usually at about the twenty-fifth day from the date of the vaccination. During the progress of the vaccine affection vesicles having the distinctive characters of vaccinia have sometimes been observed on other parts of the body. It is probable that these are caused by the patient scratching the vesicles on the arm and carrying therefrom lymph containing the virus on the finger-nails to parts where, owing to the abrasions of the skin, self-vaccination is the result. Experiments show that between the fourth and the ninth or tenth day the characteristic vesicles may be multiplied at will by revaccinating with lymph from the vesicles produced by the primary vaccination. Lichenous or vesicular eruptions, the latter lacking the distinctive features of vaccinia, not infrequently accompany or follow vaccination. Finally, permanent cicatrices denote the situation of the vaccine pocks. The cicatrix, provided the vesicle have pursued a regular course and subsequent ulceration have not occurred, is characteristic, presenting a series of depressions or pits. The period of incubation in vaccinia is sometimes considerably protracted in consequence of the existence of some other affection or from causes which are not apparent.

A most important practical point connected with vaccination is the discrimination of veritable and complete vaccination from an incomplete or a spurious affection. The development of vesicles of full size, the successive stages, and the duration of the affection, together with the characteristic appearance of the vesicles and the cicatrices, are the criteria for determining this point. Simple sores having no specific character may be the result of vaccination. Incomplete vaccinia—*vaccinoid*, as it was termed by Trousseau—is denoted by the vesicles being developed more quickly and progressing to desiccation more rapidly, by their swollen size and conoidal form, and by the absence of cicatrices or of the appearance distinctive of the true vaccine cicatrix. In view of the immense importance of a true and perfect vaccina-

tion to those who suppose themselves to be protected against smallpox, the responsibility of performing vaccination should never be undertaken by those not practically familiar with vaccinia. It is obviously far better that a person should not have been vaccinated, with a knowledge of the fact, than that he should incorrectly believe himself to have had veritable and complete cowpox, since this belief involves a false security leading to exposures which might otherwise be avoided.

It is now generally believed that cowpox is not identical with smallpox, although allied to it. The virus obtained from the cow by inoculating with the smallpox virus (retro-vaccination, as it is called) is not only unreliable as affording protection against smallpox in man, but it has been found repeatedly to communicate the latter disease. Vaccine virus thus obtained is therefore never to be employed in vaccination.¹ Experiments seem to have confirmed the correctness of the opinion held by Jenner that an affection sometimes seen in horses, known as *grease*—called by the French *des cour-jambes*—is identical with cowpox, and that vaccinia in man may be derived from this source. As to the origin of the disease in the cow, the view is entertained that cowpox is a disease *sui generis*, and there is no positive proof that it is usually or necessarily derived from any other animal. The vaccine lymph contains bacteria, but whether these organisms represent the contagium of the lymph or not is a question still undecided. The experiments of Chauveau have rendered it probable that the contagium is a molecular substance, and is not dissolved in the lymph.

Other questions, the importance of which is obvious, are, What degree of protection against smallpox is afforded by cowpox? and, What are the causes of the protection not being universal and complete? In a large majority of cases vaccination affords, for a time at least, absolute protection against smallpox. In these cases the situation of persons vaccinated, as regards susceptibility to the latter disease, is precisely as if natural or inoculated smallpox had been experienced; but in a minority of cases the protection is only partial. The susceptibility to smallpox is not destroyed, but the disease is materially modified, constituting what is called *varioid*. At certain times and places, the causes which give rise to the epidemic prevalence of smallpox being unusually efficient, a considerable number of vaccinated persons become affected with varioid. Owing, however, to the comparative mildness of varioid, the rate of mortality is very small, and therefore fails to represent the relative number of vaccinated persons who become affected with modified smallpox. It is to be remarked that smallpox in a certain proportion of cases is experienced a second time. From the following statistics it would appear that not much more protection is afforded by the occurrence of variola than by vaccination: Of 5774 boys admitted into the Royal Military Asylum at Chelsea, England, in forty-eight years, 1950 had, on admission, marks of smallpox, and 3824 either had marks of vaccination or they were at once vaccinated. Of the former, 6.15 per 1000, and of the latter, 7.06 per 1000, contracted smallpox subsequently during their residence in the asylum.²

The opinion widely prevails, and appears to be well founded, that the extent of protection afforded by cowpox is less in the latter than in the former part of the period which has elapsed since the discovery of vaccination; that is, a larger proportion of vaccinated persons have had varioid of late years than heretofore, and hence many have been led to entertain the belief that the vaccine virus has deteriorated in consequence of its transmission from person to person.

¹ Vide *Journal of the Gynecological Society of Boston*, April and June, 1872, report of discourse by Dr. Henry A. Martin.

² Vide *Reynolds's System of Medicine*.

Another reason for the increase of varioloid among those who have been vaccinated is, that the protective influence of vaccination diminishes after the lapse of a certain number of years. Varioloid occurs much oftener among those more or less advanced in life than among the young. The length of time which has elapsed after a vaccination may fairly be considered as entering into the etiology of varioloid. The importance of revaccination rests upon this fact. Revaccination after the lapse of a greater or less number of years is completely successful, as regards the production of the vaccine disease, in a considerable proportion of cases; and partial success, as shown by imperfect or vaccinoid vesicles, is still more common. The epidemic prevalence of smallpox, embracing many cases of varioloid among vaccinated persons, has been promptly and completely arrested by universal vaccination and revaccination.

The importance of revaccination being admitted, the inquiry arises, How often should it be resorted to? There is no known law governing the duration of the protective influence of a single vaccination. Probably the duration varies widely in different persons, and some persons are protected by one vaccination for life. Some have thought that revaccinations should be practised as often as every three years, and others that an interval of twenty years or more is allowable. It is evidently better that the period should be needlessly short than too long. With our present knowledge the propriety, if not importance, of revaccinating every five years is to be advocated. In case of known exposure or when smallpox prevails as an epidemic it is proper to revaccinate without regard to previous vaccinations. Revaccination, in fact, is always proper as the readiest and safest test of insusceptibility to smallpox.

There is ground for the belief that the frequent occurrence of varioloid, and also of unmodified smallpox, among those who suppose themselves to be protected by having had cowpox is due in no small measure to imperfect or spurious vaccinations. In this country vaccinators are often unqualified persons. The operation is performed not infrequently by those who make no pretensions to medical knowledge, and to a great extent by irregular practitioners. In many cases persons vaccinated are never seen after the operation, they or their friends undertaking to judge for themselves of its success. Hence many persons are either wholly unprotected or but partially protected.

A cause of inadequate protection is an insufficient number of vaccine vesicles. Many have supposed that a single vesicle is all that is required, and that the only advantage of inserting the virus in more than one spot is to diminish the risk of failure to procure a single vesicle. In many parts of this country it is not customary to procure more than one or two vesicles. Facts show that the number of vaccine-vesicles has a decided influence on the amount of protective influence of cowpox. The following results of the analysis, by Simon, of nearly 6000 cases of smallpox contracted after vaccination, with reference to the proportion of deaths to the number of cicatrices, are interesting connected with the present topic: The ratio of deaths among those who stated that they had been vaccinated, but who presented *no* vaccine cicatrix, was 21½ per cent.; among those who had *one* cicatrix, 7½ per cent.; among those who had *two* cicatrices, 4½ per cent.; among those who had *three* cicatrices, 1½ per cent.; and among those who had *four or more* cicatrices, ½ of 1 per cent.¹ In a primary vaccination it is desirable that from four to six vesicles should be produced on each arm. The number should not be less, after known exposure to smallpox, in secondary vaccinations. A less number, however, may suffice when it is desired only to test the fact of protection by previous vaccinations.

Within the past few years an important practical question relating to vac-

¹ Aitken, *op. cit.*

cination has arisen. In 1866 a case of spontaneous cowpox was discovered at Beaugency in France. The virus obtained from this animal was perpetuated, through successive inoculations in heifers conducted by Depaul under the sanction of the French Academy of Medicine and with the aid of the French government. The virus from this stock having been imported into this country by Dr. Henry A. Martin of Boston in 1870, he has kept up the supply through a continued series of heifer vaccinations; and since that date the supply has been kept up from virus derived from this stock in New York and some other cities. The terms animal and bovine virus are used to distinguish that derived immediately from the heifer, that derived from the human subject being called humanized virus. The important practical question is whether the animal virus affords greater protection against smallpox than the humanized virus? That the latter has deteriorated in consequence of removals from the cow seems certain. Vaccination with the long-humanized virus is less constantly successful in producing vaccinia than formerly; the revaccination of persons who have been vaccinated with this virus is oftener successful, and a diminished protection is shown by the greater number of vaccinated persons who become affected with varioloid. The opinion that vaccination with the animal virus secures a more complete and a longer exemption from the danger of contracting smallpox, is shared by many, and this virus is now extensively used in this country instead of the humanized virus. It remains to be determined by the results of a long experience whether—assuming that at the present time the animal virus has a greater protective power—this power may not become deteriorated by distant removals from Beaugency stock in heifers, as there is reason to believe has been the case in the human race. This, however, is a consideration which concerns the future; and a deterioration, if it occur, would only render it important to take advantage at different periods of other instances of vaccinia of spontaneous origin in the cow, in this way renewing the stock.

Vaccinia in man produced by the animal virus differs in certain respects from the disease produced by the long-humanized virus. The full development of the vaccine pock requires a longer period; the pock continues to increase for several days after the eighth day, this being the period required for the full development of the pock after vaccination with the long-humanized virus; and the pock is of larger size. The crusts are not formed until the eighteenth or nineteenth day, and they remain adherent until between the twenty-fifth and the thirty-fifth day. The vesicle does not spontaneously rupture, and the crust preserves the form of the vesicle with the umbilicated centre. The constitutional symptoms are more marked. In a small proportion of cases (1 in 50) a vesicular eruption occurs over the body, and the vesicles on close inspection are found to be umbilicated. The development of a rosular eruption after vaccination has also been observed, but this is rare. With respect to these points of difference, the disease as now produced by the animal virus corresponds with the disease as described and delineated by the earliest vaccinographers—a fact which in itself renders probable the deterioration of the humanized and the superiority of the animal virus.²

Assuming that the animal or bovine virus is equal to the humanized in its protective power (and at least this must be conceded), there are certain advan-

¹ The term *spontaneous* is here used to distinguish it from the disease produced by retro-vaccination. Whether cowpox be ever in a broader sense spontaneous is an open question.

² Vide Discourse by Dr. Martin in *Journal of the Gynecological Society of Boston*; also, "Practical Remarks on Vaccination," by Dr. Frank P. Foster, in *Newman's Handbook of Skin Diseases*, translated by Bulkley, and in article on "Vaccination" in *Pope's System of Practical Medicine*, by American Authors, Philadelphia, 1883, vol. 1; also, *Sur le Cowpox découvert à Poussy*, par Bousquet, Paris.

tages which the former has over the latter. There is far less liability to local accidents—namely, ulcerations and erysipelas. Dr. Martin states that in April, 1872, there had been at least 400,000 revaccinations made in this country with the Beaugency virus, and no case of death, of erysipelas, or of post-vaccine variola had been reported among them. Another advantage is a more uniform success in both primary vaccinations and revaccinations. Another is that the supply of virus can always be made to meet the demand. Again, an advantage which has only to be named for its importance to be apparent is the fact that the virus from the heifer is incapable of communicating syphilis. Granting that the risk of syphilis is small when humanized virus is used, there is nevertheless a risk; and syphilis has repeatedly been communicated. It is an immense advantage to eliminate all danger in this direction.

Deterioration of the humanized virus is to be added to the causes previously enumerated of the apparent inadequateness of vaccination to afford complete protection against smallpox. Assuming that this obstacle may be overcome by the use of animal virus, the other causes are removable; and were they to be entirely removed it is not improbable that the expectation which Jenner cherished of exterminating smallpox might be realized. Certain it is that were all the requisites for the most perfect vaccination to be invariably observed, and if all persons living were vaccinated and revaccinated, smallpox, if not exterminated, would be insignificant as regards its prevalence and severity. The difficulty of securing for all mankind a protection against the disease almost complete is not so much in the insufficiency of the means as in enforcing their adoption to the fullest possible extent. Vaccination and revaccination, in order to be universal, must be compulsory, and authoritative measures to secure the proper and successful performance of the operation are essential. To consider the most efficient legal provisions to accomplish these desirable ends would be to open up a wide field for discussion, which would be inconsistent with the objects of this work. Strange as it may seem, there are persons, not without intelligence, at this day who entertain toward vaccination the prejudices which Jenner had to encounter.

It remains to notice some practical points relating to the operation for vaccination. The situation for the introduction of the vaccine virus should always be that usually selected—namely, on the arms near the insertion of the deltoid muscle. Uniformity of practice in this respect enables physicians and others to ascertain without delay or doubt the fact of a previous vaccination, and to judge of its success by an examination of the cicatrices. The vaccine lymph is to be preferred to the crust. The lymph is usually taken on ivory points or pointed quills, but the virus taken in this way to be effective must be recent. With a view to preservation the lymph may be withdrawn from the vesicles in glass capillary tubes which are at once sealed by means of a spirit-lamp. Jenner considered it a "golden rule" never to take the virus from a vaccine vesicle for the purpose of vaccination after the efflorescence is formed around it. A crust enclosed in wax and covered with tin-foil retains its activity for a considerable period.

As regards the mode of vaccinating, if dried lymph be used or lymph contained in capillary tubes it may be inserted by means of slight punctures, or by scraping away the epidermis, or by minute scarifications; the latter method being preferable. Having made, with a common lancet, a number of linear and transverse scratches, not deep enough to cause the escape of more than a drop or two of blood, the lymph is to be applied over the scarified spots, which should be five to six in number and not larger than half a dime. If the incisions be sufficiently delicate, the operation gives no pain, and allowing the spots to dry before being covered by the clothing is all that is required.

If the crust be used, a small portion should be dissolved, always at the time of the operation, in a drop or two of water, and applied by means of the lancet over the scarified spots. This is preferable to making punctures and introducing small pieces of the undissolved crust. The latter mode is liable to cause sores which, aside from the annoyance they occasion, may interfere with the specific action of the virus.

The age for the performance of a primary vaccination is a point of importance. Between the second and the third month of infancy is the period to be preferred for vaccination. Any liability to exposure to smallpox, however, renders the operation advisable at an earlier period. It is desirable that the child when vaccinated should be in good health, but the operation should not be delayed on account of illness if there be a liability to exposure to smallpox. If the operation prove unsuccessful, another trial should be made, and if this fail the virus may be introduced a third time. Some persons are insusceptible to cowpox. An insusceptibility is to be inferred from two or three successive failures with virus which has proved successful in others. The attempt to vaccinate, however, should be repeated from time to time, for susceptibility may afterward exist. So long as there is insusceptibility to cowpox there is little danger of smallpox being contracted. Aside from want of susceptibility, and exclusive of inertness of the lymph or crust used, the common cause of failure is undue bleeding from the scarifications, the flow of blood preventing the absorption of the virus.

Troublesome ulcerations occasionally follow vaccination, arising from irritation by the friction of clothing or from an unhealthy condition of the system. These are to be treated like ordinary sores. Erysipelatous inflammation and abscesses may occur. These concomitants or sequels are not always evidence of any fault in the operation or impurity of the matter used. Dr. Henry G. Piffard, however, has reported cases in which the disease of the skin known as *impetigo contagiosa* has occurred as a sequel of vaccination with the virus in crusts both animal and humanized. The liability to the communication of this affection is a reason for preferring lymph to crusts for vaccination.¹ Ignorant persons sometimes attribute to vaccination diseases of any kind which may occur within a few weeks or months afterward, and to charge the physician with having used impure vaccine matter. This impression may be so rooted as not to be removable, and hence a vaccination may very unjustly prove the occasion for a withdrawal of the confidence which the physician had previously possessed. So far as the imputation of communicating human diseases is concerned, it is avoided by using the animal virus; and this is a recommendation of the latter to be added to the advantages already mentioned.

After a known exposure to smallpox, if the person exposed have not been recently vaccinated or if there be any reason to distrust a previous vaccination, revaccination should of course be promptly performed. It is proper to perform it without reference to previous vaccinations, with a view to test the susceptibility and render the security as complete as possible. It has occurred to me repeatedly to vaccinate, under circumstances involving the utmost possible exposure, persons who had never been vaccinated, and thereby to prevent the occurrence of smallpox. In one instance an unvaccinated child lived in the same room and slept with a person who had contracted smallpox. The first operation proving unsuccessful, it was repeated three days afterward with success, and the child escaped. In another instance a patient with measles was supposed to have smallpox and was sent to a smallpox hospital. He had never been vaccinated, and vaccination was at once performed. The

¹ Vide articles by Dr. Piffard in the *New York Med. Journal*, Nos. for June and July, 1872.

vaccine disease was deferred until the measles had run its course. It then became developed and smallpox did not occur. Owing to the relatively short duration of the period of incubation in cowpox, it anticipates the development of smallpox. I have not observed the coexistence of the two affections under these circumstances.

Varicella, or Chicken-pox.

Varicella—or, as it is commonly called, *chicken-pox*—is an affection quite insignificant as regards danger or distressing symptoms. It is important with reference, *first*, to the question as to its having pathological relations with smallpox, and *second*, to its discrimination from modified variola or varioloid.

It is an eruptive disease affecting usually children, but occasionally adults. The eruption is preceded generally by slight constitutional symptoms for about twenty-four hours. The eruption generally appears first on the body, and afterward on the head. It usually is more abundant on the neck, body, and scalp than on the face. The eruption is frequently quite small and is very rarely abundant. It is almost invariably discrete. It is a vesicular eruption from the first. The vesicles contain at first a transparent liquid, which afterward becomes opaline, but not purulent except when they are irritated by scratching. Desiccation occurs between the fifth and the seventh day. The crusts are granular and are rarely followed by cicatrices or pitting. Sometimes bullæ of greater or less size form instead of vesicles. New vesicles frequently continue to appear during the first three days of the stage of the eruption, and even after the desiccation of those which first appeared has begun. During the eruptive stage constitutional symptoms are slight or wanting. The disease is contagious as regards children, but very rarely as regards adults. Experiments made to determine its communicability by inoculation have so generally failed that it is a question whether, in the few instances in which it was apparently successful, the contagion may not have been otherwise received. The period of incubation varies between twelve and seventeen days. Writers have made several varieties based upon differences as regards the size and shape of the vesicles. The ordinary variety, in which the vesicles are about the size of split peas and flattened at the top, has been distinguished as *varicella lentiformis vel lenticularis*, or lenticular chicken-pox. The variety called *varicella coniformis vel conoides*, or *swine-pox*, is characterized by the conoidal form of the vesicles. *Varicella globularis vel globata*, is the name of a variety in which the vesicles are unusually large and are globular in form. The different vesicles in the same case not infrequently present the characters of these three varieties. The division into varieties is of not the least practical consequence.

The name *varicella*, which is a diminutive of *variola*, meaning *little small-pox*, implies that the disease is essentially variolous. It has been considered as a modified form of *variola*, and is so considered by some eminent teachers and writers at the present time. The non-identity of the two affections is established by the following facts: The contagium of *varicella* is never known to give rise to ordinary *variola*, whereas the severest form of the latter disease may be derived from cases of varioloid. Varioloid prevails only during the prevalence of ordinary smallpox, but *varicella* not infrequently prevails when there are no cases of smallpox. *Varicella* is very rarely communicated to adults. This is not true of varioloid. *Varicella* affords no protection against *variola*, and, conversely, persons who have had smallpox contract *varicella*. Vaccination does not protect against *varicella*, and the latter does not interfere with the success of vaccination. It is not settled that *varicella* is ever

If the crust be used, a small portion should be dissolved of the operation, in a drop or two of water, and applied over the scarified spots. This is preferable to making small pieces of the undissolved crust. The cause sores which, aside from the annoyance the with the specific action of the virus.

The age for the performance of a primary vaccine. Between the second and the third month be preferred for vaccination. Any liability to renders the operation advisable at an earlier child when vaccinated should be in good he be delayed on account of illness if there pox. If the operation prove unsuccessful if this fail the virus may be introduced susceptible to cowpox. An insusceptibility successive failures with virus which attempt to vaccinate, however, should ceptibility may afterward exist. Small pox there is little danger of small of susceptibility, and exclusive of common cause of failure is und appearance of blood preventing the absorption.

Troublesome ulcerations of the skin occasioned by the friction of clothing. These are to be treated by the application of a solution of potassium permanganate. Abscesses may occur evidence of any fault in the vaccination. Henry G. Piffard, however, has shown that the virus in cowpox communication of this virus is smallpox cases of varioloid in which the eruption is as cases of variella. The cases of smallpox prevails are generally cases of vari charge the physician with the diffusion of smallpox. sion may be so rapid that it is important to recognize it only in very unjustly by the assurance that the disease is not variol the physician communicating the virus; and it takes already

After a recent vaccination, revaccination is performed to make the vaccinee susceptible to the virus; and it takes already

tyled malignant. The disease has been divided into several varieties on differences in symptomatic characters and intensity. Three are generally recognized by writers—namely, *scarlatina simplex*, *anginosa*, and *scarlatina maligna*. Widely different as are these in respect to gravity and distinctive characters, they are not diseases, and essentially they are identical. A simpler division is into severe scarlatina, but it will suffice to consider incidentally the high belong to the latter, without treating of it separately.

MICAL CHARACTERS.—The eruption on the surface and the morbid changes in the throat constitute the leading anatomical characters in this disease.

There is usually little or no trace of the eruption to be observed on the skin. The eruption is caused by hyperæmia, combined with more or less extensive swelling of the cutis. In a case in which death took place shortly after an intense scarlatinal eruption, Birch-Hirschfeld observed lymphoid cells between the epithelial cells of the rete Malpighii, as well as in the superficial and deeper layers of the corium. He also saw extravasations of blood. Fenwick has called attention to blood-streaks in the lumen of the sweat-glands. The cutaneous affection in scarlatina is to be regarded as a superficial dermatitis of mild degree. In the mildest form of scarlatinal sore throat the mucous membrane covering the tonsils, soft palate, and pharynx is reddened and slightly swollen. The tonsils are frequently enlarged. A phlegmonous inflammation of the throat may occur in severe cases of the variety of the disease designated as scarlatina anginosa. The swelling is then extreme. The submucous and mucous layers become infiltrated with pus-cells. Abscesses form, especially in the tonsils. The phlegmonous inflammation may terminate in ulceration or in gangrene. The phlegmonous inflammation may be limited to the connective tissue in the submaxillary region, and give rise to extensive purulent collections in this situation. Erosion of the large vessels has been caused by this suppurative process in the neck. In some cases of diphtheritic inflammation of the throat has been a frequent attendant on scarlet fever. The fibrinous exudation begins on the tonsils and spreads to the soft palate and to the pharynx. It has less tendency than in diphtheria to extend into the larynx. There is much controversy as to the relation which this diphtheritic affection of the throat bears to scarlatina. There are three prominent views as to this relation. According to the first view, the diphtheritic affection is anatomically the same disease as primary diphtheria, but it is produced by the scarlatinal poison; according to the second view, the disease, both anatomically and etiologically, is identical with primary diphtheria, and it is to be regarded as a complication of scarlet fever; according to the third view, scarlatinal diphtheria differs in its anatomical characters from primary diphtheria. Heubner has attempted to prove, from an anatomical point of view, the non-identity of scarlatinal diphtheria with primary diphtheria, but the differential criteria to which he calls attention are insufficient to distinguish anatomically one disease from the other. According to Wurtz and Bourges, who have lately studied the characters of the pseudo-membrane of scarlatinous angina, it would appear that the variety of diphtheria which appears at an early stage of the disease is non-diphtheritic.

Points to which Heubner calls attention are: 1. The pseudo-membranous deposit is thinner in scarlatinal than in primary diphtheria, so that in the former the membranes are not expectorated. 2. The fibrin in scarlatinal diphtheria is between the epithelial cells and in the connective tissue of the mucosa and submucosa. He could detect no differences between the micrococci present in scarlatinal and those of primary diphtheria (*Beobachtungen über Scharlach-Diphtherie*, *Archiv der Kinderheilkunde*, 1879, xiv. p. 1).

Their observations are based upon a study of eleven cases, in nine of which the membrane appeared at an early period, while in two it was a late manifestation—seven days after the eruption in one case, thirty-six days after it in the other. In the first series the infectious agent of diphtheria—the Klebs-Löffler bacillus—was never detected, while in the second series it was found. In the first series a streptococcus identical in all respects with the streptococcus of Fehleisen—the infectious agent of erysipelas—was always present.—H.]

The inflammatory process may be propagated from the pharynx along the Eustachian tubes to the mucous membrane lining the cavity of the middle ear. Suppurative median otitis, with perforation of the tympanum, and sometimes with consecutive caries of bone, may thus be produced. Swelling and inflammation of the lymphatic glands of the neck not infrequently accompany scarlatinal angina. The glands may suppurate. The mucous membrane of the larynx, trachea, and bronchi is sometimes inflamed. The inflammation in this situation is rarely accompanied by a fibrinous exudation. Lobular pneumonia is an occasional complication of scarlatina. Lobar pneumonia is less frequent. Fenwick has observed parenchymatous degeneration of the gastric tubules in this disease. Peyer's patches and the solitary follicles of the intestine are often moderately swollen. There may be found ecchymoses in the gastric and intestinal mucous membrane, but they are rarely abundant. Dysentery is a rare complication of scarlet fever. The spleen has often been found enlarged. Swelling of the mesenteric glands, as well as of other lymphatic glands of the body, has been observed in a number of cases. Parenchymatous degenerations of the liver, kidneys, and heart occur in scarlet fever. In some cases in which the immediate cause of death has been failure of the heart-power fatty degeneration of the muscular substance of the heart has been present.

The most important sequel of scarlet fever is acute Bright's disease. Some regard this occurrence as a part of the scarlatinal process, and others, as a complication. The kidneys in cases of scarlatinal nephritis present appearances which have been described in the article on Acute Bright's Disease (p. 815). Sometimes small abscesses form in the kidneys in this disease.

CLINICAL HISTORY.—The symptomatic events of the several stages separately will be first noticed, and afterward anomalous events and complications liable to occur in either of the three stages.

Stage of Invasion.—The attack may begin with a chill more or less pronounced, but not infrequently it is wanting. Vomiting is generally an early symptom, especially in children, with, in a certain proportion of cases, diarrhoea. The pyrexia, as a rule, is notably greater than in the other eruptive fevers. Epistaxis is not uncommon. Redness of the fauces more or less vivid may generally be observed in this stage, either with or without a sense of soreness and pain in swallowing. The affection of the throat is due to the efflorescence which appears in this situation before its appearance on the skin. As regards the intensity of the pyrexia, pain in the head, prostration, and general malaise, different cases differ widely, not including cases of unusual severity. In very mild cases the symptoms are so slight that the patient does not take to the bed.

The average duration of this stage is about twenty-four hours, and the eruption usually appears on the second day. Exceptionally, it appears, on the one hand, a few hours after the attack, and on the other hand it may be delayed one, two, three, or more days after the time when it usually appears. A considerable delay in the appearance of the eruption is generally attributable to some complication.

Stage of Eruption.—This stage in children is sometimes ushered in by a transient convulsion, which at this period is not a uræmic symptom. In its development and diffusion over the body the eruption does not observe the same regularity as in smallpox and measles. It oftener appears on the body and limbs before making its appearance on the face and neck, but in a certain proportion of cases it appears first in the latter situations. It is rapidly diffused, extending more or less over the whole cutaneous surface in twenty-four hours. As regards the degree and extent of the efflorescence, different cases differ much. The first appearance is in the form of minute dots or specks. These coalesce, forming irregularly distributed patches, which vary much in size and shape, having irregular or serrated margins. Exceptionally, the eruption remains punctiform; that is, in the form of distinct maculæ or spots. The redness is most vivid and remains longest in situations where the skin is delicate, as the inner surfaces of the arms and thighs and the flexures of the joints. The redness is vermilion or scarlet; it is not uniform like erysipelatous redness, but on close inspection the patches are seen to be studded with points which are distinguished by a more deeply red color. The redness momentarily disappears on pressure, and white lines are produced by drawing a pointed hard substance—for example, a pencil—over the reddened surface. In some cases the whole cutaneous surface is covered with the efflorescence, presenting an appearance which has been compared to that of a boiled lobster. Generally, on passing the fingers over the reddened surface it is felt to be smooth, but in some cases there is a sensation of minute elevations or papules. These are the papillæ abnormally developed, as in the condition commonly known as goose-skin. Occasionally, miliary vesicles are scattered more or less abundantly over the surface. The integument is slightly swollen. This is evident on the face and is apparent to the patient when the hands are closed. The feet are also evidently somewhat swollen. The eruption is sometimes accompanied by more or less burning and pruritus. The eruption attains its maximum of intensity and diffusion on the third day after its first appearance.

There is much variation in different cases in the amount of cutaneous eruption. It is sometimes slight. This is likely to be the case when the throat affection is unusually severe. The eruption then seems to be concentrated within the throat. Occasionally the efflorescence on the skin disappears shortly after its appearance, and afterward returns. It fluctuates as regards vividness, being especially marked in febrile exacerbations, and it is generally more vivid toward evening than in the early part of the day. In anomalous cases, which will presently be referred to, the eruption is wanting.

The throat is more or less affected in the vast majority of cases, but in some very mild cases there is no throat affection. If the throat be but slightly affected, there is simply redness over the tonsils, the posterior part of the pharynx, and extending more or less over the soft palate, with little or no swelling. The affection is then only an efflorescence. In most cases, however, there is more or less swelling of the tonsils, together with a white or ash-colored exudation in greater or less abundance. This exudation is generally not like that which characterizes diphtheritic inflammation. It adheres less closely, is pultaceous, and cannot be detached in strips. It may receive a dark color from matters vomited and from the oozing of blood. In proportion to the amount of throat affection there is pain in deglutition and the voice becomes nasal. The submaxillary and lymphatic glands at the angle of the jaw frequently are swollen and tender. A still greater degree of throat affection belongs among the anomalous events of the disease and characterizes the variety distinguished as scarlatina anginosa.

The tongue early in the disease generally is coated. While the coating

remains, frequently the papillæ projecting through it have the appearance of a number of red points, and the surface of the tongue looks as if cayenne pepper or red sand had been sprinkled over it. This is seen in other affections. Another appearance is quite distinctive of scarlet fever. In the progress of the disease the coating exfoliates, leaving the surface of the tongue clean and reddened; and, the papillæ being enlarged, the appearance is strikingly like that of a ripe strawberry. The strawberry-like tongue is a pathognomonic symptom, and is peculiar to this disease. It is often but not uniformly present. It is due to a condition of the mucous membrane analogous to that of the skin in the cases of so-called *rough* as distinctive from *smooth* scarlatina.

The pyrexia is not diminished, but, as a rule, is increased, after the appearance of the eruption. The frequency of the pulse and the increased heat of the skin are more marked than in any other of the essential fevers. The pulse varies in different cases—which, although more or less severe, pursue a favorable course—between 100 and 130 or 140 per minute. In extremely severe cases, especially in children, it rises still higher. Aside from frequency, the pulse is quick, often vibratory or thrilling, but always compressible, these characters showing excited action without augmented power of the ventricular contractions. The sphygmograph, as in all the eruptive fevers, shows absence of diastole. The skin usually is dry, and the heat, as felt by the hand, is often pungent. The thermometer in the axilla shows an increase of temperature to 105° F., and in severe cases a still greater increase. It has been known to reach 112° F.

During the stage of the eruption anorexia continues, vomiting is not uncommon, constipation exists in some cases, and in some cases there is diarrhea. Thirst usually is urgent. Delirium, manifested by incoherency, generally exists, save in very mild cases. I have known a patient, not considered ill enough to require a watcher during the night, to get up and wander out of doors in a state of delirium. A melancholy instance, illustrative of the importance of watchfulness in the care of patients in the delirium of fever, occurred many years ago at the Louisville Marine Hospital during my term of service. A female adult patient affected with scarlatina, but not considered seriously ill, had been removed to a room by herself in the uppermost story of the hospital building, with a view to isolation. During the absence of her attendant for a few moments she precipitated herself from the window, and, falling upon the pavement, was instantly killed. Restlessness, jactitation, and insomnia are likely to be more or less marked. Albuminuria occurs in a certain proportion (about one-seventh) of cases during the eruptive stage. Transient, slight albuminuria occurs in scarlatina, as in various other affections, without denoting renal disease; but disease of the kidneys forms an important complication in certain cases of scarlatina, and will presently be noticed. The duration of the stage of eruption in the majority of cases is between four and six days. It is sometimes shorter; oftener it is prolonged to eight or ten days; and occasionally it continues for a longer period.

Stage of Desquamation.—The commencement of desquamation marks the beginning of this stage. Desquamation frequently begins with the decline of the eruption and prior to its disappearance. The degree and extent of the desquamation are in general proportionate to the intensity and diffusion of the efflorescence. Desquamation is rarely wanting, save in the cases in which the efflorescence fails to appear. The cuticle is exfoliated either in the form of minute branny scales, called furfuraceous desquamation, or in pieces of epidermis of greater or less size. Occasionally the epidermis of the hands is detached entire and may be stripped off like a glove. This is true also of the epidermis of the feet. Sometimes several successive exfoliations occur.

In cases which pursue a favorable course the febrile movement diminishes with the beginning of exfoliation, and gradually ceases, corresponding improvement taking place in other symptoms. The defervescence is sometimes rapid, but in most cases it is gradual. If the disease be uncomplicated and there be no untoward events, convalescence is declared during the stage of desquamation. The desquamative process is frequently accompanied with pruritus, which in some cases is excessive. Albuminuria occurs in this stage more frequently than in the stage of eruption—namely, in the proportion of one-fourth. As in the stage of eruption, so in the desquamative stage, the presence of albumen in the urine may or may not be indicative of an important renal complication. A recurrence of the eruption may take place during the stage of desquamation.

The duration of this stage is indefinite. It may end in five or six days. The desquamation is generally completed in from ten to twelve days, but exceptionally it continues for several weeks.

The foregoing sketch of the clinical history of scarlet fever applies to cases which are either mild or not extremely severe, and in which the course of the disease is regular; that is, without anomalous events or complications. Certain cases are characterized by extreme gravity of the symptoms at the outset of the disease. The pulse becomes very frequent, numbering 140, 150, 160, or more per minute. The thermometer shows notable hyperpyrexia. Great restlessness, delirium, coma, and occasionally convulsions, are other symptoms denoting severity of the disease. Death may take place in one or two days or sometimes even within a few hours from the attack. A fatal result may take place before the eruption appears on the skin or any pharyngeal redness is apparent. The disease in such cases is truly malignant. Cases of this description are liable to occur in certain epidemics. The gravity in these cases is not due to any complication, but to an unusual intensity of the essential morbid conditions which constitute the disease. Ataxic or nervous symptoms, in like manner dependent on the intensity of the disease, are liable to be developed at a later period—namely, active delirium, typhomania, carphologia, and subsultus tendinum. These symptoms characterize certain cases of severe scarlet fever.

Convulsions, coma, and delirium may be developed as effects of uræmia. Disease of the kidneys is an important complication in a certain proportion of cases. Generally, but not always, in these cases the urine is highly albuminous. Albuminuria, as already stated, may not indicate any important affection of the kidneys if the quantity of albumen be small; and on the other hand grave disease of the kidneys may exist without albuminuria. The presence of casts with white or red corpuscles in the urine is more significant of renal disease than the presence of albumen. The danger of uræmia is proportionate to the scanty excretion of urine. Clinical facts show that scarlatina involves a special tendency to renal disease, not only as a sequel, but as a concomitant. It is a rational supposition that the lining membrane of the secretory tubes of the kidneys takes on a morbid condition analogous to that of the mucous membrane of the pharynx, constituting a local affection which is serious in proportion as the excretion of urea is interfered with. General dropsy sometimes occurs during the progress of the disease as well as afterward. Symptoms pointing to uræmia, in addition to the events already stated—namely, convulsions, coma, and delirium—are cephalalgia, disturbance of respiration occurring without either bronchitis, pneumonia, œdema of the lungs, or any appreciable pulmonary affection, defective vision, vomiting, and occasionally diarrhœa. These symptoms should direct attention to the urine as regards albuminuria, the presence of casts, and especially the deficiency of urea. Uræmia, taking place either as a concomitant

or a sequel of scarlet fever, may occur without albuminuria and without dropsy. Hence the importance of examinations of the urine in all cases, with reference not alone to the presence of albumen, but of casts and the quantity of urea.

Certain cases of severe scarlatina are characterized by a great amount of throat affection. The name *scarlatina anginosa* is applied to these cases. The tonsils are greatly swollen and covered with a muco-purulent, pultaceous deposit. Deglutition is difficult, and liquids taken into the mouth are returned through the nostrils. The inflammation may extend to the posterior and anterior nares, and acrid pus flows from the nose, excoriating the face. The breath emits an intolerable fetor in some cases. Sometimes, but rarely, the inflammation extends into the larynx and bronchial tubes. Edema of the glottis is an occasional accident in adults. The structures of the eye may become involved, and destruction of both eyes has been known to follow. An extension of the inflammation through the Eustachian tube into the middle ear is liable to occur. I have met with a case in which the tympanum in each ear was perforated and the ossicles were discharged through the external meatus. Permanent deafness, facial paralysis, and in some cases caries of the temporal bone, followed by circumscribed meningitis and abscess of the brain, are effects of an extension of the local affection to the middle ear. The submaxillary and lymphatic glands of the neck become more or less enlarged, and sometimes suppuration takes place, constituting what have been called *scarlatinous buboes*. I have met with a case of extensive sphacelation of the lips and cheeks, the patient being a child well nourished and healthy up to the date of the attack. Gangrene and ulceration within the throat are very rare events. The local events belonging to *scarlatina anginosa*, inclusive of inflammation and suppuration of the glands of the neck, may occur early in the disease, or, on the other hand, they may be developed during the stage of desquamation, the symptoms having previously denoted a mild form of the disease. A true diphtheritic exudation in the fauces characterizes certain cases.

In cases of so-called *scarlatina anginosa* the cutaneous eruption may be slight and it is sometimes wanting. Albuminuria is likely to exist in these cases. Uræmic phenomena are liable to occur, but, exclusive of these and of laryngitis or œdema of the glottis, the severity of the throat affection may be sufficient to lead to a fatal result.

Hemorrhages in various situations, together with petechiæ and vibices on the skin, characterize certain cases. The name *hemorrhagic scarlatina* has been applied to these cases. They are almost invariably fatal. Hematuria may occur in connection with renal disease, and if not accompanied by hemorrhage elsewhere is not necessarily of grave omen.

Complications other than those which have been noticed, and of rare occurrence, are articular rheumatism, usually confined to a few joints, vaginitis, pleuritis or pyothorax, pericarditis, and endocarditis (sometimes of the septic ulcerative form), the two latter affections being often associated with either rheumatism or renal disease.

In irregular cases of scarlatina the disease is often, but by no means always, severe. The only local manifestation of the disease may be a slight soreness of the throat, no cutaneous eruption taking place. In these cases the disease has been distinguished as *scarlatina faucium* and *scarlatina sine eruptione*. Cases of the throat affection more or less severe, without any eruption on the skin, not infrequently occur during the prevalence of epidemics of scarlatina. An attack of this kind appears, in some cases at least, to render the patient thereafter insusceptible to the disease, but it is not uncommon for persons who have once had scarlatina in its regular form to suffer from the throat

affection when exposed to the contagium. In cases of *scarlatina sine eruptione* the nature of the disease is not infrequently overlooked. Another irregularity in very mild cases consists in the absence of any affection of the throat, the cutaneous affection being more or less marked. In these cases doubtless the disease sometimes exists without being recognized or it is confounded with roseola. It has been supposed that the disease may exist without either an affection of the throat, a cutaneous efflorescence, or febrile movement. The name *scarlatina latens* has been applied to such cases. The evidence of the existence of the disease in this latent form is the occurrence of characteristic sequels—namely, albuminuria and anasarca—in persons who had been exposed to the contagium without presenting any of the usual phenomena of scarlatina. The local manifestation of the disease in these cases is supposed to be exclusively in the kidneys. Assuming that such cases occur and that this explanation be true, it is more correct to say that the scarlatinous contagium sometimes gives rise to acute Bright's disease without causing scarlet fever. I have referred to cases exemplifying this fact in treating of acute diffuse nephritis.

Scarlatina has various sequels. The one which occurs most frequently has just been alluded to—namely, albuminuria with general dropsy. This follows the disease in a considerable proportion of cases, the proportion being found to vary at different times and places. The time of its occurrence is between ten and twenty days after the date of desquamation. The symptoms are those of acute diffuse nephritis, an affection which has been considered in connection with the diseases of the urinary system.¹ Œdema of the face and lower extremities is first observed, and anasarca frequently follows. Effusion takes place into the serous cavities if the anasarca be considerable. Hydrothorax sometimes exists to such an extent as to seriously embarrass respiration. The urine is scanty; sometimes it has a smoky appearance, and it may be distinctly bloody. It may, however, contain few or no red blood-corpuscles. It is usually loaded with albumen, but cases have been reported by Rayer and others of dropsy after scarlatina without albuminuria. Epithelial, granular, and hyaline casts are generally found in the urinary sediment. Some red, but more white, blood-corpuscles are usually present. Blood-casts are not frequent. There is notable anæmia, the appetite is deficient, the temper is irritable, and muscular debility is more or less marked. Pyrexia, varying in degree in different cases, accompanies these symptoms. Uræmic coma and convulsions, pulmonary œdema, and œdema of the glottis are grave accidents incident to the renal affection. They occur, happily, in but a small proportion of cases, and under judicious management this affection is rarely fatal. Temporary blindness is a rare event, occurring in connection with uræmic convulsions following this disease. Acute nephritis after scarlet fever rarely ends in chronic renal disease. It is more rational to consider the renal affection which follows scarlatina as a special effect of the latter than to attribute its production to cold or other causes operating after the scarlatinous poison has ceased to act.

The opinion was held by Graves and others that the kidneys are oftener affected after mild than after severe cases of scarlatina. This sequel certainly occurs after mild cases, and sometimes when, from the absence of either the throat affection or of the cutaneous eruption, scarlet fever had not been supposed to exist. A probable explanation, however, of its occurrence in a larger proportion of mild cases is afforded by the fact that of severe cases a considerable number end fatally during the progress of the fever. It is to be borne in mind that coma and convulsions may occur as sequels of scarlatina, due to uræmia not accompanied by either albuminuria or dropsy. That the renal

¹ Vide p. 815.

affection has no necessary connection with the eruption on the skin is shown by its occurrence in cases in which the scarlatinous rash was wanting.

Pleuritis, pericarditis, and acute articular rheumatism are occasional sequels as well as concomitants of scarlet fever. Chorea is also to be reckoned among the occasional sequels. External otitis is not uncommon. A purulent discharge takes place from the ears, and sometimes there is considerable deafness. If the inflammation be wholly without the tympanum, the deafness will be temporary, and under judicious management the affection may generally be removed; but it is liable to return from time to time for a considerable period after recovery.

CAUSATION.—The communicability of scarlet fever is established by irrefragable proof, and it is probable that its causation always involves a contagium. The contagium from mild is as efficient as that from severe cases. It is important that this fact be popularly known. Many persons in this country think that the disease in very mild cases differs essentially from that in severe cases, and it is a common impression that the name scarlatina applies only to the former. Physicians should take pains to correct the error of supposing that the names scarlatina and scarlet fever indicate different diseases. The contagium is contained in emanations from the body, probably in both the expired breath and the cutaneous exhalations; hence the atmosphere surrounding patients is infected. It appears to be certain that the disease has been communicated by inoculating with the serum contained in the vesicles which sometimes appear in conjunction with the cutaneous efflorescence, but such inoculation does not materially affect the duration or the severity of the disease. That the disease may be communicated by means of fomites is unquestionable. The contagium may be carried in the clothes of physicians, nurses, and others. The disease is probably often diffused in this way. Facts show that the contagium adheres to material substances and preserves its morbid power for a long period. Persons have been attacked on returning to houses in which cases have occurred weeks or months previously, even when careful efforts have been made to remove the contagium. Several instances have been recorded in which the scarlatinal virus appears to have been transported by milk. Scarlatina sometimes follows with notable frequency surgical operations and the puerperal state. In these cases, however, it is necessary to be somewhat guarded in the diagnosis, as an efflorescence which has nothing to do with scarlatina may follow these conditions and aptic fevers in general.

The period of incubation is undoubtedly, as a rule, much shorter in scarlatina than in the other eruptive fevers. Its duration, however, varies in different cases. Trousseau cites a case in which the attack took place within twenty-four hours after exposure. In a case under my observation the patient, an infant of nineteen months, was attacked twenty-four hours after the first symptom of illness in a young girl who assisted in taking care of the child. In another case the duration was forty-eight hours. It is probable that the period rarely exceeds six days.

Statistics show that the disease occurs most frequently in the third and fourth years of life—that the liability to it diminishes progressively after the fifth year, and becomes very small after forty. Children less than two years of age and infants at the breast are not, as has been incorrectly stated, insusceptible to it. Several instances of its occurrence at less than two years of age have come under my observation. In one of these a child only three weeks old contracted the disease from her mother, who was attacked a few days after confinement. Cases have been reported in which the disease was contracted *in utero*.

As a rule, this disease is experienced only once; but, making due allow-

ance for cases in which roseola may have been confounded with scarlatina, the exceptions to this rule are not extremely rare. Second or third attacks are rarely fatal.

Nothing is positively known concerning any micro-organisms which can be regarded as the cause of the disease. As in the other eruptive fevers, micrococci have repeatedly been found in various organs of the body in scarlatina, particularly when these are the seat of complications, but it is not believed that these micrococci are concerned in the production of the disease.

DIAGNOSIS.—Attention to the following diagnostic points renders the discrimination of this disease easy in the great majority of cases: The short duration of the stage of invasion, the intensity of the pyrexia, the appearance of the efflorescence in the throat prior to the cutaneous eruption, the appearance of the efflorescence on the body and upper extremities often before or simultaneously with its appearance on the neck and face, the rapid extension of the efflorescence over the cutaneous surface, the scarlet color of the efflorescence, the irregular and serrated margins of patches of efflorescence, and the persistence or increase of the pyrexia after the appearance of the efflorescence on the skin. These are positive diagnostic features belonging to the clinical history of scarlet fever as contrasted with smallpox and measles. On the other hand, the two latter eruptive fevers are excluded by the shorter period of invasion in scarlatina, pain in the loins not marked in this period, absence of the characteristic eruption of variola in the mouth and fauces, the non-occurrence of variolous papules and vesicles with depression in the centre, and of the remission of fever when the eruption appears, absence of coryza and bronchitis, which belong to the history of rubeola, and of certain distinctive characters pertaining to the eruption of rubeola, which will be stated in treating of that disease.

The difficulties in the way of diagnosis relate, in the first place, to extremely mild cases with a slight eruption and without any affection of the throat. In these cases the disease is liable to be confounded with roseola. The differential points will be noticed in treating of the latter in the next chapter. In the second place, the diagnosis may be difficult in cases in which the local manifestation is confined to the throat; that is, cases in which the cutaneous efflorescence is wanting. It must be confessed that the diagnosis in some of these cases must be, in a measure, based on their occurrence during the prevalence of scarlatina, and sometimes on the occurrence of well-marked cases in members of the same family. In some cases of doubt or error the sequels of scarlatina, especially renal disease, serve either to correct or establish the diagnosis.

A highly probable diagnosis before the efflorescence appears on the skin may be based on a sudden attack of vomiting, with high febrile movement and redness of the fauces, in a subject between three and five years of age, especially during the prevalence of scarlatina.

PROGNOSIS.—There is perhaps no disease in the nosology which presents in different cases wider extremes as regards gravity than scarlatina. In malignant cases the disease is rapidly fatal. The proportion of these cases varies much at different times and places. The prevailing type of the disease in some seasons is mild, and in other seasons severe. Whether this variation be due to a difference in the contagium or to adjunctive influences we are unable to say. Aside from the intensity of the disease, the danger depends on complications liable to occur in cases which, as regards the general symptoms, may appear to be mild. The symptoms which denote imminent danger from the intensity of the disease are—excessive frequency of the pulse,

hyperpyrexia, jactitation, active delirium, and prostration; the mode of dying in these cases being by asthenia.

The prognosis is unfavorable in cases in which the throat affection is unusually severe. It is extremely unfavorable if diphtheria become developed either during the progress of the disease or as a sequel. If laryngitis ensue a fatal result is to be expected. Great enlargement and suppuration of the glands of the neck irrespective of diphtheritic inflammation of the fauces denote great danger. If gangrene of the throat or mouth occur, recovery is the exception rather than the rule. Cases characterized by hemorrhage from mucous membranes and petechiæ or vibices are generally fatal. Uremic coma and convulsions involve imminent danger, and uræmia may occur in cases which as regards the general symptoms appear to be mild. These symptoms may be developed and sudden death take place unexpectedly if examinations of the urine have been omitted. Daily examinations of the urine are highly important. The presence of albumen or casts should always excite apprehension, but the immediate danger is proportionate to the deficiency of uræa. The patient is by no means safe after albumen has disappeared from the urine if casts continue to be found in the sediment, especially if the quantity of urine be small and the specific gravity low. The prognosis is extremely unfavorable in cases of scarlet fever occurring in the puerperal state. I have known a case in which the patient contracted the disease in the seventh month of pregnancy. She miscarried during the period of incubation; parenchymatous nephritis occurred as a complication and the symptoms denoted great danger. She, however, recovered, and the child was living.

TREATMENT.—Cases of mild scarlatina do not call for active measures of treatment. The often-quoted saying of the English Hippocrates, that scarlatina is only dangerous through the officiousness of the physician, is, however, hardly true even of these cases, for be the disease never so mild there is a liability to grave complications and sequels. On the other hand, in certain cases of severe scarlatina the malignancy of the disease renders any treatment unavailing. With respect to this disease as well as the other eruptive fevers, it is to be premised that there are no known specific remedies by means of which it may be arrested or controlled; but the inference by us means follows that judicious measures of treatment may not do much toward affording relief and diminishing the fatality. It is to be added that a comparison of different collections of cases with reference to the rate of mortality under different methods of treatment is of little value, on account of the wide diversity as regards the severity of the disease.

Certain measures heretofore employed in the treatment of scarlatina are now regarded as opposed by sound reasoning and experience. This statement applies to bloodletting, active purgatives, mercurialization, blisters, and emetics. These are never indicated, and must of necessity prove hurtful. The discovery of a remedy which will arrest the disease by destroying within the body the special cause—in other words, an effectual parasiticide for the specific organisms and germs on which the disease is supposed to depend—belongs to the future. This statement applies to all the eruptive fevers. Carbolic acid, sodium sulphocarbolate, and the sulphites have been tried with an apparently beneficial effect. I have heard testimony from physicians of experience in behalf of the usefulness of each of these remedies. It has not, however, been proved that they have a special curative efficacy. At the present time, therefore, the indications are to be drawn from particular symptoms, events, and complications in individual cases.

In the majority of mild cases hygienic treatment is alone required. In addition to free ventilation, cooling drinks, and light nourishment the

hygienic treatment should embrace measures to maintain the functions of the skin. In view of the fact that renal disease as a complication or sequel is a source of danger in these cases, attention to the skin is important, however mild may be the disease. The tepid bath once or twice daily is to be recommended. If the bath be not practicable, the application of a sheet wet with tepid water or repeated sponging of the body may be employed in its stead. There is reason to believe that the more the functions of the skin are maintained by these measures the less is the liability to an affection of the kidneys either during or after the disease. Exposure to cold is to be avoided both while the disease is in progress and in convalescence, but care in this respect should not lead to error in the way of ventilation or of oppressing the patient with an overplus of clothing. Vigilance or restlessness, if not relieved by the use of the bath, the wet sheet, or sponging, may indicate anodyne remedies. Constipation is to be relieved by simple enemata. Other symptoms may indicate appropriate palliative remedies.

In some cases the leading indication is derived from the intensity of the fever as denoted by hyperpyrexia and the frequency of the pulse. To diminish the heat and the frequency of the heart's action is an important object of treatment. This object may be most effectually accomplished by the use of water. It was in this disease that Currie was led, nearly a century ago, to employ cold affusions with a happy effect. This mode of applying water was strongly advocated by Trousseau, who stated that he employed it with highly satisfactory results in a large number of cases in private and hospital practice. It is perhaps the most efficient measure to be employed for the relief of the active delirium which sometimes occurs in this disease. The apparent boldness of the practice renders it frequently objectionable on the score of popular prejudice. Frequent sponging of the body secures to a considerable extent the same results; but the use of the wet sheet is hardly less efficacious than the cold affusion as practised by Currie. Employed as an efficient antipyretic measure, the wet sheet is applied over the whole body without any other covering, and the surface is sprinkled with cool or cold water at short intervals in the manner described in connection with the treatment of typhoid fever and insolation. The temperature is always reduced one, two, or more degrees by this measure, and it may be repeated as often as the thermometer shows a return to great intensity of heat. There is no occasion for fear on the ground of danger of repelling the eruption. The wet pack acts efficiently as a sedative and diaphoretic measure, and it has considerable potency as an antipyretic. The patient, stripped of all clothing, is enveloped in a sheet saturated with water at about the temperature of 70° F. and closely covered with several blankets. Usually after remaining in the pack for about an hour free perspiration is induced. The pack is to be removed when this effect occurs, the body wiped dry, and the patient placed in bed. The frequency of the pulse is often notably lessened by this measure. The patient is tranquillized and obtains refreshing sleep. The measure may be repeated once or twice daily. Its effect is so agreeable that patients often desire a repetition. In this disease, as in other fevers, full doses of quinia sometimes have a notable antipyretic effect.

In malignant cases, and whenever the intensity of the disease involves a tendency to death by asthenia, the chief reliance must be on sustaining measures. Alcohol is indicated in proportion to the frequency and force of the pulse, together with general prostration. I have witnessed the most striking benefit from the free use of wine or spirits in certain cases of scarlatina as in cases of typhus or typhoid fever. Alcoholic beverages are not to be given without discrimination, and the physician is to be guided in their use by watching their immediate apparent effects, proceeding as far as they

tial fevers. In children, wine-whey, milk-punch, and egg-nog are eligible forms for the administration of stimulants and nourishment.

Cases of so-called scarlatina anginosa in addition to sustaining treatment call for measures addressed to the affection of the throat. [The best of these is frequent spraying with a 20 per cent. solution of boracic acid, a 2 per cent. solution of carbolic acid, a saturated solution of salicylic acid, or thymol, or with peroxide of hydrogen. The latter, provided a reliable preparation be employed, is a remedy of undoubted efficacy. In addition, the atmosphere of the room should be charged with steam. It is undoubtedly difficult to induce young children to co-operate in the employment of the atomizer, but with gentleness and firmness it can in most cases be accomplished.—H.] The chlorine mixture is highly recommended by Watson and others. Stimulating or caustic applications to the pharynx are of doubtful utility. The difficulty of making them in children, and the perturbation occasioned by making them forcibly in spite of their resistance, are not small objections; but aside from these objections it may be doubted if they produce a beneficial effect. Antiseptic applications by gargling, if the patient be not too young, by means of a sponge if the resistance be not too violent, or in the form of a powder by insufflation, contribute at least to comfort. The solution of chlorinated soda may be used for this purpose, diluted with eight or ten parts of water. The permanganate of potash may also be used in the proportion of half a grain of the salt to five ounces of water. Other topical remedies are alum, tannic acid, the borate of soda, carbolic acid, and salicylic acid. The free use of iced drinks is useful as regards the condition of the throat. The patient may be allowed to take into the mouth small pieces of ice almost *ad libitum*; and for young children a convenient plan is to confine pieces of ice in a gauze bag which may be held in the mouth. Externally, compresses kept wet with cold water may be applied. It has been recommended to apply ice to the sides of the neck. It is customary to paint the neck with iodine over glandular swellings. If suppurative inflammation ensue, poultices or the water-dressing should be applied.

Extreme pruritus of the skin is in some cases a source of much annoyance, preventing sleep and increasing the constitutional disturbance. With reference especially to this symptom some years ago a plan of treatment proposed by a German physician, Schneemann, consisted in the application of lard to the surface of the body, the rind of bacon being used for this purpose. This plan was adopted to some extent in this country. It relieved, in some cases at least, the pruritus and diminishes the febrile excitement. Other applications, however, less disagreeable, are equally efficacious. Glycerin and the rose-water ointment, glycerin and cologne-water, in the proportion of one part of the former to four or five parts of the latter, or, what is still better, vaseline or lanolin, may be substituted.

Convulsions are generally due to uræmia, but occurring early in young children they may be incident to the development of the disease without denoting a renal complication. Whether uræmic or otherwise, if they continue the inhalation of chloroform is indicated. I have notes of cases in which this measure was employed with immediate relief and recovery followed.

Uræmic phenomena in addition to convulsions—namely, cephalalgia, disturbance of vision, and coma—render prompt measures of treatment vastly important. Saline purgatives or elaterium are to be employed at once to eliminate urea, and diaphoresis should, if possible, be procured by the use of the hot-air bath, the wet sheet, or by the hypodermic administration of the muriate of pilocarpine. Vomiting and purging should always suggest the inquiry whether they be not due to uræmia, and if so they are not to

be arrested. Albuminuria, and especially a deficiency of urea in the urine, should lead to measures with a view of forestalling the effects of uræmia. Fomentations are to be applied over the loins, the bowels are to be kept loose with saline laxatives; and with reference to this object it is important to produce diaphoresis by means of the warm bath or the wet sheet.

Restlessness and vigilance, if not relieved by measures of treatment already noticed, may require anodyne remedies. [The best of these is the hydrate of chloral. This drug is highly recommended by J. C. Wilson, who employs it habitually in the treatment of scarlatina, in doses of 1 or 2 grains every three hours to children of two or three years of age.—H.] With reference to the liability to heart-clot, Richardson advises the carbonate of ammonia given in small doses frequently repeated. Several writers have advocated this remedy as having a special salutary influence in scarlatina.

The treatment of the sequels of scarlatina need not be here considered. The most frequent of the important sequels—namely, acute diffuse nephritis—has been considered in a former part of this work, to which the reader is referred. In the treatment of pleuritis, pericarditis, rheumatism, and chorea are involved essentially the same principles as when these affections occur in other pathological connections. External otitis is often neglected, and it may therefore continue, and in the end lead to impairment of hearing. Daily cleansing of the ear by the injection of tepid water and soap will usually prove sufficient to effect a cure; but if the affection continue in spite of this measure, which from its very simplicity it is often difficult to enforce, mild astringent injections should be employed.

I shall add a remark with reference to the prevention of renal disease as a sequel of scarlatina. The occurrence of this sequel being generally attributed to cold, it is common to confine patients within doors, and sometimes even to the bed, for two or three weeks after convalescence. Regarding, however, the sequel as a remnant of scarlatina, this extreme care is unnecessary. It is sufficient to observe the same precautions with regard to exposure to cold or other morbid agencies as during convalescence from any acute affection. Gestation out of doors has seemed to me to be useful even when patients are suffering from albuminuria and general dropsy following scarlet fever.

It remains to notice the protective influence against scarlatina which has been imputed to belladonna. Satisfactory proof of its prophylactic power requires that the number of failures shall not be large; and, judged by this rule of evidence, it is extremely doubtful if there be any ground for imputing to this remedy a prophylactic power. It is, however, to be considered that to prescribe belladonna as a prophylactic is always a harmless experiment, and it is therefore objectionable only on the score of supererogation. Moreover, as the popular mind has been directed to this question, the wishes of friends are often better satisfied if the drug be prescribed. These considerations may properly influence the physician. The following are the directions for the use of the remedy: "Dissolve from one to three grains of fresh and well-prepared extract of belladonna in an ounce of cinnamon-water, adding a few drops of alcohol to prevent fermentation. Of this solution may be given, two or three times a day, one drop for each year of the child's age, to be so administered for two weeks or longer if the danger should continue."¹ The only reliable way of protection against the disease is to avoid the contagium. To do this effectually, it is necessary not only that persons do not come within an infecting range of patients, but that they avoid those who have been within this range, the houses in which there have been cases, and everything that may prove to be fomites. Cases occurring in hospitals and private houses should be at once isolated, and all articles in the apartment

¹ Stillé, *op. cit.*

occupied by patients should be properly disinfected. The best means of disinfecting clothing, bed-linen, carpets, tapestries, and stuffs which cannot be destroyed by fire is to subject them for two or three hours to steam at a temperature of 212° F. Removal without the limits of the prevalence of the disease is advisable when it is found that cases are likely to prove malignant or severe. On the other hand, if cases be pretty uniformly mild it is to be considered that the period is favorable for having the disease. Voluntary exposure with the intention that the disease shall be contracted is, however, under no circumstances to be recommended.

CHAPTER VIII.

ERUPTIVE FEVERS (CONTINUED).

Rubeola, or Measles: Clinical History; Causation; Diagnosis; Prognosis; Treatment.—
Roseola.—Rötheln.—Dengue.

Rubeola, or Measles.

RUBEOLA—so called from the red color of the eruption, called also *morbilli*, and commonly known as the *measles*—is a disease of less importance than the eruptive fevers which have been considered. It is generally a mild and often a trivial disease, but it is desirable to discriminate it as early as possible from other eruptive fevers. It is of frequent occurrence, it is sometimes accompanied by grave complications, it is occasionally followed by serious sequels, and in a certain proportion of cases the disease is intrinsically severe or even malignant. Hence, rubeola is by no means an unimportant disease. By German writers the term rubeola is used to denote an eruptive fever distinct from measles, called also Rötheln, and in this country distinguished as German measles.

Rubeola has no special anatomical characters exclusive of the internal and external efflorescence which is most conveniently considered as belonging among the symptoms of the disease. I shall pass, therefore, at once to the clinical history.

CLINICAL HISTORY.—The career of this disease is subdivided, like that of the other eruptive fevers, into the stages of invasion, eruption, and desquamation, each stage claiming separate consideration.

Stage of Invasion.—The distinctive local symptoms in this stage resemble those of a common cold, or rather an attack of influenza. There is coryza, with frequent sneezing and an acrid muco-serous discharge from the nostrils. The eyes are irritable, reddened, and watery. Epiphora is sometimes marked, the tears excoriating the face, and there is more or less intolerance of light. Subacute laryngitis, denoted by hoarseness, frequently occurs, and the symptoms of bronchitis are generally present, the cough being dry, sonorous, and painful. Occasionally the pharynx is the seat of subacute inflammation. The bronchitis, laryngitis, and coryza are due to the efflorescence which takes place on the mucous membrane of the air-passages prior to its appearance on the skin. With these local affections, which vary much in intensity in differ-

ness; in the mulatto, as a dusky-
les more distinct, reddish-brown,
the eruption in the white."

ses, as this disease is ordinarily presented
r unattended with danger; but in a cer-
se is severe and dangerous. The severity
analous events and complications which have
in the clinical history. The number of cases ren-
ce of capillary bronchitis, diphtheritic laryngitis,
considerable. The rate of mortality differs greatly
places, so that the statistics of any particular epi-
sh results applicable generally to the disease. It may
se in camps. Woodward states that of the 38,021 cases
nical returns from the armies of the United States in the
the late civil war, there were 1864 deaths. Bartholow is of
at these figures do not express the actual fatality due directly
—that is, by complications and sequels—to this disease during
and he estimates the ratio of deaths to cases as 1 to 5.¹
the war the prevalence of the disease was great among recruits,
ly those from the country, and the sequels or the effect upon the
al health incapacitated a considerable proportion for remaining in the
vice. Taking into view the mortality and the enfeebled condition remain-
ing for a long time in many of the cases which did not end fatally, measles
proved to be one of the most formidable of camp diseases. With reference
to the efficiency of troops in active service, it is desirable to isolate cases at
once wherever they occur in camp. Doubtless, the rate of mortality and the
disqualifying effects of the disease were often due to the coexistence either
of scorbutus or malarial poisoning.

TREATMENT.—In ordinary cases the disease calls for nothing but palliative
measures and attention to hygiene. The cough may be palliated by anodynes,
and these may also be indicated by restlessness or vigilance; and for the
pyrexia, if it be considerable, gentle diaphoretic and refrigerant remedies may
be prescribed. The object of treatment in these cases is simply to render the
patient as comfortable as possible, the disease pursuing a favorable course
without therapeutical interference. It is a widely-diffused popular notion
that saffron (*Crocus sativus*) is a valuable remedy in measles, as well as in the
other eruptive fevers, given for the purpose of promoting the eruption. There
is little ground for this notion, but the remedy is harmless. Cathartics in
this as in the other eruptive fevers are not indicated, and are likely to do
harm. Emetics are rarely if ever indicated. The patient should be confined
to a room in which the temperature is agreeable, but free ventilation should
be secured. The air of the room in the treatment of cases of this fever, as of
the other essential fevers, and, indeed, of all acute diseases, should be effect-
ually changed after short intervals by opening the windows, protecting the
patient against draughts by covering the face as well as the body. The body
may be sponged, portions at a time, with tepid or cool water. This may
be done without any fear of causing the eruption to disappear prematurely.
If the degree of pyrexia call for antipyretic treatment, the wet sheet may be
resorted to. Refrigeration will not render the patient more liable to pneu-
monia or other pulmonary complications. Quinia, salicin, and antipyrine may
also be given for an antipyretic effect. As a protection for the eyes the room
should be moderately darkened.

¹ *Sanitary Memoirs of the War*, New York, 1867-69.

on auscultating the chest. The irritability of the eyes continues, and infrequently there is conjunctivitis. Pharyngitis in some cases continues and sometimes the inflammation extends into the Eustachian tube, occasioning partial deafness. The pyrexia does not disappear or diminish with the development of the eruption. On the first and second day of the eruption the temperature of the axilla may rise to 104° F. and even higher. From this date, in the natural course of the disease, the temperature rapidly diminishes. Other symptoms denoting constitutional disturbance are proportionate to the pyrexia. The latter, save in exceptional cases, is much less degree than in scarlatina. The tongue is generally coated, and not infrequently the elongated papillæ, projecting through the coating, present the appearance of red points.

Stage of Desquamation.—This stage may be considered as having begun when the eruption begins to fade. The duration of the stage is between four and eight days. In uncomplicated cases pursuing a favorable course this stage is the stage of convalescence. Actual desquamation occurs in only a certain proportion of cases. It may be more or less marked. It is always furfuraceous, the epidermis being exfoliated in branny scales, not in patches or flakes. Coincident with the decline and disappearance of the eruption the pyrexia diminishes and ceases. More or less cough and expectoration are likely to continue after the cutaneous eruption has disappeared, and persisting conjunctivitis is not uncommon. Occasionally the eruption on the skin reappears after having existed for the usual period and having disappeared. Diarrhœa, usually mild, is likely to occur in this stage.

The career of the disease is thus extended between twelve and sixteen days.

The foregoing sketch of the clinical history relates to cases in which the disease pursues a typical course. Anomalous cases occur, the disease in some being very severe or malignant, and in others unusually mild. In exceptional cases the eruption appears first on some other part of the body than the face. The affections of the Schneiderian membrane, larynx, and bronchial tubes are sometimes wanting. Writers have considered these cases as constituting a variety of the disease, called *rubeola sine catarrho*. To a certain extent, doubtless, cases which have been considered as of this variety have been cases of roseola. On the other hand, it is supposed that cases occur in which the local manifestations are limited to the mucous membrane; hence there is another variety, called *rubeola sine eruptione*. It must be difficult to decide positively that rubeola exists when the cutaneous efflorescence is wanting. In the cases belonging to the two varieties just named the disease is unusually mild. The severe form of the disease is characterized by the occurrence of petechiæ and hemorrhage in various situations. The phenomena of purpura are associated with measles in these cases. Of this rare form of the disease the following case is an example: The patient was a man aged about twenty-five. The rubeolous eruption was abundant, presenting the characteristic appearances, but was somewhat darker than usual. Scattered among the efflorescence over the whole surface of the body were petechiæ between the size of a pin's head and that of a split pea. There was a hemorrhage from the nose and mouth. Blood also was discharged from the urethra and was contained in the urine. The tongue and gums were pallid, and at certain points which were stained with exuding blood. Blood was beneath the conjunctiva, infiltrating the whole surface of the eyeballs and the cornea. The case terminated fatally. This form of the disease is distinguished as *hemorrhagic rubeola*. It has been called also *rubeola*

mouth, and occasionally the anus,

trachea and larynx, sometimes occurs in connection with rubeola. Other morbid conditions than those belonging to the latter, it is to be presumed, must intervene in giving rise to this event. It has been observed chiefly in young children in eleemosynary institutions. Aside from any such local events or attendant complications, this disease sometimes assumes a severe form, presenting the ataxic and adynamic symptoms of typhus or typhoid fever, and ending fatally from an intrinsic tendency to death. Such cases, however, are very rarely met with.

In the great majority of the cases in which the disease is severe the gravitation is dependent on complications. The important complications most likely to occur are seated in the respiratory system. Diphtheritic laryngitis or true diphtheria is sometimes developed. Capillary bronchitis is another fatal complication, capable of occurring in children; and, occurring in children of less than three years of age, it generally destroys life. It is more liable to occur in hospital than in private practice. Broncho-pneumonia and lobar pneumonia are the most frequent of the serious complications. The latter in young children is almost always to prove fatal, and it is by no means devoid of danger in adults. Pleurisy is an occasional complication, but it is far more infrequent than pneumonia. Croup, capillary bronchitis, and especially pneumonia, are not less likely to occur as sequels than as concomitants of rubeola.

Delay in the appearance of the eruption is generally an effect of some attendant complication. The occurrence of an important complication may be followed by a notable diminution and sometimes to a retrocession of the eruption. A popular error to attribute the complications to the retrocession of the eruption; the latter is a consequence, not a cause, of the former. Irregularity as regards the situation in which the eruption first appears is sometimes observed. In rare instances the efflorescence first makes its appearance on the lower extremities, and extends thence over the body, upper extremities, and head.

After recovery from rubeola, pulmonary phthisis, acute tuberculosis, and suppurative meningitis are observed in a proportion of cases not large, but sufficient to show that the system is left in a condition favorable for the development of these affections. Affections distinguished as scrofulous are more likely to follow as sequels—namely, scrofulous ophthalmia, coryza, otorrhœa, enlargement of lymphatic glands, etc. After an extensive prevalence of the disease in any place it is observed for some years that the mortality among children exceeds the average mortality at other times. The practical importance of these facts is obvious.

Nephritis is a rare complication of measles. Some albuminuria, at the termination of the disease, is not rare.

TRANSMISSION.—Rubeola, like scarlatina and variola, is a contagious disease. The contagium is not only received by those brought into close proximity to persons affected with the disease, but it may be transported to a distance by means of fomites. Persons contract the disease from the contagium adhering to the clothes of those who may have recently visited rubeolous patients. Physicians may in this way diffuse the disease.

The disease may be communicated by inoculation, either with blood from a cutaneous patch or with the secretion from the eyes and nostrils. The activity of the rubeolous contagium, however, is much less persistent than that of the contagium of smallpox and scarlet fever. The communication, not alone by inoculation, but by means of an infected atmosphere or dust, belongs to the stage of invasion as well as to the eruptive and efflorescent stages.

The duration of the period of incubation varies within widely separated

limits—namely, between one day and thirty days. In the majority of cases the attack occurs between six and ten days after exposure. The duration within these limits in a dozen cases under my observation in which the time of exposure could be definitely fixed, with a single exception in which the duration was fourteen days. The average duration of the period of incubation may be given as ten days. When produced by inoculation the period of incubation is somewhat shorter than it is usually when the disease occurs naturally.

The susceptibility to the disease exists at all ages. Cases are much more frequent in children than in adults, but this is owing to the fact that the majority of persons have the disease in childhood, and are generally thereby made insusceptible. They who escape the disease in early life on account of not being exposed to the contagium are liable to contract it at any subsequent age. The susceptibility is very slight during the first six months of infantile life. As a rule, this disease, like scarlatina and variola, renders the system ever afterward insusceptible to it, but exceptions to this rule are not very rare. Well-authenticated cases in which the disease has occurred three and even four times have been reported. Prevailing in camps, schools, hospitals, and communities as an epidemic, this disease presents at different times a great diversity as regards mildness or severity and the tendency to particular complications; in other words, the character of different epidemics of rubeola, as of other epidemics, is by no means uniform, but varies much in different seasons and places.

DIAGNOSIS.—The diagnosis of rubeola after the appearance of the efflorescence on the skin is generally unattended with difficulty. The diagnostic characters which have been embraced in the clinical history are sufficiently distinctive. The more important of these are—the long duration of the stage of invasion; the affection of the air-passages; the appearance of the eruption almost invariably first on the face, and its gradual diffusion over the body; the color of the eruption, its papular character, the softness of the papules, and the tendency of the papules to assume a crescentic arrangement. So far as the eruption is concerned, early in the eruptive stage there is some resemblance to the papules of smallpox, but the differential points which have been presented in treating of the latter disease should enable the practitioner to make the discrimination. In a case of rubeola in which the cutaneous efflorescence is not abundant and the air-passages are unaffected the disease is liable to be confounded with roseola; but the eruption in these two affections differs, and, moreover, such cases are extremely rare. Cases in which the air-passages are alone affected—that is, in which there is no cutaneous efflorescence—hardly admit of a positive diagnosis, but such cases are extremely rare. Their occurrence during the prevalence of rubeola in persons known to have been exposed is the chief ground on which the diagnosis is to be based.

The diagnosis cannot be made with positiveness prior to the appearance of the efflorescence on the skin. The occurrence, however, of coryza, irritability of the eyes, and bronchitis, with pyrexia, in persons who have never had measles at a time when the disease is prevailing, renders a diagnosis during the period of invasion highly probable. The diagnosis is sometimes delayed by the early occurrence of complications which interfere with the regular course of the disease, especially as regards the eruption. The appearance of the latter, however, sooner or later in the great majority of cases, removes the difficulty which may previously have existed.

Of this fever, as of all the eruptive fevers, the diagnosis in the negro must, of course, be based on other points than those relating to the color of the eruption. "In the pure negro the eruption appears as yellowish spots slight

and extremities and not on the face. It continues for twenty-four or forty-eight hours only, in a majority of cases. It disappears without desquamation and is liable to return. It is sometimes accompanied with considerable pruritus. The affection has neither sequels nor complications. A roseolar eruption may, however, occur in the course of other affections, especially in the stage of invasion in varioloid, in articular rheumatism, and in epidemic cholera after reaction. Roseola is not a grave disease. One attack affords no protection against recurrences. It is oftener presented in females than in males. It prevails not infrequently as an epidemic, chiefly during the summer season. Some authors consider it to be contagious.

Attention to the foregoing points will suffice for the discrimination of the affection from scarlatina and from rubeola. It does not call for treatment.

The use of the balsam of copaiba by some persons induces an efflorescence analogous to that of roseola, and more rarely the use of cubebs, the iodide of potassium, turpentine, antipyrine, and the sulphate of quinia. A variety of the affection belongs to the history of syphilis.

Rötheln.

The affection called by German writers *rötheln* and rubeola (*German measles*), and called also rubella, is probably not a new disease in this country, but it was formerly confounded with measles, with roseola, or with scarlet fever. Prof. J. Lewis Smith studied an epidemic occurring in New York in 1874, and found the characters which distinguish this affection. It occurs as an epidemic and is probably contagious. It affects all ages, but especially children. It differs from measles in having a period of invasion rarely longer than a day; in a much less degree of pyrexia; in the more frequent appearance of the eruption first on the body and neck; and in the rapid diffusion of the eruption. The eruption, moreover, is less elevated; the spots are round, or at least usually less irregular than the papules of measles, and there is no tendency to a crescentic arrangement. There is slight coryza, but the larynx and bronchial tubes are rarely much affected. In some epidemics the cervical and to a less extent other lymphatic glands are swollen.

The color of the eruption sometimes resembles that of scarlet fever rather than that of measles. The affection bears a close resemblance to extremely mild cases of these diseases. In making the discrimination reliance is to be placed on the occurrence of other cases having the diagnostic characters of *rötheln* and the non-prevalence of scarlet fever or of measles. It is hardly possible to diagnosticate an isolated sporadic case of *rötheln*, but when a large number of cases with similar characters occurs epidemically, the diagnosis can generally be made.

It is probable that cases of *rötheln* and of roseola have been not infrequently supposed to be cases of measles and scarlatina, and in this way is perhaps to be explained some of the reported instances of the latter diseases occurring in the same person more than once.

That this disease is essentially distinct from measles and scarlet fever is proven by its epidemic occurrence, by its affording no protection against these diseases, and by the fact that the latter afford no protection against it. These are sufficient grounds for recognizing a separate special cause. *Rötheln*, like roseola, is devoid of danger, and rarely calls for more than hygienic treatment.¹

[A valuable contribution to the study of rubella was made by Dr. J. P.

¹ A valuable article on this disease by Dr. W. A. Edwards was published in the *Am. Journ. of the Med. Sciences*, October, 1884.

In cases in which the disease is rendered severe by complications the treatment will have reference to the latter. The general principles of treatment in these cases are the same as when the complicating affections occur in other pathological connections. It would, therefore, be a repetition to consider the indications derived from the different complications. A practical question relates to the retardation, diminution, or retrocession of the eruption in some complicated cases. Is it important to resort to active measures designed to promote the appearance of the eruption? The importance of this object of treatment has doubtless been much exaggerated. Certain measures employed for this object, such as emetics, active stimulants, the hot or vapor bath, and overloading the body with clothing, are not to be employed. This general rule may be adopted—namely, measures should not be employed for this object if, aside from the object, they are likely to be hurtful. The tepid bath, stimulating pediluvia, and sinapisms or other rubefacient applications to the skin, are not excluded by this rule. It is to be considered that the complications do not occur in consequence of the eruption being delayed, or insufficient, or “striking in;” and it is more probable that the latter are effects of the former.

Cases presenting ataxic or adynamic symptoms, either with or without complications, claim the tranquillizing and supporting measures indicated in other diseases with the same symptoms.

It is important to bear in mind the liability to scrofulous and tuberculous affections after recovery from this disease. Patients should be placed under hygienic influences which will tend to invigorate the system, with a view to obviate a tendency to the development of these affections.

Protection against this disease and the prevention of its diffusion can be secured only by means of the isolation of cases and measures of disinfection. Children should be kept from school and other places in which they are brought into contact with other children whenever, from the symptoms at the stage of invasion, the nature of the disease is to be suspected. There is ground for the opinion that the communicability is greater during this stage. The clothes worn by patients, the bedding, and the apartments should be disinfected. These protective and preventive measures are especially important during the prevalence of an epidemic in which there is a tendency to great complications. They are of less importance in mild epidemics, inasmuch as the subsequent insusceptibility which, as a rule, the disease confers, is especially desirable.

Roseola.

The eruptive fever called *roseola* or *rose rash*, and sometimes called *measles*, is an affection of very little importance, exclusive of its liability to be mistaken for rubeola or scarlatina.

The eruption is preceded by symptoms of constitutional disturbance one or two days. These symptoms are—cephalalgia, loss of appetite, sometimes nausea and vomiting, and occasionally diarrhoea, chilly sensation, movement, and general malaise. In young children convulsions may occur. The constitutional disturbance is more or less marked, but it is slight. The affection of the throat and of the air-passages which is the history of scarlatina and rubeola in the stage of invasion is slight in roseola.

The eruption appears in the form of rose-colored spots or patches, not elevated, the redness disappearing momentarily on pressure. It appears on different parts of the body, not beginning on the head and spreading over the body, as in rubeola. Frequently it appears

valescence is often tedious, and the recovery of strength, appetite, ely to be slow. The average duration of the disease is about eight elapses are not infrequent. As regards incidental events and sequels, sions in children occasionally usher in the attack; delirium like that irium tremens has been observed to succeed protracted vigilance, and in quant women miscarriage is liable to take place. A rheumatic condition of the joints, abscesses, boils, and carbuncles are not infrequent sequels.

The extent of prevalence of this epidemic is remarkable. Wragg computes the number of cases at one time in Charleston at 10,000, and during the epidemic seven- or eight-tenths of the population were affected. All classes are attacked, persons of either sex, children and octogenarians.

The duration of epidemics is brief, ceasing usually in six or eight weeks. Of the special cause nothing is known. J. W. McLaughlin of Austin, Texas, has cultivated from the blood of dengue patients a micrococcus which he regards as the special agent of infection.¹ Sufficient evidence in support of this view, however, has not been adduced. Dickson regarded the affection as contagious. This opinion is opposed by the rapid and almost simultaneous diffusion of the affection, by the limitation of its prevalence to towns or within a circumscribed area, and by the short duration of epidemics. He also was of the opinion that, as a rule, immunity from subsequent attacks is secured when the disease has been once experienced. In proof of this opinion he stated that at Charleston, where the disease prevailed in 1850, only those escaped who had experienced it during the epidemic of 1828. The occurrence of a few cases of the disease among those who had it in 1828 he accounts for by supposing that after an interval of twenty-two years the susceptibility was renewed.² It is an affection chiefly occurring in warm climates, and it prevails especially in cities and large towns. To the latter rule there are, however, striking exceptions.

This affection, although extremely distressing, and presenting not infre-

² *Elements of Medicine*, 2d ed., p. 748.

Crozer Griffith of Philadelphia in 1887.¹ Of the 150 cases on which his report was based, only 1 was an adult. The great majority of cases occur between the ages of five and fifteen. The contagious nature of the disease is shown by its prevalence in "homes" and other public institutions.

The characters of the eruption of rubella are far from uniform, for which reason it has been described as a polymorphous exanthem. The only two varieties of the eruption which are of practical importance are those known as *rubella morbilliforme* and *rubella scarlatiniforme*. These terms indicate the remarkable resemblance which the exanthem of rubella may bear to either measles or scarlatina. From these affections rubella may be distinguished by the shortness and mildness of the prodromal symptoms, the comparative mildness of the catarrh of throat, nose, and conjunctiva, and the brief duration of the fever. In sporadic cases, as well as at the commencement of an epidemic, mistakes in diagnosis are liable to occur, but may be avoided by observing the rapidity with which the exanthem develops, often in the midst of apparent health, as well as the subsidence of the fever while the eruption is at its height. Enlargement and tenderness of the cervical glands are also important diagnostic signs of rubella. In doubtful cases inquiry should always be made as to whether the patient has been recently taking drugs such as antipyrin, quinia, and chloral, which may give rise to an eruption remarkably like that of rubella.

As this disease tends intrinsically to recovery and is attended with few or no distressing symptoms, there is little to be said concerning its treatment. Confinement to bed during the febrile period, and a mild, non-stimulating diet composed mostly of farinaceous substances and milk, are all that are needed as a rule. An occasional warm bath will, while serving the purposes of cleanliness, promote the development of the eruption, allay pruritus, and tranquilize the nervous system. The pharyngitis, if severe, is to be treated with emollient and astringent gargles and applications, precisely as in mild cases of scarlatina.—H.]

Dengue.

Dickson's name is especially identified with the epidemic affection commonly called *dengue*, an unclassical name of uncertain derivation, supposed to be synonymous with "dandy fever." He was the historian of its visitation in this country in 1828, and he contributed more largely to what is known respecting it than any other American writer.

The affection prevailed extensively in the West India Islands in 1827 and 1828, and about the same time in many parts of the Southern States of this country. An affection supposed to be the same prevailed in Philadelphia in 1780, and was described by Rush. It was then, as since, frequently known as the *breakbone fever*. Other epidemics supposed to be identical have occurred at various periods in Egypt, India, and other parts of the world. It prevails especially in tropical and subtropical countries. An extensive epidemic occurred along the southern coast of this country in 1880.²

The development of the affection is either abrupt or slow, more frequently the former. The symptoms attending its development are anorexia, chilly sensations, but rarely a pronounced chill, languor, lassitude, and general malaise. These symptoms exist in some cases for only twenty-four hours, but in other cases for several days before the affection is fully developed.

After the access or forming period follows a febrile stage or a paroxysm of fever. The duration of the pyrexia varies between nine hours and three or four

² J. Forrest, *Am. Journ. of the Med. Sciences*, April, 1881.

the tonsils or the soft palate. The pseudo-membranous exudation is often, although not necessarily, preceded by a simple (catarrhal) inflammation. The false membrane is observed first as a grayish-white, slightly elevated patch, which cannot be detached from the mucous membrane without leaving a bleeding surface. The white patches may remain distinct, or they may coalesce and form one membrane, which covers the greater part of the tonsils, the soft palate, and the pharynx. As the pellicular deposit increases in thickness it acquires a yellowish or dirty-gray color. Sometimes it has a reddish or a brown hue from admixture with blood. The membranous exudation is sometimes soft and pulpy in consistence; but often it is firm, almost leather-like, and elastic, and can be detached in a single layer. At autopsies the membrane is generally found to be softened. In the course of three or four days, sometimes a longer and sometimes a shorter period, the false membrane becomes loosened from its attachment to the mucous membrane, so that it can be readily separated without injury to the subjacent tissue. The separation of the membranous exudation, either as a coherent layer or as a soft, disintegrated mass, leaves the subjacent mucous membrane either smooth and intact or ulcerated. The mucous membrane is left in an ulcerated condition chiefly in those severe cases in which the fibrinous exudation extends into its substance. Ulcers may be produced also by a suppurative process in the mucous membrane.

Outside of the pseudo-membranous exudations the mucous membrane is reddened. It usually presents ecchymoses in greater or less number. It is swollen from oedematous infiltration and the presence of inflammatory products. The tonsils especially are often greatly enlarged. The uvula may be swollen to twice its normal size. The inflamed mucous membrane is usually coated with a muco-purulent secretion which may be present upon the false membranes.

The extension of the membranous exudation into the larynx is not uncommon, and this is a serious event in the clinical history of the disease. The characters of the fibrinous exudation in the larynx, the trachea, and the bronchi are the same in diphtheria as in membranous croup. (Vide p. 208.) The false membrane in the trachea and bronchi is of the typical croupous variety; that is, it lies loosely upon the mucous membrane. In most parts of the larynx it is also loosely attached, but on the epiglottis and the vocal cords it is usually adherent. As a rule, the pseudo-membrane is readily separated from mucous membranes covered with cylindrical epithelium and having a well-marked basement membrane, whereas it is more adherent to mucous membranes lined with flat epithelium.

The false membranes are composed of fibrillated fibrin, epithelial cells, leucocytes, red blood-corpuscles, and low vegetable organisms. The fibrillated fibrin is derived from the fibrinogen contained in the inflammatory exudation from the blood, the fibrin ferment being furnished by necrotic leucocytes and tissue-cells. The epithelial cells in part undergo coagulation necrosis, and thereby lose their nuclei and undergo various changes in shape. These necrotic epithelial cells may form a coarse, glistening, homogeneous network, allied both in appearance and in composition to fibrin. The leucocytes may likewise undergo coagulation necrosis and assume an irregular shape and a hyaline appearance. The structure of the false membrane varies considerably according to its situation. Upon mucous membranes covered with cylindrical epithelium, as in the trachea, the bronchi, and the greater part of the larynx, the pseudo-membrane is composed chiefly of fibrillated fibrin, containing some epithelial cells and a larger or smaller number of red and white blood-corpuscles. Upon mucous membranes covered with laminated flat epithelium, as upon the tonsils,

quently severe symptoms, is very rarely, if ever, fatal. Its apparent intensity is in striking contrast to the absence of danger.

The affection is self-limited, and there are no known means by which it can be arrested or abridged. The treatment, therefore, consists of palliative measures. Opiates to relieve the pains, restlessness, and vigilance are indicated. Rubefacients to the spine and in other situations are useful. Alcoholic stimulants, given pretty freely, have been found beneficial. A high temperature is an indication for antipyretic treatment. Charles recommends moderate doses of belladonna. During convalescence tonic remedies and hygienic measures to promote appetite and the recovery of strength are indicated.

[Leprosy—Lepra.

ETIOLOGY.—Leprosy is a chronic infectious disease of which the principal lesions are cutaneous. It is now universally believed to be caused by a micro-organism—a bacillus—discovered by Hansen in 1880, and hence often called "Hansen's bacillus." Morphologically the bacillus lepræ is remarkably like the bacillus tuberculosis. In fact, the two can scarcely be distinguished except by their different reactions to certain dyes. Unlike the bacillus of tubercle, the bacillus lepræ is stained by the ordinary anilin dyes as well as by Gram's method, by neither of which can the bacillus tuberculosis be colored.

There has been much discussion concerning the heredity of leprosy, but the weight of authority is against the view that it is transmitted from parent to child. "In syphilis, the type of a hereditary disease, we find all grades of direct hereditary transmission, from the fœtus dead in utero or the infant born with, or showing shortly after birth, manifestations of the disease, up to those where parental disease causes only more or less lowering of health in the children. There is nothing of the kind in leprosy. There is no disease of the fœtus, and rarely any of the infant, and there are no characteristic signs, as in syphilis, to distinguish hereditary from acquired leprosy." A strong argument against the hereditary transmission of leprosy is afforded by the fact that the disease is rare in childhood. On the other hand, the advocates of heredity refer to cases in which the affection has manifested itself many years—twenty-seven in one case (Bidenkap), thirty-two in another (Hallopeau)—after removal from all possible sources of infection. They claim that a period of incubation so protracted is scarcely conceivable, assuming as a matter of course that the disease is more apt to be latent for a protracted period when transmitted by inheritance. To the writer it seems quite as likely to remain dormant in the one case as in the other. Leprosy is most prevalent between the ages of twenty and forty, and attacks both sexes in about equal degree. It occurs in all latitudes; in fact, it prevails most extensively in regions the climatic conditions of which are diametrically opposite. For example, lepers are numerous in Norway and Sweden, and equally so in India. In the latter country there were in 1880 174,294 cases. In America there are colonies of lepers in the province of New Brunswick, in Minnesota, Louisiana, Key West, and Mexico. It is a singular fact, to which attention was first called by Bidenkap,¹ that leprosy is rare in large cities, even though it be prevalent in the country districts around them. Mr. Jonathan Hutchinson attributes the origin of leprosy to the use of salted fish, and asserts that the "real influence in spreading leprosy over Europe in the Middle Ages was probably not the returning Crusaders, but the advance of Christianity, which enforced frequent fast-

¹ Van Harlingen, *Annual Univ. Med. Sci.*, vol. iv., 1892.

² *An Abstract of Lectures on Leprosy*, by J. L. Bidenkap, Christiania, 1886.

days on which salt fish was largely consumed." In accordance with this view, he holds that leprosy may be extinguished by the substitution of other kinds of food for fish, more especially for salt fish.¹ The last-mentioned hypothesis is referred to on account of the eminence of its advocate, but those whose acquaintance with leprosy is most intimate regard it as having little basis of fact to rest upon.

SYMPTOMS.—Leprosy is universally divided by systematic writers into two forms: the anæsthetic or nervous—*lepra nervosa*—and the tuberculous—*lepra tuberosa*—in accordance with the predominance of the disease in the integument or peripheral nerves. It is probable, however, that in all cases both the skin (and mucous membranes) and the nerves are the seat of the specific infiltration.

Lepra Nervosa.—Decreased cutaneous sensibility, either with or without obvious change of the skin, is the first symptom of the anæsthetic variety. When gross changes are present, they assume the form of erythematous spots from two to three centimetres in diameter, sharply defined, and but slightly elevated. They persist usually for months, and then fade slowly from the centre outward. They generally reappear in the same regions, and occupy a larger space and are more prominent than during the first outbreak. They may also be attended with desquamation, so as to resemble psoriasis vulgaris. The affected regions are more or less anæsthetic, and areas of anæsthesia may be detected on careful examination in regions which present no gross appearances of disease.

The next symptom is an outbreak of vesicles resembling those of pemphigus. The vesicles burst, and leave a raw surface which may heal with more or less loss of substance and leave behind a shining white anæsthetic cicatrix. The vesicular eruption is often attributed by the patients to scalding, frost-bite, or pressure, and doubtless such traumatisms are concerned in their production, for, on account of the anæsthesia, the hands and feet are sometimes unconsciously injured to such an extent as to impair their vitality. Muscular atrophy and contractures of the muscles of the extremities, especially those of the hand, supervene, and examples of the claw-hand (*main-en-griffe*) are not uncommon. Paralysis, especially of the orbicularis palpebrarum muscles, develops, and may, through the resulting inability to close the eye, lead to destructive inflammation of the cornea.

The ulcers resulting from the vesicular eruption may, instead of healing, extend in depth and involve the periosteum. In this way the phalanges of the fingers and toes may be gradually destroyed and cast off spontaneously. The nerves of special sense and the lymphatic glands are seldom involved in this variety of the disease. Amyloid degeneration of the kidney and other glandular organs is not uncommon. The disease is to a certain extent paroxysmal, each vesicular outbreak being attended with fever, and sometimes with delirium and coma. As the disease progresses the patient becomes more and more emaciated and falls into a state of profound cachexia. Death is due to intercurrent disease or may occur in one of the febrile paroxysms. The average duration of *lepra nervosa* is variously estimated at from ten to twenty years. Sometimes the disease appears to be arrested, the eruptions disappearing and the general health improving in a marked degree. It is even stated that sensation may return to the anæsthetic spots. *Lepra nervosa* may become converted into *lepra tuberosa*, in which event it is generally rapidly fatal.

¹ *Trans. X. internat. med. Congress.*, vol. v.

Lepra Tuberosa.—Tuberculous leprosy may begin somewhat abruptly, with fever and cutaneous eruption, or insidiously. Ill-defined spots on the surface, especially of the face (cheeks and eyebrows), are generally the first symptoms to excite suspicions of the disease. They are of a livid or brownish hue. At a later period these spots become infiltrated, so as to form distinct projections or marked tuberosities. The integument of the face, especially of the superciliary region, becomes greatly thickened, and the countenance acquires the characteristic leonine expression. The hair and even the down (lanugo) of the affected parts entirely disappear. The sensibility is not impaired unless the nerves are affected, and the case, therefore, one of the mixed variety. By degrees the entire skin of the face, including that of the ears, is involved in this species of pachydermatous thickening. At a later stage distinct rounded tubercles of the size of a pea or larger, and deeply pigmented, project from the thickened base. The parts chiefly affected are the face and extremities. The hairy scalp is never attacked, and the neck, breast, and back may remain free from the infiltration throughout the course of the disease.

In the acute form of tuberculous leprosy there are febrile paroxysms followed by eruptions which often resemble patches of erythema nodosum or erysipelas. They may fade, leaving behind some thickening or pigmentation, or in late stages they may suppurate. In the course of time the mucous membranes of the mouth, nose, and throat are attacked, causing hoarseness and increased secretion of nasal mucus. Swelling of the lymph-glands is an early and prominent symptom. The tuberosities upon the skin have been observed to disappear during the course of an intercurrent eruptive fever, and general tuberculosis, to which many lepers succumb, seems to cause a recession of the leprous deposit.

The usual course of lepra tuberosa is the following: The tubers eventually become depressed in the centre and disappear by slow absorption from centre to circumference. This may occur without ulceration. In other cases the epidermis disappears from the depressed portion of the tubercle, and a slow process of ulceration begins, which may extend in depth and destroy the underlying cartilages and bones. In this manner—by softening and ulceration of the leprous deposit—the cartilaginous framework of the nose, the laryngeal cartilages, and the cornea and other tissues of the eye may be entirely destroyed. In this stage of the disease the cachexia is decided and febrile paroxysms are frequent. The latter may be as regular in occurrence as the paroxysms of intermittent fever. The symptoms now point to an involvement of internal organs. This is not necessarily of a leprous character, for, as already stated, amyloid degeneration of the kidneys and other glandular organs is a frequent complication. A persistent diarrhoea may be due to amyloid degeneration of the mucous membrane of the intestine or to the specific leprous deposit.

ANATOMICAL CHARACTERS.—The leprous tubercles ("lepromata") are classified by Virchow among the granulomata. They are composed essentially of round cells the most of which are believed to have emigrated from the vessels. There has been considerable discussion as to whether the bacillus lepræ is within or outside of the cells of which the specific deposit is composed. Late researches indicate that during the early stages of the process the bacillus is intracellular. At a later period many of the cells are disintegrated and the contained bacilli set free.

The **DIAGNOSIS** presents no difficulty except in the early stages, and even then suspicions of the disease should be excited by the spots of erythema

succeeded by bullæ, especially if such symptoms were observed in one who had formerly resided in a country in which leprosy was endemic. In doubtful cases of the tuberculous form a fragment of the diseased integument should be excised and examined for Hansen's bacillus.

PROGNOSIS.—The prognosis is always unfavorable, but long periods of improvement may occur during the course of the disease, and in some few it appears to come to a standstill. Of the two varieties, *lepra nervosa* offers the better prognosis.

TREATMENT.—It is customary to attribute the rapid decrease of leprosy in central Europe during the Middle Ages to the strict measures of isolation at that time enforced, and there is scarcely any authority who questions the advisability of a separation of the infected from the non-infected. Nevertheless, it cannot be denied that leprosy has declined in places where the isolation of the infected was but partial. This is true, for example, of Norway, the Faroe Islands, and Iceland. The conclusion seems, therefore, inevitable that there have been other causes, apart from mere isolation, tending to the extinction of the disease. As suggested by Bidentkap, these may possibly be found in the improved social conditions, the greater comfort and cleanliness, and the better food coincident with the progress of civilization.

The curative treatment is both hygienic and medicinal. If possible, the patient should be removed to a mild, equable climate where the greater portion of his time may be spent in the open air. Frequent baths (both warm-water and steam) are beneficial both generally and locally. Tonics, especially iron and quinia, are applicable to most cases, and during the febrile paroxysms the latter drug may be given in larger, antipyretic dose. Cod-liver oil, arsenic, iodine, and phosphorus, have also been employed. Among local remedies there are two—gurjun oil and chaulmoogra oil—which have been regarded as curative in early stages of the disease. The first mentioned is made into a liniment by mingling it with equal parts of lard oil and lime-water, and rubbed into the affected parts under moderate pressure. It is also given internally in doses of 5 to 15 minims in emulsion in lime-water. This drug is largely employed by the physicians of India. Chaulmoogra oil mingled with twice its quantity of lard or lanolin is also used both locally and internally. The affected areas are rubbed with this ointment several times daily, and during the intervals the skin is covered with a cloth saturated with it. Internally, it is given in doses of 5 minims three times a day, which may be gradually increased up to the point of tolerance. Intolerance of the drug is manifested by diarrhœa and vomiting. Instead of the oil itself its active principle, gynocardic acid, may be given in 1-grain pills thrice daily after meals. Unna has reported good results in one case from the employment, both local and internal, of ammonium sulphichthyolate. Internally, this substance is given in pill form in daily doses of from 5 to 15 grains. Koch's tuberculin has been employed in the treatment of leprosy, but, as might have been anticipated, with negative results. In cases complicated with tuberculosis the effect of this remedy might be positively injurious. Leprous ulcerations are to be treated on general surgical principles.

palate, and pharynx, a considerable part of the false membrane is made up usually of epithelial cells and of leucocytes which have been transformed in the manner already described by the process of coagulation necrosis; but here there is also some fibrillated fibrin, as well as nucleated epithelial cells and leucocytes. The false membrane may be composed, in addition to the constituents mentioned, of the superficial layers of the mucous membrane which have undergone coagulation necrosis.

Beneath the false membrane the mucous membrane contains inflammatory products—namely, serum, emigrated white blood-corpuscles, escaped red blood-corpuscles, and frequently fibrillated fibrin. The walls of the blood-vessels and other parts of the mucous membrane frequently present a homogeneous, hyaline appearance, variously described as hyaline degeneration, fibrinoid degeneration, and coagulation necrosis.

In this connection it is well to refer once more to distinctions which have already been described in previous articles. The terms croupous exudation or inflammation and diphtheritic exudation or inflammation are used in a purely anatomical sense, without any necessary relation to the diseases known as croup and diphtheria.¹ A croupous exudation is a fibrinous false membrane which rests loosely upon the mucous membrane without extending into its substance. The primary necrosis which antedates all fibrinous inflammations of mucous membranes involves only the epithelial covering. A diphtheritic exudation is a fibrinous false membrane which at first is closely adherent to the mucous membrane, and which is composed wholly or in part of necrotic portions of the mucous membrane. Here the necrosis involves not only the epithelium, but also the superficial layers of the mucous membrane. Many of the false membranes on the tonsils and pharynx are closely adherent to the mucous membrane, and thus far they appear like diphtheritic exudations; but upon microscopical examination it is often found that only the epithelium, and not the mucous membrane proper, enters into the formation of the false membrane. Such apparently diphtheritic exudations are designated by Weigert as pseudo-diphtheritic. It is doubtful whether anything be gained by the distinctions which are thus made between croupous, diphtheritic, and pseudo-diphtheritic exudations, especially as they do not refer to any essential differences in the nature of the morbid process, but only to differences in degree. It is necessary, however, that the reader should be familiar with these distinctions, as they are in common use. Some writers call all fibrinous inflammations of mucous membranes croupous inflammations, without distinguishing different varieties. Such a plan avoids the manifest confusion attending the foregoing classification.

As would naturally be expected, the false membranes, being exposed more or less directly to the atmosphere, contain a variety of micro-organisms. Inasmuch as diphtheria is an eminently contagious disease, there is reason to believe that it is caused by some form of micro-organism. [The organism that is now generally recognized as the specific infectious agent of diphtheria was first thoroughly described and studied by Löffler,² although it had been previously observed by Klebs.³ It is therefore commonly spoken of as the Klebs-Löffler bacillus. Löffler found this bacillus to be a constant accompaniment of diphtheria, but at first expressed himself with reserve as to its specific nature, because he had once found it in the mouth of a healthy child. Later researches by Löffler himself, by Roux and Yersin, Escherich, Brieger, and others have removed all doubts concerning the specific nature

¹ Thus we speak of diphtheritic inflammations of the intestine or of the bladder when there is no thought of the existence of the disease known as diphtheria.

Later researches by Löffler himself, by Roux and Yersin, Escherich, Brieger, and others have removed all doubts concerning the specific nature

¹ Thus we speak of diphtheritic inflammations of the intestine or of the bladder when there is no thought of the existence of the disease known as diphtheria.

² *Mittheilungen aus d. Kais. Ges.-Amte*, Bd. 2, 1884.

³ *Cong. für inn. Med.*, Wiesbaden, 1883.

of this organism. The confusion in which the etiology of diphtheria has been involved is due to the fact that all cases of membranous pharyngitis are not diphtheritic. It is now well recognized that a distinction is to be drawn between diphtheria and pseudo-diphtheria. For example, the membranous angina so frequently observed in scarlatina is generally pseudo-diphtheritic, although genuine diphtheria may occur under the same circumstances. The only certain method of establishing the diagnosis of diphtheria in doubtful cases is a bacteriological examination, including cultures of the organisms of the fibrinous deposit. The presence of the Klebs-Löffler bacillus stamps the case as one of genuine diphtheria.—H.]

In certain cases of great severity portions of the mucous membrane of the mouth and pharynx are separated in the form of sloughs which undergo decomposition and emit a foul odor. The necrotic process may extend into the deeper tissues. This malignant form of the disease is called *gangrenous diphtheria*. Sometimes thick pseudo-membranous deposits are so disintegrated and decomposed as to give a false appearance of gangrenous diphtheria.

The lymphatic glands of the neck, especially those near the angle of the lower jaw, are more or less enlarged. As a rule, the amount of enlargement corresponds to the severity of the affection within the throat. The glandular affection rarely proceeds to suppuration. A diffuse inflammation of all of the tissues of the neck may occur, but this is not common.

The lungs may present a variety of appearances, none of which are characteristic of the disease. When death has resulted from suffocation in consequence of involvement of the air-passages, the anterior and upper parts of the lungs are found to be emphysematous. Bronchitis and broncho-pneumonia are not infrequent complications of diphtheria. Lobar pneumonia is a rare complication. The extension of the fibrinous exudation to the bronchi has already been mentioned. Œdema glottidis may develop in the course of diphtheria.

When the disease has been attended with symptoms of severe blood-poisoning, ecchymoses in the serous membranes and parenchymatous degeneration of the heart, liver, kidneys, and muscles have been found after death. Acute fatty degeneration of the heart and acute myocarditis have been found in certain cases which terminated suddenly with signs of paralysis of the heart. The kidneys may be the seat not only of parenchymatous degeneration, but also of an acute nephritis. Oertel has found colonies of micrococci in the kidney, but they are accidental and not often present. Acute ulcerative endocarditis is a rare complication of diphtheria. The spleen is not infrequently somewhat enlarged and softened. These changes in the internal organs are those which characterize acute infectious diseases in general.

CLINICAL HISTORY.—Diphtheria presents, in different cases, such differences as regards general and local symptoms—the latter incident especially to the localizations of the diphtheritic affection—that some writers have instituted several varieties of the disease. Without adopting formally any of these, it will suffice to indicate the important diversities in connection with the symptomatology.

A marked point of difference relates to the development of the disease. The attack is sometimes abrupt, beginning with a chill more or less pronounced, and followed by considerable or marked pyrexia, or the disease may begin with symptoms denoting great prostration; but not infrequently the development is gradual and insidious, the patient complaining of indefinite ailments, and the characteristic affection of the throat being discovered on inspection when there are few or no local symptoms pointing to the existence

of the disease. After the development of the disease the symptoms are naturally divided into general and local, the latter being referable especially to the parts affected with the diphtheritic process.

The affection of the fauces is rarely accompanied by notable pain or soreness, and hence there is a liability to overlook its existence. The sensibility of the parts appears, in some cases, to be diminished. Deglutition is sometimes painful, but in other cases it is unattended with pain. Incomplete paralysis of the muscles concerned in deglutition, which will be noticed as a sequel, is sometimes a concomitant of the disease, giving rise to more or less difficulty of swallowing, especially liquids. These may regurgitate through the nose. If the exudation be abundant and loose, pharyngeal râles occur with respiration, especially during sleep. The breath in some cases is notably fetid, suggesting the idea of gangrene of the throat or lungs—events not frequent in the history of the disease. The extension of the false membrane over more or less of the buccal mucous surface occasions greater or less pain in connection with the introduction of food or drinks into the mouth, together with pyalism and stiffness of the parts, involving difficulty of articulation and absence of taste. The affection of the anterior nares is preceded and accompanied by a discharge which produces excoriation and swelling of the upper lip, limited to one side of the lip if one nostril only be affected. In other situations accessible to view, on a mucous surface or on the skin, the diphtheritic process gives rise to more or less pain or soreness, and is attended by a sero-purulent discharge variable in quantity, frequently ichorous, and sometimes fetid. As a rule, the gravity of the disease is commensurate with the extent of the local affection and the abundance of the exudation. It does not follow from this fact that the gravity depends on the local affection. The latter may be a criterion, not the cause, of the former.

The symptoms denoting an invasion of the larynx are essentially those which belong to the history of fibrinous laryngitis or true croup. These have been already considered.¹ Cough, having more or less of the characters known as croupous, feebleness of the voice with elevation of pitch, or aphonia, and labored, stridulous respiration, point to this most serious localization of the affection. The embarrassment of respiration may be increased paroxysmally, as in simple laryngitis or in true croup, by the addition of spasm of the muscles of the glottis. Swelling of the tonsils and pharynx may be sufficient to occasion some obstruction to respiration without invasion of the larynx. It is to be borne in mind that laryngitis may be excluded so long as the voice remains unaffected. Diminished respiratory murmur and embarrassment of the respiratory function out of proportion to the amount of laryngeal obstruction, with the presence of moist bronchial râles, denote an extension of the affection to the bronchial tubes.

Passing to symptoms other than those directly referable to the parts affected with the diphtheritic process, cases differ widely as respects the amount of constitutional disturbance. Irrespective of an affection of the larynx, which of necessity involves great danger, cases are either mild or more or less severe. In some mild cases the disease is almost trivial, patients not taking to the bed, and perhaps not keeping within-doors; but, however mild cases may be at the outset and during more or less of the career of the disease, there is always a liability to the occurrence of diphtheritic inflammation in new situations, to the development of grave symptoms, and to important sequels. In the cases in which the disease is mild throughout its career the local affection is confined to the fauces, or, exceptionally, to a limited space in some other situation.

In cases of greater or less severity the clinical history embraces symptoms

¹ Vide p. 209.

referable to the different anatomical systems—namely, the circulatory, cutaneous, respiratory, digestive, nervous, and urinary.

The pulse in some cases becomes very frequent; in other cases the acceleration is moderate, and it is sometimes slight. In the course of the disease the pulse is sometimes at first more or less rapid, afterward suddenly falling below the average of health. Aside from frequency, the pulse is soft or compressible. It is sometimes irregular—a symptom of unfavorable omen if it be independent of pre-existing organic disease of the heart. Hemorrhage from the nostrils is not an infrequent symptom, and it occurs occasionally from the throat and mouth. Epistaxis is sometimes so profuse as to require mechanical means for its arrest. Under these circumstances it denotes great gravity and danger, and hemorrhage in other situations is to be regarded as ominous.

The skin rarely presents much increase of heat. In some cases there is no increase, and not infrequently in the course of the disease the surface becomes cool or cold. The pyrexia, as a rule, is less than in most other acute diseases. The temperature may, however, be high. Petechial spots or ecchymoses are sometimes observed, occurring generally in connection with hemorrhage from mucous surfaces. In grave cases the skin presents an anæmic aspect even when hemorrhage has not occurred. In the cases in which the air-passages become affected there is more or less lividity of the surface, especially marked on the face and prolabia. The disease has no characteristic eruption. Rose-spots are sometimes observed and other forms of eruption—namely, erythema nodosum, urticaria, and sudamina—but these are accidental.

The symptoms referable to the respiratory system are due to fibrinous inflammation of the larynx, trachea, and the bronchial tubes. These have been already referred to among the symptoms incident to the local affections characteristic of the disease. If life continue sufficiently long, false membrane in these cases is expectorated, sometimes in the form of hollow tubes like macaroni, but generally in patches of irregular size and shape.

The desire for food is generally either notably diminished or lost. Aside from pain and difficulty in deglutition or the suffering caused by food and drinks when the mouth is affected, there is often an invincible repugnance to nourishment, so that in children, if given at all, it must be forcibly administered. Vomiting is a frequent, and in some cases a prominent, symptom. This, as well as anorexia, is serious on account of the interference with alimentation. Diarrhœa is not uncommon, and is a symptom of bad omen. In the cases in which the diphtheritic affection extends into the œsophagus false membrane is expelled by vomiting in the form of ribbons, provided death do not take place before the exfoliation is completed.

In the majority of cases the mind is unaffected. Slight passive delirium occasionally occurs, and sometimes the delirium is active. The latter denotes great gravity of the disease. Convulsions and coma are rare, but both are of occasional occurrence. Convulsions have been observed at all periods of the disease, and coma is the forerunner of a fatal termination. It is probable that coma and convulsions, occurring in this disease, are generally due to uræmia.

Albuminuria is a frequent symptom. The proportion of cases in which it occurs is variable. It varies considerably at different times and places. Generally, the albumen contained in the urine is small in amount, but it is sometimes abundant. In the cases in which it is abundant the diphtheritic exudation is generally large and the swelling of the glands of the neck is unusually great. General dropsy in connection with albuminuria is rare; it has, however, been observed in a small number of cases. There may be evidences of the development of acute Bright's disease, in which case casts and usually some red and white blood-corpuscles will be found in the urinary sediment.

Hæmaturia has been observed in cases presenting the symptoms of purpura or the hemorrhagic diathesis. As in the other febrile diseases, the urine contains a larger amount of urea than in health—a fact showing an increased waste of the tissues.

The duration of the disease is between one and two weeks. In fatal cases the duration may fall short of a week, death sometimes taking place within forty-eight hours. On the other hand, the illness may continue for an indefinite period beyond the maximum duration of the career of the disease, owing to consecutive affections or sequels.

Aside from the characteristic diphtheritic affections which are properly components of the disease, complications are rare and accidental. Pneumonitis is occasionally developed, and the affection of the kidneys, giving rise to an abundance of albumen in the urine, and sometimes to general dropsy, is perhaps to be regarded as a complication. The disease, however, may be associated with other diseases. Its concurrence with scarlatina, measles, and smallpox has been repeatedly observed. Painful swelling and redness of the joints, like that in acute rheumatism, is a rare complication.

The sequels of this disease form an important part of the clinical history. Anæmia and general debility are likely to persist for a considerable period. Feebleness of the action of the heart sometimes exists to such a degree as to lead to sudden death from syncope.

Paralysis affecting more or less the voluntary and sometimes the involuntary muscles is a characteristic sequel. The muscles of the soft palate and pharynx are oftenest affected, and paralysis here generally precedes its occurrence elsewhere. The palatine muscles are sometimes affected during the course of the disease, but generally not until after a period varying between one week and four weeks from the date of convalescence. In a slight or moderate degree the paralysis in this situation is denoted by a nasal intonation and by a certain amount of difficulty in deglutition and the regurgitation of liquids through the nostrils. In a greater degree and associated with paralysis of the œsophagus—which is happily rare—there is very great difficulty in swallowing, and it may be even necessary to introduce aliment by means of the stomach-tube. Under these circumstances sudden death has been caused by the passage of aliment into the larynx. On inspection the soft palate is seen to be relaxed and immovable. There often is anæsthesia of the mucous membrane of the throat. The paralysis affects the reflex action, so that the palate remains motionless when irritated with a pointed instrument. The existence of paralysis in this situation is indicated by a nasal intonation of the voice, and sometimes by a snoring sound in respiration. The paralysis in some cases affects the tongue and muscles of the face, so that articulation is difficult and the patient may be unable to perform the acts of suction and whistling. The act of gargling is also difficult or impossible.

The paralysis is sometimes limited to the muscles of the palate, pharynx, and mouth, but not infrequently it extends to other muscles. Exceptionally, the paralysis is manifested primarily or solely elsewhere than in the throat. Paralysis of one or more of the laryngeal muscles, either unilateral or bilateral, and associated often with anæsthesia of the laryngeal mucous membrane, may occur. Paralysis of the muscles of accommodation of the eye is not uncommon, causing defective power of adjustment in the eye for distant or near objects. This disorder is generally bilateral, but it is often more marked in one eye than in the other. Other muscles of the eye may be paralyzed, not infrequently causing strabismus. Amblyopia and transitory amaurosis occasionally occur. There is reason to believe that the amaurosis is sometimes attributable to uræmia. Disordered vision is in some cases the first of the paralytic sequels, and the paralysis is sometimes limited to the organs of

sight. The other special senses—namely, taste, smell, and hearing—are sometimes affected, but rarely as compared with the sense of sight.

Paralysis of the extremities is not a rare form of diphtheritic paralysis. Certain muscles only or all of the muscles of an extremity may be involved. The lower limbs are most likely to be affected, and paralysis here generally takes precedence of its occurrence in the upper extremities. The paralysis is developed gradually, and is often preceded or attended by subjective sensations of tingling, numbness, and coldness. The loss of power over the muscles may be complete or there may be different degrees of paresis. The paralysis sometimes assumes the form of paraplegia, sometimes of hemiplegia, or one of the upper extremities may be paralyzed in connection with paraplegia, or the upper limb on one side and the lower limb on the opposite side may be alone affected. Trousseau observed the paralysis to affect the different extremities successively and recurrently. Finally, the paralysis is sometimes general—that is, all of the extremities are paralyzed—and in addition the paralysis may involve the muscles of the face, the throat, mouth, neck, and trunk, and certain of the involuntary muscles. Cases in which the paralysis is so extensive are extremely rare.

The paralysis is of the atrophic variety. The paralyzed muscles are relaxed and may present the reaction of degeneration. The knee-phenomenon or patellar tendon reflex is usually abolished, and this often occurs after an attack of diphtheria, even when no paralysis is developed.

Acute ataxia, generally of the lower extremities, has been repeatedly observed as a sequel of diphtheria, without paralysis.

In connection with the paralysis of the extremities the sensibility of the affected parts, when tested objectively, is often intact; but it may be notably diminished both as regards the sense of pain and touch. Exceptionally, there is hyperæsthesia of the integuments.

The paralysis sometimes affects the intercostal muscles and the diaphragm, giving rise to dyspnoea and involving danger from inability to carry on the respiratory acts. The muscles concerned in defecation are sometimes paralyzed, causing either retention of, or inability to retain, the feces. In like manner, the paralysis may affect the bladder, causing retention and incontinence of urine. Notable impairment or loss of virile power may be mentioned as one of the rare sequels of diphtheria.

As regards the frequency of the paralytic sequels, a nasal intonation of the voice and more or less impairment of deglutition are common, but paralysis elsewhere occurs in a minority of cases. These sequels take place in cases of mild as well as of severe diphtheria.

In cases of diphtheritic paralysis lesions have been found in the central nervous system, in the spinal nerve-roots, and in the peripheral nerves. The anatomical basis of the paralysis does not seem to be the same in all cases. In several cases which have been carefully investigated the lesions of a multiple degenerative neuritis (p. 725) have been found. The characters of the paralysis, particularly the usually rapid recovery, are in favor of the peripheral nature of the lesion in many cases.

PATHOLOGICAL CHARACTER.—Diphtheria is a general disease or an essential fever. The pyrexia and constitutional symptoms are not merely symptomatic of the inflammation involved in the local diphtheritic affections. [but are largely due to the entry into the blood of toxic products secreted by the specific organism of the disease, the Klebs-Löffler bacillus. At the same time symptoms of septicæmia may be produced by the absorption of putrid products of the local inflammation.—H.]

A question which has occasioned much discussion and concerning which

opinions differ is, whether diphtheria and membranous croup be distinct diseases. [This has been settled by the discovery of the Klebs-Löffler bacillus, although in practice the application of bacteriological tests to fibrinous exudations is often difficult or impossible. The clinical points of distinction between diphtheria and certain forms of pseudo-membranous laryngitis have already been discussed under the head of Membranous Croup.—H.]

A diphtheritic affection of the throat occurs as an element of scarlatina, and the two diseases may exist in combination. The combination of the two diseases is the probable explanation of reported instances in which patients with scarlet fever apparently communicated diphtheria, and *vice versa*. The following instance came under my observation: The patient, a boy aged four years, had well-marked diphtheria and no eruption. After convalescence he became affected with complete hemiplegia and general dropsy, the urine denoting acute diffuse nephritis. During his convalescence a sister was attacked with scarlet fever, the efflorescence being abundant. The boy had the sequelæ of both scarlatina and diphtheria, following what appeared to be purely an attack of the latter, and he communicated to his sister the former and not the latter disease.

CAUSATION.—Diphtheria is eminently an epidemic disease. Sporadic cases, however, occur, and of late years in large cities the disease is never wholly extinguished. Diphtheria is a contagious disease. Evidence of this is found in instances in which the disease has followed the accidental introduction of some of the diphtheritic exudation into the mouth, nostrils, eyes, or wounds of the skin. Many such instances have occurred among physicians in attendance upon diphtheritic patients. These cases prove that the contagium is present in the diphtheritic exudation. It is true that Trousseau and Peter failed to produce the disease in themselves by voluntary inoculation, but a similar immunity in individuals exists toward many diseases the contagiousness of which is acknowledged. In this regard positive evidence outweighs any number of negative facts. [The disease has been repeatedly communicated to the lower animals by inoculations with the Klebs-Löffler bacillus.—H.] Further evidence of the contagiousness of diphtheria is afforded by the introduction of the disease into situations where it had not previously existed by patients coming from places in which it was prevailing. There are some instances recorded of the special poison being transported by individuals who did not themselves become infected with the disease, but such cases are rare. The contagium of diphtheria often adheres tenaciously to localities where it has once gained a foothold. Thus the disease has been contracted by those occupying rooms where many months before there had been a patient affected with diphtheria. Observations have been reported which show the possibility of the transmission of the diphtheritic poison by means of milk.¹

[Certain of the lower animals, such as the calf, the turkey, and the cat, are subject to a disease which closely resembles diphtheria and is believed by some to be identical with it. The facts appear to the writer to be in favor of the view that the disease may be transmitted by these animals to man.—H.]

Defective sewerage, imperfect ventilation, overcrowding, and other unsanitary conditions favor in no small degree the development of the disease in both its sporadic and epidemic form. It is probable that this effect is produced, not by the spontaneous generation of the diphtheritic contagium, but by a favorable influence upon the multiplication of the disease-germs outside of the body or by increasing the susceptibility of the persons exposed thereto. Diphtheria, however, is not infrequent under the best hygienic surroundings.

¹ Vide article by Hart in *Proc. of International Med. Congress of 1881*.

Sporadic cases occur under circumstances which seem to render it impossible that the special germ of diphtheria had been introduced from without; but a similar apparently spontaneous development of other contagious diseases occurs, so that these instances cannot overthrow the general belief in the contagiousness of diphtheria. Still, it remains true that it is often impossible to trace the source of infection in cases of diphtheria.

The susceptibility to diphtheria is not equal at all periods of life. This susceptibility is greatest between two and seven years of age. After this period the susceptibility progressively diminishes, but it exists in considerable degree even in adults. During the first year of life diphtheria is rare. Circumstances pertaining to sex, social position, occupation, etc. do not appear to be connected with the causation. Diphtheria occurs at all seasons of the year, but it is most frequent during cold, moist, and changeable weather, perhaps because then ordinary inflammations of the throat are most common, and these may increase the readiness with which the diphtheritic virus gains entrance to the system. One attack of diphtheria does not protect against subsequent attacks. The period of incubation is generally between two and eight days; it may, however, be longer.

Some persons are much more susceptible to diphtheria than others. It is often impossible to explain to what this increased susceptibility is due, but sometimes it is associated with chronic enlargement of the tonsils or with a tendency to simple, catarrhal inflammations of the throat.

Epidemics of diphtheria are irregular in their occurrence. It is a remarkable fact that they were scarcely known in America from the time of the epidemic in 1771, described by Bard, to about 1856, and since the latter date they have occurred in all parts of the continent. The disease is often limited in its prevalence in particular sections to a circumscribed area. For example, it has been observed to be restricted to a few houses or a single house or to a narrow strip of land on the banks of a stream. The special cause seems to require auxiliary causes, at present unknown, which are peculiar to certain localities.

Epidemics differ as regards certain features of the disease and the rate of fatality. In some epidemics there is an unusual tendency to an invasion of the larynx, and the amount of exudation in other situations is unusually large in the majority of cases. In other epidemics the local affection is confined to the fauces, as the rule, and the disease is generally mild. In respect to variations at different times and places, diphtheria resembles other epidemic diseases.

DIAGNOSIS.—It is important to define clearly the comprehensiveness of the term diphtheria in respect to diagnosis. Some physicians are accustomed during an epidemic to consider cases of simple or follicular pharyngitis as cases of diphtheria. This is sanctioned by writers who recognize as a variety of the disease "catarrhal diphtheria;" that is, diphtheria without the local diphtheritic characteristics. It is perhaps a rational supposition that the special cause may give rise to a pharyngeal inflammation and pyrexia without fibrinous exudation; but, however rational, this is only a supposition. On the other hand, it is well known that pharyngitis without diphtheritic characters is a common affection. False statistics in regard to death-rate, and erroneous conclusions respecting the effect of treatment, can be avoided only by recognizing as an essential criterion the local diphtheritic characteristics. Adopting this rule, the diagnosis cannot be positive prior to the membranous exudation, which may be preceded for a variable period by pyrexia and other general symptoms. These, from their violence, may mislead, unless an examination of the throat be made. Thus, I have known an attack with high fever and delirium shortly after confinement to be mistaken

for a time for puerperal fever. When it is an intercurrent disease in the course of another fever, it is liable for some time to be overlooked. In a case related to me by a medical friend, there being notable abdominal tenderness and great prostration, the disease for twenty-four hours was supposed to be acute peritonitis.

The diagnosis is easy when the local manifestations have taken place. The only liability to error is in confounding with the diphtheritic affection pharyngitis or tonsillitis with a deposit of mucus or an abundant follicular secretion. The appearance in some cases resembles that of a true exudation. The distinctive points are the following: A deposit of mucus or of follicular secretion is generally limited to, or especially marked over, the tonsils; it can be wiped off, but is not removable in strips; it may be seen to dip into the follicular depressions; and it is often thrown off within twenty-four or thirty-six hours. On the other hand, a diphtheritic exudation has the characters of a false membrane; it generally extends more or less over the soft palate and uvula; if removed it comes away in strips; and it is never exfoliated in thirty-six hours. [The only positive criterion of the nature of the false membrane—and hence of the disease—is afforded by a bacteriological examination of the exudate.—H.]

PROGNOSIS.—The proportions of deaths in collections of cases reported by different observers present much variation. This is measurably due to the fact that, irrespective of treatment, the fatality in different epidemics varies within widely-separated limits. The variations in statistics are also due in a measure to the error of confounding with diphtheria pharyngitis or tonsillitis with follicular secretion, and the error of applying the name diphtheria to all cases of sore throat occurring during an epidemic. Without attempting, therefore, to express the average death-rate in figures, it must suffice to say that it is sometimes very large and sometimes comparatively small.

The danger is, first, from an invasion of the larynx. Of the cases in which the air-passages become involved the vast majority end fatally. The prognosis in these cases is always exceedingly unfavorable. Apnoea either causes or contributes largely to the fatal result whenever the larynx becomes involved. The patient cannot be considered as secure against diphtheritic laryngitis so long as the career of the disease continues, but the danger from this source progressively diminishes after the first week.

The danger is, second, from asthenia or exhaustion. The violence of the disease may destroy life within forty-eight hours from the date of the attack, or perhaps even at an earlier period. In these cases the disease is truly called malignant. Using the language of metaphor for the want of precise knowledge of the general conditions on which the fatality in these cases depends, the vital powers are said to be overwhelmed with the force of the disease; but in the larger proportion of the cases in which the disease proves fatal by asthenia the powers of life are gradually exhausted, and death takes place in the second week. In the cases in which the larynx is unaffected the prognosis is always unfavorable if the diphtheritic membrane extend from the fauces into the posterior and anterior nares, if it pervade extensively the buccal membrane, or if it exist abundantly in other situations. The septic and gangrenous forms of diphtheria offer an especially unfavorable prognosis. Other unfavorable prognostics are—frequent vomiting, diarrhoea, copious epistaxis or hemorrhage in other situations, great frequency, irregularity, or feebleness of the pulse, coldness of the surface, abundance of albumen in the urine, convulsions, delirium, and coma.

A fact important to be borne in mind is the liability to sudden, fatal syncope in this disease. It may occur in cases which, as regards the general

symptoms, do not present an appearance of great gravity. It generally follows some unusual exertion, as in getting out of bed; and it has been known to occur even during convalescence. It is probable that in some of the cases in which a fatal result occurs suddenly or unexpectedly the death is occasioned by the formation of a thrombus in the right cavities of the heart. It may also be referable to parenchymatous degeneration of the heart.

The paralytic affections which are liable to supervene do not, in general, involve danger. The danger incident to these affections relates to innutrition in the cases in which deglutition is extremely difficult or impossible, and to apnoea when the respiratory muscles are involved in the paralysis.

TREATMENT.—With reference to therapeutical indications it is convenient to divide cases into those with and those without a diphtheritic affection of the larynx. The treatment of cases in which the larynx does not become affected will be considered first. The indications in these cases relate to the general condition and to the local affection.

It is obvious that views which relate to the pathological connection between the pharyngeal affection and the general condition must have great influence upon the rational indications as regards local treatment. If the disease be produced by bacterial germs or organisms, which, received into the mouth or nostrils, find a habitat generally in the mucous membrane of the throat, and that generated here are broods of parasites which poison the system with the products of their activity, it is a reasonable supposition that local treatment is first in importance. According to this view, the object is to destroy the parasites as early, quickly, and effectually as possible. There is sufficient probability of the correctness of this view to dictate the propriety of making trial of different articles and methods with reference to a parasitocidal effect. Another view renders local treatment rationally important—namely, that which attributes the general symptoms, in a greater or less degree, to the absorption of septic matter, not accepting the theory that the morbid agency of this matter is due to a specific diphtheritic organism. According to this view, it is a reasonable supposition that to prevent septicæmia is an important object of local treatment. Rational considerations, however, no matter how strongly they may seem to be supported by morbid anatomy, together with accepted doctrines of etiology and pathology, are never sufficient for the establishment of therapeutical rules without the results of clinical experience. Making proper allowance for the variableness of the disease in different epidemics, we have not, at present, sufficient clinical data for determining the relative value of the different kinds of either the local or the general treatment of diphtheria, and we lack the important standpoint for deciding upon the influence, collectively, of all kinds of treatment—namely, the mortality when the disease is allowed to pursue its course unaffected by any therapeutical measures.

Caustic and irritating applications to the throat—namely, the nitrate of silver, hydrochloric acid, the sulphate of copper, and the strong solutions of the pernitrate or persulphate of iron—have heretofore been in vogue. They are still employed by some practitioners, and their use is sanctioned by some standard authors. They are objected to on the following rational grounds: Impairing the continuity of tissue facilitates the entrance of organisms or septic matter into the system; and observation teaches that secondary diphtheritic exudation is liable to occur in any situation on the mucous surface or skin in which there is abrasion; as, for example, after the application of a blister. Many physicians have testified to the apparent hurtfulness of these applications. On the other hand, testimony of their usefulness is not want-

ing. A medical friend of much experience is convinced that by the prompt and thorough application of nitric acid, if the part primarily affected can be seen and reached, the progress of the disease may with certainty be arrested. He claims that want of success can only be explained by lack of thoroughness in the application. It should be made by bringing into contact over the whole of the affected part either lint or several thicknesses of linen cloth holding the acid, with sufficient pressure for the acid to penetrate the exudation and act upon the underlying tissue.

Cauterizing applications have of late years, to a great extent, given place to those supposed to be useful by means of a disinfectant or antiseptic effect. Remedies applied for this effect are carbolic acid, salicylic acid, permanganate of potassa, chloral hydrate, sulphite of soda, benzoate of soda, subsulphate of iron, bromine, oil of turpentine, and the chlorate of potassa. Two or more of these are sometimes combined. The applications in a liquid form may be made by means of a probang, a camel's-hair brush, or a spray-producer. The latter is preferable, especially in children. The salicylic acid is conveniently applied in the form of a dry powder combined with bismuth, or it may be used in the form of a solution of salicylate of sodium (7 parts to 100 of water). The chlorate of potassa may be taken dry into the mouth, combined with pulverized sugar. It is to be remembered that the absorption of large quantities of chlorate of potassa is often attended with danger. The applications are to be made by means of injections into the nostrils if the exudation be seated in the Schneiderian membrane. Whatever be the disinfecting or antiseptic articles employed, they should not be concentrated sufficiently to cause local irritation, and they should be repeated at short intervals. Oertel advises a spray from a solution of the chlorate of potassa and salicylic acid, with, in severe cases, the addition of the permanganate of potassa, to be continued for a quarter of an hour and repeated every hour or even every half hour. The thorough cleansing of the affected parts by gargling or injections with tepid water holding some disinfectant in solution is an important part of the local treatment. Oertel attaches much importance to the promotion of suppuration, and advises for this end the frequent inhalation of hot steam. Various solutions have been used as local applications with the view of dissolving the false membrane. For this purpose lime-water, lactic acid, pepsin, trypsin, and papayotin have been employed, but it is uncertain whether they exert any decidedly favorable influence. When there is much fever swallowing bits of ice is grateful to the patient.

The degree of efficacy to be attributed to local treatment, and the particular applications to be preferred, are to be settled by further clinical experience. Physicians differ as to the importance of topical applications and as regards preferences among those which are in use. In view of the deficiency of data for exact conclusions the opinions of individual observers will have weight in proportion to their opportunities for observation and the confidence placed in their opinions.

[Dr. J. Lewis Smith of New York recommends the following treatment of diphtheria, which has been used with success at the New York Foundling Asylum: "Trypsin, when well prepared and fresh, is an active solvent of pseudo-membranes, but it requires an alkaline medium for its activity. Sulphur, as shown by E. R. Squibb of Brooklyn and others, requires moisture in order to obtain its full activity and efficiency as an antiseptic agent. Therefore, by means of a steam atomizer, the vapor of the following prescription is constantly directed toward the face of the patient:

R. Sodii bicarbonat.,
Aque calcis,

3ij;
Oij.—M.

Or this:

R. Ol. eucalypti,	ʒij ;
Sodii benzoat.,	ʒj ;
Sodii bicarbonat.,	ʒij ;
Glycerini,	ʒj ;
Aquæ calcis,	Oij.—M.

While this spray is being used the following powder is blown by the insufflator over the fauces and into the nostrils every hour or two hours:

R. Trypsin,	
Sodii bicarbonat.,	āā. ʒss ;
Pulv. sulphuris,	ʒij.—M."

Of late years peroxide of hydrogen has been largely employed as a topical remedy in diphtheria, but, it must be confessed, with discrepant results. These are, in all probability, due to variations in the strength and quality of the preparation. When it gives rise to decided smarting, it is either too strong or too acid. Smith recommends for spraying the fauces a 15-volume solution diluted with ten times its bulk of water, and for the nares the same solution diluted twelve or fifteen times. He advises that the mother or nurse first apply the spray to her own throat, and dilute it if it causes pain. The writer believes in the efficacy of the peroxide of hydrogen when employed with the above-mentioned precautions. It is a powerful germicide and disinfectant, and, being free from taste and odor and non-poisonous, is especially applicable to the treatment of diphtheria in children.—H.]

With reference to the general treatment, if the germ theory be adopted it is a legitimate purpose of clinical observation to discover a remedy to be taken into the system for a parasiticial effect. Several remedies are supposed to have this effect. Some physicians attribute to the sulphites efficacy in this way, given in full doses after short intervals. Twenty or thirty grains of the sulphite of sodium may be repeated every two or three hours. The sulphocarbolate of sodium, in doses of a scruple to an adult every hour or two, in the practice of a medical friend of much experience, has seemed to him to be signally useful. This remedy, improperly prepared, is sometimes extremely offensive to the taste, but, properly prepared and given with an agreeable syrup, it is not repulsive. The benzoate of sodium, given hourly in doses aggregating in twenty-four hours between fifteen and twenty-five grammes, has been used with apparent benefit in Germany, but it has no special efficacy. It is claimed by Dr. E. W. Chapman, on the basis of clinical experience, that alcohol, given early and as largely as can be borne without symptoms of alcoholism, acts as an antidote, and that, conjoined with quinia, it is an effective curative agent. Calomel, corrosive sublimate, and other preparations of mercury, given in frequently-repeated doses, are recommended for their germicide effects, and have apparently proved useful. Pilocarpine has been administered internally with the idea that by inducing abundant secretion it aids in the detachment of the false membrane, but the favorable results at first reported as following the use of this remedy have not been confirmed by subsequent experience. We may hope that for this disease and for other infectious diseases remedies may be discovered which will have a controlling influence, like that of quinia in the malarial fevers; but at present we know of no drug which exerts a specific curative influence over diphtheria.

Aside from remedies for a special controlling influence, in view of the fact that if the larynx be not affected the danger is chiefly from asthenia, the great object of treatment is support. Much importance belongs to alcohol as the

most efficient factor in the supporting treatment. The principles which should govern its employment are the same as in the essential fevers and in other diseases tending to destroy life by asthenia. These principles need not here be repeated. In this disease, as in the essential fevers, there is sometimes a notably increased tolerance of alcoholics. Jenner cites a case in which two drachms of brandy were given hourly with advantage to a child three years of age. In a case of great severity which came under my observation half an ounce of brandy was given hourly, the patient being thirteen years of age, without any excitant effect, the case ending in recovery. In the use of alcoholics the physician is to be guided by the indications and by carefully watching the immediate effects. Alimentation is an essential part of the treatment. The diet should be concentrated and highly nutritious, and it should embrace the necessary variety of alimentary principles. Milk meets pre-eminently these requirements. A serious difficulty in the treatment often arises from the invincible repugnance to nutriment, and sometimes from the persistence of vomiting. Owing to the difficulty of alimentation in some cases, and sometimes a want of appreciation of its importance, death takes place from innutrition. Of tonic remedies, the sulphate of quinia and the tincture of the chloride of iron are very useful.

The measures heretofore known as antiphlogistics—namely, bloodletting, general or local, purgation, emetics, and nauseants—are rationally contraindicated by the simple fact that the danger is not from the inflammatory manifestations of the disease, but from the general condition which tends to destroy life by asthenia. Clinical experience has abundantly shown these measures to be injurious. Blisters and other counter-irritant measures are not to be employed, occasioning, as they are likely to do, new foci of diphtheritic inflammation.

Symptoms incidental to the disease claim palliative treatment. Vomiting is to be relieved by bismuth, creasote, hydrocyanic acid, etc. Diarrhœa calls for opium and astringents. Anodynes—that is, opium or its succedanea, the bromides, or the chloral hydrate—are often indicated by restlessness and vigilance. Hemorrhage indicates the use of hæmostatics topically and internally.

The treatment of cases in which diphtheritic laryngitis becomes developed involves the same general principles as that of cases without the laryngeal affection; but, in addition, measures are indicated to hasten the separation of the false membrane within the larynx, precisely as in cases of laryngitis with false membrane disconnected from diphtheria; that is, in cases of sporadic or primary so-called true croup. The most efficient of the measures for this end is the inhalation of warm vapor or steam. With reference to this measure and other points relating to the treatment directed to the laryngeal affection the reader is referred to the article on Laryngitis with Fibrinous Exudation.¹

The rules with respect to tracheotomy when the danger from laryngeal obstruction is imminent are the same as in cases of primary croup. There is undoubtedly less hope of success from surgical interference than in the latter affection. With reference to the propriety or importance of the operation, however, the simple question is, Are lives ever saved by it? This question is undoubtedly to be answered in the affirmative. The question, How many lives are saved? is of less importance in its practical bearing. If lives be ever saved by tracheotomy in diphtheria, a practitioner is reprehensible if he allow a patient to die from laryngeal obstruction without opening the trachea. The patient is entitled to the chance of being saved by the operation, however small that chance may be.

The method of treating laryngeal stenosis by passing a tube into the larynx

¹ Vide p. 210.

(intubation) has been practised with considerable success by Dr. O'Dwyer of New York, and has been recently advocated by him. Other practitioners have in general had less favorable results in employing this method than those obtained by Dr. O'Dwyer. [The remarks on intubation in connection with the subject of Membranous Croup are equally applicable here.—H.]

The propriety of precautions against contagion has been already referred to. Patients affected with the disease should be at once isolated. Whenever practicable, the removal, especially of children between three and twelve years of age, from an infected house or district is advisable. Thorough disinfection of the dejections, of all articles which have been in contact with patients, and of the apartments which they have occupied is to be enjoined. Auxiliary causes are to be sought after in defective sewerage or drainage, overcrowding, want of ventilation, etc., and these removed if discovered.

The diphtheritic paralyses may be treated by massage, by the employment of the galvanic current, and by hypodermic injections of small doses of strychnine.

Milk Sickness.

During the early decades of this century the disease known in the lower animals as the *trembles*, and in human beings as the *milk sickness*, prevailed extensively in many of the frontier settlements of what were then the Western and South-western States of this country. The disease has gradually receded before the advances of improved agriculture, but it still retains a foothold in certain districts where it has been endemic. The States in which the disease has most frequently been observed are Indiana, Illinois, Ohio, Kentucky, Tennessee, Missouri, and Michigan; but cases have occurred in Western Pennsylvania, Virginia, Alabama, Georgia, and North and South Carolina. The disease is not known to have occurred east of the Alleghany Mountains, west of the Great American Desert, or in the countries of the Old World. The descriptions of the disease, coming as they do in great part from recently-settled regions where medical science has not reached a high development, are very imperfect. Notwithstanding the doubt which has been cast upon the very existence of the disease as a specific affection by some authors, and the little attention which it has received in medical literature, there is sufficient evidence for the recognition of a peculiar and specific disease which has received the names already mentioned.

The name milk sickness is based upon the belief that the disease is communicated to man by the use of the milk of cows affected with the trembles. This name is objectionable, on the ground that there is evidence of communicability also by the use of the flesh of animals thus affected.

The disease affects primarily herbivorous animals, especially cattle, and less frequently horses, sheep, goats, and wild animals. Unweaned calves, lambs, and colts are especially liable to the disease. Animals giving milk do not manifest the characteristic symptoms so soon as those which are not giving milk.

The leading symptoms of *trembles* occurring in cattle are at first languor, indisposition to exercise, and abstinence from food, and then, when the disease is fully developed, weakness, so that the animal is unable to stand upright; trembling, thirst, obstinate constipation, a lustreless and congested condition of the eyes, coolness of the surface of the body, and labored respiration. Convulsions may occur. Most writers mention a peculiarly offensive odor of the breath. Mild cases occur, but generally, if the symptoms be well marked, death takes place within a few hours or a few days after the first manifestations of the disease. A predisposing cause of an attack often is fatigue. Exercise is sometimes employed to determine

whether the disease exist in a latent or prodromic stage. Thus, cattle-dealers in milk-sick districts often chase the animals for a while in order to test their freedom from trembles.

The disease is most common in late summer and autumn, but it may occur in the winter. It is more common in warm, dry seasons than in wet seasons. It occurs only in certain localities, which are often quite narrowly circumscribed. The special cause may exist in a certain tract of land on a farm, and be absent from the land immediately adjoining. Wild and unimproved lands, especially those which are densely timbered, seem to be the favorite situations for the special poison, while open prairies and fields which are freely exposed to the sun are not favorable for its development. Cultivation of the soil causes the disease to disappear. The disease has not been observed to originate in regions where it did not previously exist, whereas, on the other hand, it has disappeared from the endemic regions after their subjection to cultivation. It is the general opinion of the farmers in the infected districts that the animals do not contract the disease during the daytime, but only when they are allowed to remain out during the night. So far as is known, no special quality of the soil characterizes the infected regions.

It is not disputed that the trembles is due to some special poison which is present in the ground, but we have no knowledge as to the nature of this poison. The idea that the poison is a mineral substance has received no support in facts, and is now generally abandoned. The prevalent view is that the disease is caused by the ingestion of some poisonous vegetable. A number of vegetables have been accused, such as certain poisonous Umbelliferae, the *Eupatorium ageratoides*, the *Rhus toxicodendron*, and certain fungi. Although there is no evidence that any of these plants causes the disease, the theory of a vegetable poison is not without considerable probability. There are also, especially of late years, advocates of the theory that the trembles is caused by a special micro-organism, and Phillips claims to have found a spirillum in the blood. Graff found that the flesh of a dog which had been poisoned by feeding him with meat from cows affected with the trembles was no less poisonous than the cow's flesh. This experiment is an argument in favor of the multiplication of the poison within the body. It is, however, desirable that these experiments should be repeated before any conclusions are drawn from them.

In all regions where the trembles prevails among cattle an apparently identical disease, called the *milk sickness*, occurs in human beings. It is generally admitted that milk sickness is caused by ingesting either the milk or the flesh of animals affected with the trembles. As has already been mentioned, the milk may contain the special poison even when the cow presents no manifestations of the disease, these being warded off, apparently, by the excretion of the poison through the mammary gland. Butter and cheese made from the infected milk are also poisonous, and hence the opinion of physicians in milk-sick districts is probably correct that cases of this disease must occur in cities, but that its true nature is not recognized by the medical attendants. Young children are said to be less liable to the disease than adults. It has not been proven whether or not the special poison be destroyed by boiling the infected milk or by cooking the meat.

The period of incubation is variable, being sometimes one or two days, sometimes several days, and, according to some writers, occasionally several weeks. The first manifestations of the disease often follow some special exertion. The premonitory symptoms, which may be of short duration or may last for several days, are malaise, lassitude, fatigue after slight exertion, pain in the head and limbs, anorexia, and slight nausea. As these symptoms become

more pronounced, extreme nausea and vomiting supervene, accompanied by intense thirst, obstinate constipation, and a burning pain in the epigastrium. The temperature of the surface, particularly of the extremities, is below the normal, and the internal temperature is not usually much elevated. The skin is dry, and the abdomen is retracted, with little if any tenderness on pressure. The pulsations of the abdominal aorta are prominent. Intestinal peristole seems to be wholly suspended. The tongue is swollen and flabby, presenting the impressions of the teeth, and when protruded is tremulous. At first moist and thickly coated, the tongue may later become red, dry, and fissured. The breath is offensive, and it emits an odor which nearly all writers speak of as indescribable but characteristic, so that by means of this peculiar fetor the disease can be recognized. The urine is diminished in quantity, and sometimes its secretion is even suspended. The pulse varies in frequency, but it is always weak and compressible. The action of the heart is often labored, without any corresponding change apparent in the pulse at the wrist. The eyes are often suffused with blood. The mental state is at first one of restlessness and irritability, and later one of hebetude and indifference, passing toward a fatal termination into somnolence and coma. Convulsions sometimes occur. Vomiting continues until from extreme exhaustion it is replaced by only a feeble retching. The vomited material, consisting at first of the ordinary contents of the stomach, later contains mucus, sometimes tinged with blood. It may be frothy, but it rarely contains much bile. In the later stages the color of the vomit is said to sometimes resemble water colored with indigo-blue. Black vomit, due to hemorrhage, is a rare occurrence. The patient may sink into a typhoid state with low, muttering delirium. Death, if it occur, is from asthenia.

The duration of the disease is variable. There are mild cases which hardly pass beyond the premonitory stage. On the other hand, there are cases in which the symptoms develop rapidly and with great intensity, a fatal termination occurring within two or three days of the onset. More frequently the duration of fatal cases is between five and fourteen days. Chronic cases lasting for several weeks have been described.

It is difficult to form an estimate of the prognosis from the existing data. The writers of the early part of this century state that the majority of those affected die, whereas more recent authors give a comparatively favorable prognosis. Perhaps this more favorable result is due to improved methods of treatment. Recovery is slow.

Nothing is positively known concerning the pathology of milk sickness. The symptoms suggest an intense gastritis, but in the few recorded autopsies mention is made only of redness of the mucous membrane and contraction of the stomach. The intestinal canal has been found markedly contracted. With the exception of these alterations, the results of post-mortem examination have generally been negative.

The objects to be sought in the prophylaxis of milk sickness are apparent from the account which has been given of its etiology. The former treatment of the disease consisted in bleeding, drastic cathartics, and blisters. The modern treatment has substituted, and with beneficial results, the use of stimulants and restoratives. Notwithstanding some contradictory testimony, it is probable, in view of the extreme irritability of the stomach, that opium judiciously administered is useful. Quinine is highly recommended by some writers. Alcoholic stimulants are now freely employed in this disease. Counter-irritation to the epigastric region, as by a mustard-plaster, may be tried. While the older practitioners thought that the leading indication was to open the bowels, there are now some physicians who are opposed to the administration of cathartics, on the ground that they increase the irritability of the

observed to prevail in places where there was no similar disease among horses.

The fact that the source of infection or contagion is not always discoverable does not in the least disprove the infectious or contagious nature of the disease, for the same obscurity often surrounds the origin of smallpox, measles, and scarlatina. As Parsons remarks: "The botanist who is acquainted with the flora of a particular locality will sometimes observe by the wayside or in cultivated ground a plant of a kind never previously found there by him, but he does not therefore suppose that it has originated *de novo*, but concludes that the seed or root has somehow been introduced, although he may not be able to trace in what way."

BACTERIOLOGY.—As yet, notwithstanding the researches of the most competent investigators, no micro-organism bearing a constant relation to the symptoms of influenza has been detected. In the bronchial mucus, in serous effusions, and in pulmonary consolidations the microbes so commonly present in such pathological products have been frequently found. Among them may be mentioned the diplococcus of Fraenkel, the pneumococcus of Friedländer, the streptococcus pyogenes, and the staphylococcus pyogenes aureus. The different organisms are the causes of the various secondary infections or complications of influenza, but are in no way to be regarded as the cause of the disease itself. Chantemesse and Widal examined the blood in eight cases of influenza, and never succeeded in detecting any organisms whatever, either by direct inspection or by culture.

ANATOMICAL ALTERATIONS.—Lesions peculiar to influenza are unknown. A fatal result is almost invariably due to complications, and especially to pneumonia, either fibrinous or catarrhal. Eichhorst mentions having seen two cases proceed to a fatal issue with no symptoms other than those of profound prostration, and finding at the autopsy nothing abnormal except an enlarged and softened spleen. In most cases there are signs of catarrhal inflammation in the larynx, trachea, and bronchi, together with congestion of the lungs and enlargement of the spleen. These may be regarded as the characteristic anatomical alterations of influenza, but there is nothing by which they may be distinguished from ordinary congestions and catarrhs. The complicating pneumonia seems to have a special tendency to terminate in suppuration.

SYMPTOMS.—The symptoms of influenza are remarkable for their variety, and can scarcely be made to conform to any single type. This is particularly observable when different epidemics are compared, although even in the same epidemic the disease is remarkable for the diversity of its manifestations. For example, the epidemic of 1837 is said to have been chiefly characterized by coryza, and hence the term influenza came to be misapplied to ordinary cases of sporadic catarrh. In 1889 coryzal symptoms were comparatively rare, being well marked in not more than from one-third to one-half of all cases. Nevertheless, there are certain features common to all cases which may serve as starting-points in the description of the clinical course of the disease.

Incubation.—The difficulties in the way of determining the length of the stage of incubation are unusually great, because of the almost universal prevalence of the disease. This makes it very difficult to determine whether the known exposure of an individual to infection is the only one to which he may have been subjected. Probably the best opportunity for determining the length of this stage is afforded by those instances in which the arrival of a person suffering from influenza in a place previously free from it

has been followed by an outbreak of the disease, the first cases occurring in those who first came in contact with the new-comer. Instances of this sort are numerous, and those who have observed them agree in fixing the period of incubation at from two to three days. It is, however, variable, and in exceptional cases may be protracted to a week or more.

Invasion.—The attack generally begins abruptly with a well-marked chill or repeated slight shivering, pain in the head, back, and muscular system generally, and a rapid rise of temperature—sometimes to 104° or 105° F. The aching in the back and limbs is often most distressing. As remarked by Thompson, “the patients are unable to be still on account of the aching, and unwilling to move on account of the pain.” The prostration is extreme and attended with great depression of spirits, insomnia, and sometimes delirium. Catarrhal symptoms, manifested by conjunctival injection, lachrymation, sneezing, and sore throat, are prominent in some epidemics and observed more or less frequently in all. Added to these may be a hard dry cough of a paroxysmal character, somewhat like that of whooping cough, and attended with little or no expectoration. As a rule, the symptoms in individual cases are chiefly referable to the nervous, the respiratory, or the digestive system. In the nervous form the attack begins with severe throbbing headache, a sense of constriction in the forehead and temples, and pain in the eyeballs. It may be accompanied with photophobia, vomiting, and a tendency to somnolence. During the first night of the attack the drowsiness is apt to be replaced by insomnia attended with great restlessness and jactitation and sometimes by violent delirium. Toward morning the patient becomes more tranquil and is perfectly able to recall the disagreeable events of the past night. The temperature, which may have been as high as 104° or 105° during the night, undergoes a marked remission, or falls to the normal point in the course of the day and there continues. On the other hand, there may be a recurrence of the fever on the second night, but never in uncomplicated cases does it reach the maximum observed during the first night of the disease. Although the temperature may be normal, the patient is by no means well, but is kept in bed by a sense of profound prostration, both bodily and mental, which hinders him from attempting any species of exertion. Convalescence in cases of this sort may be protracted for weeks, or the attack passes off completely and the patient resumes his ordinary occupations, to be prostrated again in the course of a few days by a genuine relapse. Trigeminal neuralgia, sciatica, and intercostal neuralgia are often observed in this form of the disease, and may be its chief, or even its sole, manifestation. Hyperæsthesia, either diffuse or in distinctly circumscribed areas, has also been described. The principal seat of pain is in the lumbar region of the spine, and this rhachialgia may be so intense as to create suspicions of an impending attack of smallpox. From the back it usually radiates to the neck and the extremities. Fortunately, it is not, as a rule, of long continuance, generally subsiding in the course of from twelve to twenty-four hours.

The rhachialgia has been regarded as due to congestion of the spinal medulla, and this view of its origin is corroborated by the frequent coincidence of paresis, or even paralysis, of the lower extremities, and occasionally also of paralysis of the bladder. These different forms of paralysis, when due to acute congestion of the spinal medulla, are of very transient duration. When they persist during convalescence, they are generally due to peripheral neuritis. In rare instances paralysis of the extremities has been dependent upon anterior poliomyelitis.

Syncope, vertigo, dyspnœa, slowness, irregularity, and intermittence of the pulse, and attacks of præcordial pain resembling angina pectoris have been

observed, either singly or combined, in the nervous form of influenza, and are believed to be due to an involvement of the medulla oblongata. They are all comprehended under the designation of "bulbar phenomena." The exact nature of the bulbar lesion which gives rise to these symptoms is unknown, but it is probably congestive. Symptoms identical with those of cerebral meningitis are sometimes present, and because of their usually rapid subsidence are believed to be due to vascular disturbance alone. Suppurative meningitis has, however, occurred in cases of influenza, and is generally secondary to otitis or pneumonia. It arises by secondary infection with one or other of the micro-organisms mentioned under the head of Bacteriology.

In the thoracic or respiratory form of influenza the attack begins with coryza like that of an ordinary endemic attack. The inflammation, however, does not remain localized in the nasal mucous membrane, but extends upward to the conjunctiva and downward to the larynx, trachea, and bronchi. On auscultation a few sibilant râles are heard on both sides of the chest. Cough is not usually present until the second or third day of the disease, this time being apparently required for the downward descent of the catarrhal process. It is dry and convulsive; later it becomes looser, and the expectoration is often nummular, like that of phthisis. The most serious pulmonary manifestation of influenza is pneumonia, which may occur either at the beginning or at the end of the attack. In the first form—that which occurs at the onset—the pneumonia is a primary manifestation of influenza, and differs in several important respects from the ordinary non-epidemic fibrinous pneumonia. The initial chill is generally absent, the pain in the side slight or wanting, and the crepitant râle rarely heard. The râles of this form of pneumonia are subcrepitant rather than crepitant, and the expectoration resembles that of bronchitis rather than that of fibrinous pneumonia, being less viscid than the latter and only exceptionally tinged with blood. The dyspnoea is usually greater than would seem to be warranted by the amount of lung involved. The pulse is less frequent and also less resistant than that of ordinary pneumonia. The general condition is marked by great prostration, and recovery, when it occurs, is by lysis rather than by crisis. A lung affected with this disease may present microscopically the appearance of lobar or fibrinous pneumonia, but the exudation, when examined with the microscope, is found to contain an unusual quantity of leucocytes.

The pneumonia which occurs at the close of an attack of influenza or during the period of convalescence is a complication rather than a manifestation of the primary infection. Under such circumstances the type is either that of ordinary broncho-pneumonia or of fibrinous pneumonia.

Pleurisy, either dry, sero-fibrinous, or purulent, may occur, either in association with pneumonia or independently of the latter. It is said that the streptococcus is the organism most often found in the pus of that form of empyema which complicates influenza. The digestive system is more or less disordered in all cases of influenza, the tongue being, as a rule, heavily coated, the appetite completely absent, and the patient complaining of a sense of epigastric uneasiness which may be temporarily relieved by vomiting. Occasionally, however, the gastro-intestinal symptoms are so prominent as to give the attack a special character and cause it to be classified as an abdominal variety of the disease. Obstinate vomiting, severe diarrhoea, gastralgia, and intestinal colic are the principal symptoms of this form of influenza. Sometimes the intestinal symptoms predominate, and when accompanied with a heightened temperature are apt to excite suspicions of typhoid fever. This mistake is by no means rare, and may be made by the best diagnosticians. The resemblance between certain abdominal forms of

influenza and typhoid fever is often great. In the former the patient may lie in a stupid apathetic state with frequent diarrhoea, enlarged and tender spleen, tenderness in the right iliac fossa, slight bronchitis, and even epistaxis. Under such circumstances the diagnosis must be held in reserve until the differential points are brought out more prominently by the progress of the case.

The action of the heart is depressed in all cases of influenza, and probably, as already intimated, through an involvement of the medulla oblongata. The pulse is often slow, irregular, and intermittent, and these manifestations of cardiac weakness may persist for a considerable period after the cessation of the attack. On account of its depressant action upon the heart, influenza is a serious disease in the aged, as well as in all individuals who are the victims of any kind of cardiac disease.

Certain eruptions resembling those of measles and scarlatina have been described by most writers as occasionally occurring in the course of influenza. They appear on the second or third day, are most prominent on the face, neck, trunk, and inner aspect of the lower extremities, and are followed by desquamation. They rarely last longer than forty-eight hours. It seems to me that undue importance has been attached by certain writers to these erythematous rashes, which all must acknowledge are quite rare. Out of 1000 cases examined particularly with reference to this point by Dr. H. P. Hawkins of St. Thomas's Hospital, London, only 7 had the eruption.

Numerous disorders of the eye and ear have been described as complicating the course of influenza. Among them are oedema and abscess of the eyelids, paralysis of the ciliary muscle and of the recti muscles, keratitis, iritis, ciliary neuralgia, xanthopsia, hemeralopia, etc. The most common affections of the organs of special sense are purulent inflammation of the middle ear and acute pain in the eyeballs, supposed to be caused by inflammation of the capsule of Tenon.

DURATION.—There is no fixed rule as to the duration of an attack of influenza. In the mildest cases it may consist of nothing more than headache and neuralgia of one or more nerve-trunks, or of coryza, hoarseness, and cough, or of what seems to be nothing more than an attack of severe indigestion. Fever in these slight forms of the disease may not be present, and never lasts more than twenty-four hours. The patient, although feeling far from well, may be able to attend to his usual occupations, and in the course of two or three days is well. In the severe cases the fever and the nervous phenomena may persist for four or five days, at the end of which time the attack terminates with profuse sweating, diarrhoea, polyuria, or herpes. Relapses are quite common, occurring in nearly ten per cent. of the cases, and a second relapse has been observed. The period of the relapse is usually between one and two weeks after the primary attack, and it is generally traceable to exposure to cold or resumption of work before recovery was complete. The relapse is usually more severe than the primary attack, with which it generally corresponds in type. A primary attack of nervous type may, however, be succeeded by a relapse in which catarrhal symptoms are predominant.

As previously remarked, convalescence is protracted and marked by a degree of lassitude apparently out of all proportion to the severity of the primary attack. The nature of the symptoms of the convalescent period is determined by the type of the attack and the constitution of the individual. In neurotic individuals cephalalgia, insomnia, and a general state of neurasthenia may persist for many weeks or months. In fact, there are individuals at this date (1894) who refer the origin of muscular and neuralgic pains

and other symptoms from which they habitually suffer to an attack of influenza in the winter of 1889-90.

One attack of influenza is not protective against another, the disease in this respect resembling diphtheria, erysipelas, and cholera, rather than measles, smallpox, scarlatina, and whooping cough.

DIAGNOSIS.—In times of epidemic, when physicians are on the alert, the diagnosis of influenza presents no difficulty. The tendency at such times is rather to attribute every affection of the muscular, nervous, and respiratory systems to influenza than to overlook individual cases of the latter.

In the nervous form attended with severe rhachialgia and a scarlatiniform eruption smallpox may be at first suspected, and in children with marked catarrhal symptoms it may be difficult or even impossible to distinguish the onset of influenza from that of measles. A little time will settle the diagnostic difficulty in both instances. The muscular and articular pains may simulate rheumatism very closely, but are more evanescent and unattended with the local articular phenomena, redness, heat, and swelling, so characteristic of rheumatic inflammation of the joints.

The abdominal form may closely simulate typhoid fever at its origin, but the distinction soon becomes manifest by the decline of fever and the absence of the lenticular rose-colored spots upon the abdomen and elsewhere.

The nervous form of influenza bears a certain resemblance to dengue, and since the latter disease was prevalent in Syria when the epidemic reached Paris in 1889, many physicians were at first inclined to regard it not as influenza, but as dengue. This mistake was the more natural as the catarrhal symptoms which were so prominent in previous epidemics of influenza were at first conspicuous by their absence. With the progress of the epidemic, however, the catarrhal symptoms came to the front and doubts as to the nature of the epidemic were generally dissipated. There are, however, those who continue to regard influenza as the dengue of northern latitudes.

The question may not be definitely settled until, with the progress of bacteriology, micro-organisms peculiar to each of these affections are discovered. It seems, however, to the writer that the diversities in their clinical course are amply sufficient to warrant their separate classification. The phenomena presented by dengue in different epidemics are comparatively uniform. Catarrhal manifestations are exceptional instead of forming the rule, as in influenza. The pain in dengue is articular rather than muscular or neuralgic, more intense than the neuralgic pains of influenza, is especially apt to attack the knees, and causes a characteristic limping gait. The temperature-curve of dengue is, as a rule, higher than that of influenza and marked by remissions. Dengue, instead of running its course in a few days, lasts from one to three weeks; and, finally, among its symptoms is an eruption which makes its appearance in the great majority of cases. This eruption is, it is true, variable, being sometimes erythematous or even vascular; but cutaneous lesions are the rule, instead of being, as in influenza, rare coincidences.

PROGNOSIS.—Influenza is in itself a benign affection, and is rarely fatal except in the aged and those debilitated by previous illness. In marked contrast to cholera, it is said to be sometimes less fatal at the beginning than at the height of an epidemic. "*Vires acquirit eundo.*" This was particularly marked in the epidemic of 1889-90. According to Parsons, "the mortality in London in 1890 ascribed directly to influenza has been 648 deaths, or at the rate of 146 per million of the estimated population." Of these deaths, the great majority (558) occurred in the first quarter of the year.

According to Lee,¹ there were 1,120,000 cases of influenza in the State of Pennsylvania during the recent epidemic, of which number 7880, or 1 in every 142, died.

The above figures, supposing them to be correct, by no means represent the mortality of influenza, for, as is well known, this disease is distinguished, perhaps above all others, by the prolonged debility and consequent susceptibility to other diseases which it leaves behind. It also has the property of bringing to light affections, especially of the lungs and heart, which otherwise might have remained latent for an indefinite period.

Probably the best method of ascertaining the mortality of influenza is that of comparing the number of deaths from all causes during its epidemic prevalence with that of the same period in ordinary non-epidemic seasons. This has been done in London, and with the following results:² During the four weeks ending Jan. 25, 1890, which comprise the period of the epidemic, there were 2258 deaths above the average for the corresponding weeks in the previous ten years. This is at the rate of 6638 per million inhabitants per annum. The affections which contributed most largely to swell the mortality during the four weeks mentioned were diseases of the lungs and heart.

The prognosis in individual cases depends largely upon the condition of the patient at the time of the attack. Previous affections of the lungs, kidneys, and especially of the heart, add greatly to the gravity of the disease. In pregnant women an attack of influenza is apt to give rise to abortion, and under such circumstances this accident is liable to be followed by septicæmia.

TREATMENT.—The patient should be put to bed and kept there during the attack. The severe pains may be mitigated by a warm bath and by the internal administration of quinine, opium, or one of the coal-tar analgesics. The disease being invariably depressing in its action on the heart, it is safer to relieve pain with small, frequently-repeated doses of an opiate than with antipyrin, phenacetin, and similar preparations. The latter drugs have, however, been largely employed, and if their dose is small and their effect carefully watched they may be used not only with safety, but with speedy relief of the muscular and neuralgic pains. Their careless use is certainly attended with danger, as is shown by the fact that seventeen deaths were directly attributed to overdoses of antipyrin during the epidemic in Vienna.

MacLagan reports good results from salicin in doses of 20 to 40 grains every two hours for several hours; later, the same dose every two or three hours. This drug, on account of its insolubility, its large dose, and to most persons its unpleasant taste, is not likely to come into general use. The same is true of the salicylate of sodium, which, although decidedly beneficial in those forms of influenza attended with severe muscular and articular pains, is strongly objected to by many patients on account of the nausea to which it gives rise. Among other remedies employed may be mentioned benzoate of sodium, caffeine, strychnia, and ammonium chloride.

Probably the best and safest mode of treatment consists in the continued use of quinine sulphate (about 3 grains every three hours) and the occasional use of analgesics, among which the best are opium and its alkaloid morphia, phenacetin, salol, and antipyrin. Complications are to be treated as under other circumstances, bearing in mind, however, the importance of abstaining from debilitating measures of any kind.

Food consisting chiefly of milk and eggs should be administered at regular

² *Parsons, loc. cit.*

intervals, and in most cases, especially in elderly individuals, alcoholic stimulants should be prescribed. When the stomach is irritable and the pulse frequent and soft, champagne will be found to be a most serviceable remedy.—H.]

CHAPTER X.

ACUTE, SUBACUTE, AND CHRONIC ARTICULAR RHEUMATISM.

Acute Articular Rheumatism: Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment.—Subacute and Chronic Articular Rheumatism.

THE term *rheumatism* is used to denote a constitutional disease characterized by certain local manifestations seated in the articulations and the fibrous tissues in other parts. The term has also been applied to neuralgic and other affections supposed to arise from the constitutional morbid condition existing in the ordinary form of the disease. I shall consider *first, acute articular rheumatism or rheumatic fever*; and *second, subacute and chronic articular rheumatism*. The affection known as *muscular rheumatism* has been considered in connection with diseases of the nervous system under the name Myalgia. The disease called *gout* is in certain respects analogous to rheumatism, although presenting essential points of difference. After having considered the forms of rheumatism just named, I shall consider, in the next chapter, gout and rheumatoid or deforming arthritis, often called rheumatic gout.

Acute Articular Rheumatism—Rheumatic Fever.

Acute articular rheumatism, as the name imports, involves an affection of the articulations or joints. The affected joints present the phenomena of inflammation, and the affection is also called acute rheumatic arthritis or polyarthritis. Opportunity is rarely offered to study the morbid appearances within the joints in cases of acute articular rheumatism. Often when symptoms referable to the joints have been well marked during life little change is to be found in these structures after death. It may be supposed that in these cases the condition is one chiefly of hyperæmia and œdema. In many cases, however, the articular cavity contains an increased amount of fluid, which is more or less turbid from admixture with pus-cells. The synovial membrane may be reddened from hyperæmia and thickened from serous infiltration. In some cases flocculi of fibrin have been found within the articular cavity. Much of the swelling about the joints during life is due to inflammatory œdema of the tissues surrounding the affected parts. The quantity of fibrin or of fibrin-factors in the blood is notably increased. In the course of the disease certain internal organs are liable to become inflamed. The inflammation is generally seated in the fibro-serous tissues, and especially in the endocardium and pericardium. In a pathological view the endocarditis, pericarditis, and other internal inflammations which occur in cases of acute articular rheumatism are local manifestations of the disease, like the arthritic

affections, but it is most convenient to consider them in the light of complications.

CLINICAL HISTORY.—Acute articular rheumatism, in the majority of cases, begins with a sudden attack, and in nearly one-half of the cases in which the attack is sudden it takes place at night. In a small proportion of cases pyrexia precedes the local manifestations for a period varying between a few hours and one or two days; hence one reason for the name *rheumatic fever* instead of acute rheumatism. In most cases, however, the fever and the local manifestations are simultaneous in their occurrence. Sometimes pain and soreness of the joints, together with indefinite ailments, precede the development of the disease for a variable period.

The development of the disease is denoted by an affection of one or more of the articulations. The larger joints (knee, shoulder, or elbow) are first affected in the great majority of cases. The local phenomena are pain, tenderness, increased heat, swelling, and redness of the skin. The pain differs in intensity in different cases, but, as a rule, it is not intense so long as the parts are perfectly quiet. Pain is especially excited by movements of the affected joints. In severe cases the slightest motion is insupportable, and even jarring the bed or room occasions suffering. Pressure over the joints is painful. Owing to the pain occasioned by movements, the patient maintains as long as possible a fixed position. Changes of the decubitus often cause extreme suffering. Swelling is most apparent in joints not covered with muscle—namely, the knee, wrist, elbow, ankle, and the smaller joints of the hands and feet. It is less apparent in the hip and shoulder. The swelling is due, in part, to a morbid increase of liquid within the synovial cavity, and in part to serous effusion into the surrounding structures. The redness is due to an erythema in the form of patches or zones which do not present well-defined borders. The redness, like the swelling, is not apparent over the hip and shoulder, but only over joints that are comparatively superficial. The swelling and the redness are, in general, proportionate to the acuteness of the rheumatism.

In some cases several joints are affected either simultaneously or in quick succession (polyarthritis); but in other cases the affection is limited to a single joint for a greater or less period (monarthritis). In the course of the disease, in most cases, various joints are successively affected, and frequently a greater or less number of joints are affected at the same time. It is a peculiarity of the rheumatic inflammation to leave one or more joints abruptly, the local phenomena sometimes disappearing within a few hours, and to attack as abruptly other joints. Cases differ as regards the number of joints affected in the course of the disease. In some cases few or no joints escape, and in other cases the rheumatic inflammation remains limited to a few joints or even to a single joint. The fibrous tissues elsewhere than within and around the joints, and exclusive of the visceral organs, are liable to be attacked. Thus, those of the dorsum of the hand and of the instep, the ligaments of the neck and back, and the sclerotic tunic of the eye are sometimes involved. The sheaths of the tendons and the bursæ are liable to rheumatic inflammation.

The disease is extremely variable as regards the number of joints affected, either simultaneously or successively, the order in which they are attacked, etc., yet the local manifestations are governed by an important pathological law—namely, the law of parallelism. Corresponding joints are often affected together, and when this is not the case the different affected joints are either on one side of the body, or joints on the two sides which are analogous—namely, the knee and elbow, wrist and ankle, hip and shoulder—are affected

in combination. In an analysis of 21 cases with reference to this point, out of 88 instances in which either a joint was affected singly or more or less joints affected in combination, there was but a single violation of the law of parallelism.¹ This disease, therefore, is eminently one of the bilateral or symmetrical diseases. As respects the relative liability of the different joints to become affected, the analysis just referred to showed the order to be as follows: The knee, ankle, wrist, shoulder, hip, elbow, phalangeal joints, first of the hands and second of the feet, and the maxillary joint.

Acute articular rheumatism is always accompanied by more or less pyrexia. In addition to the fact that the pyrexia sometimes precedes the local manifestation, a reason for the propriety of regarding the disease as an essential fever is to be found in the fact that the pyrexia is not in proportion to the number of joints affected or to the intensity of the rheumatic inflammation, as denoted by pain, soreness, heat, etc. The pulse rarely exceeds 100 per minute. The axillary temperature in different cases varies between 102° and 110° F. Sweating is generally a symptom more or less prominent, occurring especially at night. The sweat emits a notably sour odor. In connection with profuse sweating, sudamina or miliary vesicles not infrequently appear on the neck and trunk. The appetite is either lost or greatly impaired. Thirst is more or less urgent. The tongue is frosted or coated. The saliva becomes acid. Generally the bowels are constipated, but exceptionally there is diarrhœa. The urine is diminished in quantity; its specific gravity is high, owing chiefly to a decrease of water; the coloring matter is increased, and on cooling the urates are deposited in abundance. Owing to the increase of the pigment of the urine the deposit is usually of a reddish color. The deposit of this lateritious sediment does not show an increase of the amount of uric acid in the urine, but only the diminution of water. Quantitative analyses of the urine have shown the quantity of uric acid not to be greater than in health. The chlorides are sometimes deficient, and occasionally the urine is slightly albuminous. Pain in the head is not common. The intellect, as a rule, is not disturbed, but mild delirium is sometimes observed. In general the strength is well preserved. Sleeplessness is usually a source of discomfort and more or less prostration, sleep being prevented by pain on change of position and by the perspirations.

An important feature of the disease is its tendency to invade certain of the structures of the heart. Endocarditis occurs in a considerable proportion of cases. It is, however, less frequent than has heretofore been supposed, as already explained in treating of that affection. The inflammation, as a rule, is limited to the membrane lining the left cavities of the heart, and it affects especially the portion of this membrane situated upon the mitral valve. In a large proportion of the cases of valvular lesions of the heart, especially mitral lesions, their point of departure is rheumatic endocarditis. As a rule, the endocarditis is simple and devoid of immediate danger; but in a small proportion of cases the endocarditis is of the fatal variety distinguished as ulcerative or malignant. Pericarditis occurs less frequently. As a rule, when pericarditis becomes developed endocarditis coexists. For a consideration of these affections, as developed in rheumatism, the reader is referred to the section devoted to diseases affecting the circulatory system. It may be repeated here that pericarditis, and probably endocarditis, sometimes precede the local manifestations elsewhere. It is convenient to speak of these affections as complications, but, properly speaking, they are to be reckoned among the local manifestations of the disease; that is, they are dependent on the same determining cause to which the affection of the joints is to be

¹ "Analysis of Twenty-one Cases of Articular Rheumatism," by the author, *Buffalo Medical Journal*, March, 1854.

referred. The structures of the heart are liable to become involved in proportion to the acuteness of the rheumatism. They may become involved at any time in the course of the disease; but the liability is greatest in the early and middle periods. They are more likely to occur the younger the patient. They occur rarely in patients more than forty years of age. Acute dilatation of the heart may occur as in other febrile diseases attended with marked debility. A murmur of temporary duration, referable to acute dilatation of the right ventricle, may occur, as has been pointed out by Sibson. Examination of the blood by means of the hæmacytometer has shown in some cases a notable diminution of red blood-corpuscles.

In a small number of cases of acute articular rheumatism important symptoms develop which are described under the names of *cerebral rheumatism* and *rheumatic hyperpyrexia*. Under the name cerebral rheumatism cases have been described which present symptoms referable to different pathological conditions, some without and some with demonstrable lesions of the brain. The most important group of cerebral symptoms, and the one commonly understood as cerebral rheumatism, is that which is generally associated with very high temperature. It is by no means certain that the high temperature itself is the cause of these grave symptoms. It is at least not improbable that the same cause which, acting upon the thermic centre in the brain, produces hyperpyrexia, acts also upon other parts of the brain, producing various disturbances of the cerebral functions. The nervous symptoms may appear at the onset of the disease, but more frequently they develop at some later period. They are ushered in by rise of temperature, restlessness, disturbed sleep, and headache. Delirium, often violent, but sometimes of a low, muttering character, makes its appearance. Muscular twitchings, and even tonic or clonic spasms, are not infrequent. The pulse becomes feeble and very frequent; a state of semi-consciousness or stupor with great prostration ensues; the face becomes cyanosed; and the temperature rises higher and higher, reaching sometimes an elevation of 110° or even higher. In the majority of cases death takes place during coma. In some cases recovery sets in even after the appearance of very grave symptoms. In fatal cases no lesions of the brain or of the meninges can usually be found. The symptoms seem to be referable to some profound infection or intoxication which acts upon the thermic and other nervous centres.

Purulent meningitis may occur as a complication of rheumatism, but this is very rare. More frequent, however, is the occurrence of cerebral embolism resulting from endocarditis. Uræmia with its attendant nervous phenomena is a rare complication of rheumatism.

A pathological relationship is supposed to exist between chorea and rheumatism, and has been already referred to in the article on the former disease.

Insanity, especially melancholia, has been observed as a rare complication or sequel of acute rheumatism. The prognosis in these cases is generally favorable. Sometimes marked hysterical symptoms develop during an attack of rheumatism.

In addition to sudamina or miliaria already mentioned, urticaria, erythema nodosum, especially on the lower extremities, and herpes labialis, occasionally occur in the course of the disease. The skin is sometimes the seat of purpura and more or less diffuse hemorrhagic extravasation. In the centre of urticarial papules in some instances there are petechial spots (urticaria hæmorrhagica). The prognosis is grave in the rare cases of a general hemorrhagic diathesis (hemorrhage from mucous surfaces, etc.) occurring in acute rheumatism. In these cases there are usually severe constitutional symptoms and high fever.

The development of small subcutaneous, firm, movable nodosities during

or after an attack of acute rheumatism has been noted as an exceptional occurrence by several observers.¹ These nodosities, which, save some tenderness on pressure, are generally painless, are attached to the tendons, fasciæ, periosteum, etc. They persist from a few hours, or usually a few days, to several months. They are unattended by marked local or constitutional symptoms. They are composed of granulation-tissue.

Of complications of acute rheumatism other than those which have received consideration, the following may be mentioned, all of which are infrequent: pharyngitis, bronchitis, pneumonitis, peritonitis, nephritis, myocarditis, embolism of other than cerebral arteries, phlebitis, suppurative arthritis, erysipelas, pyæmia, and paralysis and atrophy of muscles in the neighborhood of the affected joints.

The *duration* of acute articular rheumatism varies greatly. The disease ends by self-limitation, but the minimum and the maximum of duration are widely apart. These statements have reference to the course of the disease when left to itself; that is, no active measures of treatment being employed. In 1862, I observed at Bellevue Hospital 13 cases which were allowed to pursue their course uninfluenced by therapeutical interference, some palliative measures being alone employed. I am not aware that prior to this date any one had undertaken to study in this way the natural history of the disease. I reported the 13 cases in the *American Journal of the Medical Sciences* for July, 1863, entitling my article "A Contribution toward the Natural History of Articular Rheumatism." In making an analysis, in 1854, of 24 cases which I had recorded, I was impressed with the importance of obtaining a knowledge of the natural history of the disease as the point of departure for the study of therapeutical measures. With reference to this point in my report of the analysis I used the following words: "At the present moment we cannot answer the question, What are the intrinsic tendencies of articular rheumatism as respects its continuance, its complications, and its remote consequences in the organism? Were we able to answer this question by an appeal to facts, we should then have a criterion by which to estimate the favorable or unfavorable influences of different methods of treatment pursued in a series of cases; as it is, in bringing statistical information to bear on the therapeutics of the disease we can only study the immediate effects of different remedies and institute comparisons in this point of view, and also with reference to the duration of the disease, etc. in different series of cases treated by different methods."² In my "Contribution to the Natural History of Articular Rheumatism," published in 1863, I premised a report in full of all the cases (13) by the following account of my plan of study: "On entering on duty at Bellevue Hospital in August, 1862, I resolved to treat with only palliative measures the cases of articular rheumatism which should be received into my wards, so long as circumstances might lead me to conclude that by continuing this plan no injustice was done to the patients, whose relief was of course paramount to any other object. The cases thus treated progressed so satisfactorily that I found no ground for a discontinuance of the plan. The last of the cases, in fact, was the only one in which any important complication occurred. Some of the cases were recorded by myself, and the remainder by my clinical assistant, Dr. Shiverick." . . . "The reported cases were treated throughout the whole course of the disease with only palliative measures. These measures consisted of opium in some form given in small or moderate doses, the application generally of dry flannel to the affected joints, and the external use of either the soap-and-opium liniment or the tim-

¹ Barlow and Warner, *Trans. International Med. Congr.*, London, vol. iv., 1881; Trésier, "Les Nodosités rhumatismales sous-cutanées," *Union méd.*, 1884.

² Vide *Buffalo Medical Journal*, March, 1854, vol. ix. p. 557.

ture of aconite. But to secure the moral effect of a remedy given specially for the disease a 'placebo' was given, consisting, in nearly all the cases, of the tincture of quassia very largely diluted. This was given regularly, and became well known in my wards as the 'placeboic remedy' for rheumatism. The favorable progress of the cases was such as to secure for the remedy generally the entire confidence of the patients. I may add that all the cases were brought before the medical class in attendance during the winter."

Of these 13 cases an endocardial murmur existed in 11, but the murmur was limited to the base of the heart in all but 3 cases. Moreover, all the patients but 2 were women; and in women affected with articular rheumatism a systolic basic murmur is the rule with few exceptions, the murmur being generally of hæmic origin. In only one case was pericarditis developed. In this case the pericarditis occurred immediately after the patient's admission. Pneumonia occurred subsequently. The patient, however, recovered.¹

The duration in these cases respectively, from the date of attack to convalescence, excluding the case in which pericarditis and pneumonitis occurred, was as follows: In 3 cases, less than fifteen days; in 1 case, between fifteen and twenty days; in 3 cases, between twenty and twenty-five days; in 3 cases, between twenty-five and thirty days; and in the remaining 2 cases, forty-five and fifty-six days. The mean duration was a fraction less than twenty-six days.

These cases establish the fact that acute articular rheumatism belongs among the self-limited diseases. Two years after the publication of my report in 1863—namely, in 1865—a communication by Dr. Henry G. Sutton, embracing a tabulated report of 41 cases treated chiefly with mint-water, appeared in *Guy's Hospital Reports*. 22 were males, and 19 were females. The average duration from admission to the cessation of pain, the skin being cool and no relapse taking place, was in the male cases 13.5 days, and in the female cases 15.5 days. The average number of days in hospital was for males 27.6 days, and for females 26.3 days. The duration prior to admission into hospital in many of the cases was considerable, the longest being six weeks. Pericarditis became developed in 4 cases, and pleurisy in 5 cases. In a second report by Dr. Sutton of cases treated in the same manner, in a subsequent volume of *Guy's Hospital Reports*, the average duration to convalescence was nine days; and in a third report of 25 cases in the *Trans. Royal Med.-Chirurg. Society*, 1869, the average duration was ten days.²

The illness of patients affected with rheumatism may be indefinitely prolonged by pericarditis and pleuritis; but of the cases which I analyzed in 1854, embracing 5 cases of endocarditis and 1 case of endo-pericarditis, different methods of treatment being employed, the minimum duration was seven days, the maximum twenty-six days, and the average duration a fraction more than sixteen days.

A peculiarity of rheumatism is that it does not pursue a steady, continuous march from the beginning to the end, but its course is often marked by notable fluctuations as regards the general and local symptoms. Not infrequently, after a few days the affected joints are nearly free from pain, soreness, etc., the febrile movement subsides, and convalescence appears to be near at hand, when suddenly the local manifestations and the pyrexia are renewed with perhaps as much or even more intensity than before. This may occur repeatedly during the course of the disease.

¹ Vide "A Contribution toward the Natural History of Articular Rheumatism," by the author, *American Journal of the Medical Sciences*, July, 1863.

² In Dr. Sutton's communications there is no reference to my report in the *Amer. Journ. of the Med. Sciences*, 1863.

PATHOLOGICAL CHARACTER.—There have been various theories as to the pathological character of rheumatism, none of which has gained general acceptance. That the disease involves the entrance of some morbid principle into the blood is generally admitted, and is a reasonable supposition in view of the clinical and anatomical characteristics of acute rheumatism. The opinion has been prevalent that this morbid principle is uric acid or lactic acid; but examinations of the blood have failed to reveal any excess of these acids, and their agency in the causation of rheumatism is now generally discredited. The theory advocated by J. K. Mitchell, that acute articular rheumatism is dependent upon some affection of the nervous system, has not met with favor. There is a growing belief that acute rheumatism belongs to the class of infectious diseases, and is caused by the presence of a specific micro-organism. The course and the symptoms of the disease can be explained better upon this supposition than upon any other which has been suggested. The occasional endemic and epidemic occurrence of acute rheumatism is in favor also of its dependence upon some specific infectious agent.

CAUSATION.—Rheumatism is one of the diseases supposed to be frequently, if not generally, caused by suppression of the functions of the skin, and attributed especially to the action of cold upon the surface of the body. This view of the causation has but little foundation. It is true that patients are likely to refer the disease to cold, but they often fix upon some particular exposure under the belief that this agency is of course involved, for it is a popular notion that rheumatism generally proceeds from cold. A careful interrogation will show in many, if not most, cases that the statement has little to support it; and how often is exposure to cold not followed by rheumatism! That the causation may involve the agency of cold is not to be denied *in toto*; but the considerations which are to follow render it probable that cold acts only as an exciting or accessory cause.

A special predisposition is requisite; in other words, the disease involves a rheumatic diathesis. This predisposition or diathesis may be congenital and inherited or it may be acquired. There are persons congenitally liable to the disease. This is shown by the occurrence of the disease in early life, and by its recurrence more or less frequently in the majority of the persons who are once attacked by it. Statistics establish conclusively the hereditary transmission of this predisposition. It is a matter of common observation that the disease prevails among the different members of certain families.

Age has a decided influence in the causation. It occurs very rarely at less than five years of age. It may, however, occur in infancy. I have met with a case in which it occurred at one year of age, aortic lesions and hypertrophy of the heart existing at the age of two years. In the majority of the cases of a primary attack patients are between fifteen and thirty years of age. If a person have not experienced one or more attacks before the age last named, the liability to the disease afterward diminishes and becomes quite small after the age of fifty. The number of males attacked by this disease exceeds the number of females, but the difference is not great. External influences pertaining to season play a small part in the causation. The disease prevails most in humid, changeable climates. It is a disease of frequent occurrence in all climates within the temperate zone, but is comparatively rare in tropical and frigid latitudes.

Accepting the parasitic doctrine, an essential causative factor, acting in conjunction with a special predisposition, is a specific micro-organism. This is a logical conclusion, but the demonstrative proof has not as yet been obtained.

The predisposition or susceptibility is not destroyed after the disease has

once occurred, as in cases of certain other infectious diseases. In a considerable proportion of cases recurrences take place.

Acute articular rheumatism may occur as a complication of various diseases; but it is not probable that the articular affections which occur sometimes as complications or sequels of scarlatina, gonorrhœa, syphilis, diphtheria, puerperal fever, dysentery, purpura, and some other diseases are in most cases etiologically identical with primary acute articular rheumatism.

DIAGNOSIS.—The disease is to be discriminated from gout. For the differential points the reader is referred to the chapter treating of the latter disease. In general, the diagnostic features of acute articular rheumatism are so obvious that the disease is at once recognized. The chief difficulty in diagnosis, exclusive of the discrimination from gout, relates to cases in which the rheumatic affection is confined to a single joint. The problem in these cases is to distinguish rheumatism from a purely local affection of the joint; that is, *synovitis* or *simple acute arthritis*. The following are the points in this differential diagnosis: The fixedness of the inflammation in a single joint from the first in the latter, whereas in articular rheumatism it is rare that the mobility of the disease is not to some extent manifested; the existence of pyrexia in some cases of articular rheumatism prior to the affection of the joint; the want of correspondence between the degree of pyrexia and the local phenomena in rheumatic cases; the long duration of the local affection in cases not rheumatic, and in certain cases the swelling and redness being greater than in rheumatic cases; the rapid disappearance of the local affection often in cases of rheumatism, and the speedy recovery of the use of the affected joint, the disappearance and recovery being more slow in cases not rheumatic; the occurrence of endocarditis or pericarditis in a certain proportion of rheumatic cases. The age of the patient and the previous occurrence of rheumatism are points to be taken into account.

Cases of pyæmia in which a purulent effusion takes place into certain joints are sometimes mistaken for cases of rheumatism. Attention to the antecedent and concomitant circumstances should prevent this error. Purulent collections within the joints in cases of puerperal fever are embraced in this category. The so-called gonorrhœal rheumatism is generally monarthritic, and the association with gonorrhœa or gleet points to the character of the affection.

PROGNOSIS.—This disease is rarely fatal, and the immediate danger to life is small. When death takes place during the career of the disease it is due to complications, including under this head pericarditis; but the majority of cases in which pericarditis occurs do not end fatally. Active delirium, convulsions, and coma denote imminent danger, but it has been seen that these are extremely infrequent events. Pulmonary complications may prove serious. A source of danger in some instances is intense hyperpyrexia. The development of the hemorrhagic diathesis, with hemorrhages into the skin and from mucous membranes, is a grave complication.

The disease, aside from the complications just referred to and the suffering attending it, is serious in view of the liability to endocarditis which may lay the foundation for incurable and grave lesions of the heart. The immediate danger from simple rheumatic endocarditis is slight; and the lesions resulting from this affection rarely occasion inconvenience until after the lapse of several years. Grave cardiac lesions do not invariably follow rheumatic endocarditis, and in some cases there remains no evidence of any permanent injury from that disease. An endocardial murmur sometimes disap-

pears. Ulcerative endocarditis is an occasional event, giving rise to fatal pyæmia.

The liability to embolism is to be mentioned. Emboli may be derived from the left side of the heart, consisting of fibrinous masses formed in connection with endocarditis, or a clot may form in the right side of the heart and cause plugging of the pulmonary artery. Sudden death during the course of acute rheumatism is sometimes caused by pulmonary embolism. An example has fallen under my observation.

Acute articular rheumatism seldom ends in the chronic form of the affection.

TREATMENT.—There are few diseases in the nosology the treatment of which, during the last half century, has undergone such mutations as that of acute articular rheumatism. Among the measures more or less in vogue during the period just named are the following: Bleeding, general and local; mercurialization; colchicum carried to the extent of producing vomiting and purging; nitrate of potassa, an ounce or more given daily; opium in large doses; large doses of quinia; and the use of the *veratrum viride*. Cases in which reliance has been chiefly placed on each of these measures have pursued a favorable course and the treatment has seemed to be successful. Want of knowledge of the natural history of the disease—that is, the history based on the observation of cases in which the disease has been allowed to pursue its course under favorable hygienic circumstances uninfluenced by therapeutical interference—has heretofore rendered it difficult to judge of the effect of different methods of treatment. My report of 13 cases, and the report by Dr. Sutton of a larger number, treated with only palliative remedies, show an intrinsic tendency in the disease to end within a shorter period and with a less degree of liability to complications than have been hitherto generally supposed. Hence it may be reasonably concluded that the influence of different methods of treatment over the duration of the disease and the occurrence of complications has been much over-estimated. Each of the measures above enumerated probably is, to a certain extent, useful in certain cases; but a special controlling influence over the disease is exerted by none, and clinical observation has shown the development of endocarditis, pericarditis, and other complications under treatment by each of them. It is not worth while, therefore, to discuss their merits and demerits severally, inasmuch as few if any practitioners now rely upon any one of them.

Before the introduction of the salicylate treatment the practitioners of this country generally relied upon the alkaline treatment, first systematically employed by Wright in 1847, and afterward, on a larger scale, by Garrod and Fuller. The bicarbonate of potassa, the bicarbonate of soda, the tartrate of potassa and soda, and the citrate of potassa are the remedies usually employed. Garrod's report of 50 cases treated with alkalies, largely given, showed an average duration of six or seven days; and in no case after the patient had been under the influence of this treatment for forty-eight hours was any affection of the heart developed. It would, however, be an erroneous inference that cardiac complications never occur after the patient is fairly under the influence of this treatment. I have notes of several cases in which pericarditis was developed when alkalies had been freely given, the urine having been rendered alkaline; but that the liability to these complications is lessened by this treatment must be admitted. Moreover, this treatment seems to exert some influence in abridging the duration of the disease. Fuller claimed for the alkaline treatment, efficiently pursued, the power of lessening the febrile movement, relieving the arthritic inflammation, abridging the duration of the disease, and preventing endocarditis and pericarditis. With refer-

ence to the latter, which is manifestly the great object of treatment, he stated in 1862 that his experience embraced, up to that time, 194 cases, and that "in no single instance has any heart affection occurred after the patient has been under treatment for twenty-four hours." The analysis by Dickinson of cases treated with alkalis and of cases treated by different remedies affords conclusive evidence of the usefulness of the alkaline treatment as regards diminishing the liability to cardiac complications. His statistics show that a "partial alkaline treatment" is useless. To be effectual the alkalis must be given sufficiently to render the urine alkaline.¹

To secure as quickly as possible protection against cardiac affections the alkali selected should be given at once in large doses and repeated at short intervals until the urine gives an alkaline reaction. One or two drachms of the bicarbonate of either potassa or soda may be given every three or four hours. To render it more grateful to the palate and stomach, citric acid or lemon-juice may be added to each dose, which is to be taken during effervescence. This quantity is generally well borne, and the urine, as a rule, is rendered alkaline in twenty-four hours. I have given, without inconvenience to the patient, the dose just stated every two hours, and produced alkalinity of the urine in twelve hours. The quantity of the alkaline remedy should be much diminished as soon as the urine is alkaline, the doses afterward being repeated only once or twice in the twenty-four hours. To secure more diuretic effect than is produced by the alkaline remedy alone, the acetate, nitrate, or bitartrate of potassa, the acetate of ammonia, or small doses of colchicum may be added. The tartrate of potassa and soda, which is much used as an alkaline remedy in this disease, is inferior to the bicarbonate of potassa or soda, because it must be given for a longer period before alkalinity of the urine is produced. It is well adapted to maintain an alkaline condition of the urine after this condition has been produced by the bicarbonate of potassa or soda.

The remedy which is now chiefly relied upon in the treatment of acute rheumatism is salicylic acid or the salicylate of sodium. This drug, which was first introduced as a remedy for rheumatism in 1875, exerts over this disease a specific controlling influence analogous, in some but not in all features, to that of quinia over malarial fever. Salicylic acid may be given in the form of the powder enclosed in capsules in doses of 8 grains repeated every hour until ten or fifteen doses have been taken, or until ringing in the ears, the first symptom of salicyl intoxication, has been produced. Salicylate of sodium may be given in 10-20-grain doses repeated every hour until eight to twelve doses have been administered or ringing in the ears is produced. Another method is to administer at the beginning a single large dose of 60 to 80 grains of salicylate of sodium. This dose need be repeated only once or twice during the day. In general, the quantity of salicylate of sodium should not exceed 1½ to 2 drachms during the twenty-four hours.

The employment of salicylic acid or of salicylate of sodium in large doses is liable to lead to the symptoms of salicyl-poisoning. These symptoms are tinnitus aurium, nausea, vomiting, partial deafness, disturbed vision, vertigo, headache, shivering, rapid deep respiration, and delirium. The intensity of the toxic effects is generally in proportion to the amount of the drug which has been taken, but some persons have a special susceptibility to the action of this remedy and develop toxic symptoms after only moderate doses. As a rule, the unpleasant symptoms subside rapidly after the discontinuance of the remedy. A very few instances have been reported in which the fatal termination has been attributed to the action of salicylic acid, particularly upon the heart, but it is not certain that this has been the correct explanation.

¹ Vide article by Dr. Wm. H. Dickinson in *Trans. Med. and Chirurg. Society*, 1862.

labor being brief and easy. She was treated with quinia in large doses, alkalis, and sponging the whole body with cold water. The latter was employed constantly during the hyperpyrexia. These measures proved efficient and the patient recovered.

The palliative treatment embraces opiates or other anodynes for the relief of pain, restlessness, and inability to sleep. Thirst may be relieved by the free use of water or lemonade. Lemon-juice given in large quantity is one of the remedies for this disease in vogue within late years. It is, in fact, an alkaline remedy, but taken in sufficient quantity to render the urine alkaline the stomach often rebels against it, and the alkaline carbonates are to be preferred.

The affected joints claim local measures of treatment. The application of cloths saturated with an alkaline and opiate solution, as recommended by Fuller, is useful. Fuller's solution consists of from 4 to 6 drachms of the carbonate of soda or potassa, dissolved in a mixture of an ounce of Battley's solution (for which laudanum may be substituted), 2 ounces of glycerin, and 9 ounces of rose-water. The soap-and-opium liniment is a good local application. A liniment containing chloroform has been found useful. I have found the tincture of aconite applied to the parts to afford marked relief. Some practitioners prefer to envelop the joints with dry flannel or cotton. In the choice of local applications the sensations of the patient may serve as a guide. Extension of the limbs by means of an apparatus for that purpose, or simply a cord, pulley, and weight, in order to diminish the pressure of the articulated surfaces upon each other, affords marked relief. The application of pasteboard splints lined with cotton and confined by a firm bandage has been found not only to relieve pain, but to promote the disappearance of the inflammation. Any measure which has the latter effect lessens the pyrexia, for, assuming the disease to be an essential fever, the pyrexia is in part symptomatic of the arthritis. Cold applications to the affected joints, and even the ice-bag, are recommended by German authors. Much relief is afforded in some cases by what may be termed methodic friction. Using some lubricating embrocation, the friction at first over the affected joints, if they be extremely tender, must be as light as possible to avoid giving pain. The force of the friction, however, may be gradually increased, until at length the patient is sometimes able to bear without suffering as much pressure as can conveniently be made. Methodic friction, gradually increased up to as much pressure with the hands as can be borne without pain, leaves the affected joints more comfortable for several hours, and the operation may be repeated once or twice daily.

It is important, in order to avoid relapses, that the patient should not leave the bed and should not make unnecessary exertion until some time—if possible a week—has elapsed after all acute symptoms have subsided.

The treatment of rheumatic endocarditis and pericarditis has been already considered. Pleuritis and pneumonitis are to be treated according to the indications in individual cases, as when they occur in other pathological connections. The indications pertaining to active delirium, convulsions, and coma are derived from the pathological conditions with which these events may be associated—namely, hyperpyrexia, cerebral meningitis, or uræmia.

DaCosta has reported 30 cases treated with the bromide of ammonium in doses of 15 or 20 grains every three hours. Of these cases, in 23 there was no cardiac complication when this treatment was begun, and in none of the 23 cases was any cardiac complication subsequently developed. The mean duration of the disease was 22.5 days.¹ Senator has made some observations on the treatment with benzoic acid. Giving 2½ to 3 drachms of

¹ Vide *Pennsylvania Hospital Reports*, 1869, vol. ii.

the acid, or from 3 to nearly 4 drachms of the benzoate of soda, during the twenty-four hours, the disease was apparently shortened. This result I have observed in a few cases. Its efficacy is vastly inferior to that of salicin and salicylic acid. Trimethylamine, employed largely in this disease by Arvenarius of St. Petersburg a quarter of a century ago, has more recently been employed with success by Lagrange and Dujardin-Beaumetz in France.¹

Subacute and Chronic Articular Rheumatism.

The terms subacute and chronic rheumatism are applied not alone to cases having the distinctive features of the disease just considered, save acuteness, but to affections resembling articular rheumatism only in their situations, and also to persistent pains in different parts of the body supposed to involve a rheumatic diathesis. I shall notice under this heading true articular rheumatism in so mild a form as to be distinguished as subacute, and the chronic form, involving, as there is reason to suppose, a constitutional condition, if not identical with, allied to, that in the acute disease. The affection called rheumatoid arthritis will be noticed after gout has been considered.

Subacute rheumatism may have all the characters of the acute disease, minus intensity. It is then the same disease in a mild form. There is a liability to the cardiac complications, although it is much less than when the disease is acute. The treatment is the same, with modifications which are suggested by the want of acuteness of the symptoms. The alkaline remedies are indicated as protective against cardiac complications.

Both acute and subacute articular rheumatism may end in a chronic arthritic disease. The essential constitutional affection in these cases may not continue, but there remains an affection of one or more of the joints previously involved. The arthritic affection is perhaps a sequel of the rheumatic disease, rather than the latter persisting in a chronic form.

In most cases of *chronic rheumatism* the disease is subacute from the first. It depends doubtless upon an internal determining cause. If it cannot be affirmed that this cause is identical with that in acute articular rheumatism, a relationship between the two diseases may fairly be inferred.

Cases of chronic rheumatism are frequently met with in medical practice. The patients are generally in middle or advanced life. A greater or less number of joints may be affected. The affection remains fixed in certain joints; that is, it does not shift from joint to joint, as in cases of acute rheumatism. The affected joints are tender, painful to the touch, sometimes swollen from intra-articular effusion; their temperature is more or less raised, and the surface may be reddened. Motion is painful, especially at first after periods of rest. A grating sensation and sound often accompany the first movements after these periods. The local symptoms vary much in degree at different times, and patients often observe a connection between an increase of these symptoms and certain atmospherical conditions. They often say that their sensations enable them not only to judge of existing conditions, especially as regards moisture, but to foretell changes which are soon to take place.

Pyrexia is wanting except when there is an exacerbation as regards the local symptoms. The digestive and nutritive functions may be but little or not at all affected. There is no liability to cardiac complications or to disease of internal organs other than the heart.

The diagnosis involves discrimination from rheumatoid arthritis, which will be considered in the next chapter. In the latter occur anatomical changes, dislocations, and distortions which do not belong to the history of

¹ Vide *National Dispensary*, 1879.

chronic rheumatism. Subacute or chronic synovitis, not rheumatic, is to be excluded. The points to be considered in differentiating the latter from rheumatoid arthritis are those which have been stated in connection with the diagnosis of acute articular rheumatism. Whenever chronic rheumatism has been preceded by the acute disease, this fact has of course an important bearing on the diagnosis.

Chronic rheumatism is devoid of immediate danger, but it persists in many cases indefinitely, and in not a few instances during life. Ankylosis of the affected joints sometimes takes place. Notable atrophy of muscles may be a result of their inaction when the disease interferes greatly with muscular movements, or possibly the result of some nervous disorder.

In cases of chronic rheumatism the TREATMENT so important in the acute disease is less effective. Alkalies are of comparatively little service. Salicin or salicylic acid has little controlling influence. A great variety of remedies with reference to a constitutional effect have had advocates. Observing proper care not to do harm by medication, trial should be made of different remedies. Of these may be mentioned the preparations of guaiacum—namely, the simple tincture, the ammoniated tincture, the mixture or the compound decoction of sarsaparilla into which guaiacum enters—the bichloride of mercury, iodide of potassium in large doses, colchicum in small or moderate doses, the hydrochlorate of ammonia, sulphur, and arsenic.

The local treatment is important. Benefit may be obtained from flying blisters or the application of the tincture of iodine. Methodic friction or shampooing, as described in connection with the acute form of the disease, and stimulating embrocations are often of much utility. Counter-irritation by "firing" has been recommended. Palliation of pain may frequently be procured by the application of the tincture of aconite or the veratria ointment. The treatment has reference to two objects—namely, the removal of, *first*, the inflammatory condition, and *second*, the effects of the inflammation. In order to prevent stiffness and ankylosis passive motion is advisable so soon as the inflammatory condition subsides.

Rendering the affected joints immovable by means of pasteboard splints and bandaging should be tried. The immobility, however, should be continued for only a few days at a time, and in the intervals passive movements may be important to prevent ankylosis. Local douches with either cold or warm water, or with each in alternation, may prove of service. Electricity, especially the constant current, has been found serviceable.

External measures acting upon the entire surface are perhaps, in certain cases, not less useful than internal remedies. Reference is had to the simple tepid bath, the alkaline bath, the Turkish bath, the sulphur vapor-bath, and hydropathic packing. The resources of treatment should not be considered as exhausted without a fair trial of these measures.

Measures having reference to improvement of the general health and the invigoration of the system form an essential part of the treatment, embracing tonic remedies, with attention to diet, clothing, exercise, etc. It is unnecessary to go into details which are essentially the same in the treatment of many chronic affections. Change from a cold, changeable, and humid climate to one mild, uniform, and dry often proves the most effective measure which can be adopted. The mineral springs are frequently resorted to with advantage by persons suffering from chronic rheumatism. Of the different waters, the alkaline, sulphurous, saline, and chalybeate are each useful in certain cases. Doubtless, however, much of the benefit derived from watering-places is due to the various incidental hygienic influences.

CHAPTER XI.

LITHÆMIA; URICÆMIA.—GOUT.—RHEUMATOID ARTHRITIS.—RHACHITIS.

Lithæmia; Uricæmia.—Gout: Anatomical Characters; Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Treatment.—Rheumatoid Arthritis.—Rhachitis: Anatomical Characters; Diagnosis; Prognosis; Treatment.

[Lithæmia; Uricæmia.

THE term lithæmia was first employed by Murchison to designate a diathetic condition believed by him to be due to disordered function of the liver. This view of the pathogenesis of the affection was based on the theory that uric acid represents a stage in the formation of urea, and consequently accumulates in cases in which the apparatus chiefly concerned in the formation of urea (the liver) is deranged in its mechanism. Although there is little or nothing in the way of fact to support Murchison's theory concerning the relations of uric acid to urea, there is no question concerning the existence of "lithæmia," and little doubt that it is dependent upon an accumulation of uric acid in the system.

The relation of lithæmia to gout is most intimate. In fact, it has been called by DaCosta, who has drawn its outlines and filled them up with consummate skill, "American gout." In this country, where typical gout is seldom seen, it is of special importance that lithæmia should be recognized, and for such recognition we are chiefly indebted to the teacher just mentioned. Like most American products, lithæmia is acquired rather than inherited.

The lithæmic state is characterized by multifarious symptoms chiefly referable to the nervous system and by certain deviations of the urine from the standard of health. The latter will first be considered, since it is upon them that the diagnosis must be based.

The urine of lithæmia is, as a rule, high-colored, scanty, very acid, and deposits on standing pink or brick-dust sediments of urates, and sometimes crystals of uric acid. Its specific gravity is increased, ranging from 1020 to 1030, and has been found as high as 1035. Crystals of oxalate of calcium may also be found in the urinary sediment. The normal proportion of uric acid to urea—which, according to Haig, is as 1 to 33—will generally be found by chemical analysis to be preserved. An excess of uric acid may not manifest itself by a urinary precipitate, and therefore, in cases of suspected lithæmia in which the urine, though highly acid, remains free from brick-dust sediment, the only method of determining such excess is by chemical analysis.

Lithæmia may be a temporary condition in the healthiest after over-indulgence in rich food or alcoholic stimulants, but what in most persons is an occasional result of an extraordinary cause is in some almost a daily occurrence, either from the food being always excessive in amount or unduly stimulating, or from some innate defect of power, often hereditary, in the liver, in virtue of which its healthy functions are liable to be deranged by the most ordinary articles of diet. Most persons appear to have more liver just as they have more lung, than is absolutely necessary for the due performance of its functions. But in others, not unfrequently the offspring of gouty parents, the organ in its natural condition seems only just capable of performing its healthy functions under the most favorable circumstances.

and functional derangement is at once induced by articles of diet which most persons digest with facility. This functional derangement may manifest itself by various symptoms of indigestion, by disturbances of circulation and of other physiological systems, but especially by deposits of lithic acid, lithates, and pigments in the urine."¹ In this country, as above stated, the symptoms of lithæmia are predominantly nervous, and consist of mental depression, vertigo, insomnia, neuralgia, muscular twitchings and cramps, irritability of temper, and occasional headache which may assume the type of hemicrania. Persistent severe headache is, however, not often observed.

It is of the greatest practical importance to be conversant with the fact that albuminuria may be a symptom of lithæmia, because the prognosis of albuminuria from this cause is vastly more favorable than that of albuminuria dependent upon structural lesions of the kidney. The lithæmic origin of albuminuria may be suspected in cases in which the amount of albumin in the urine is small and variable, but the crucial test of the matter is the response to treatment. As a rule, in cases of the kind referred to, this is prompt and decided. Casts, in the proper sense of the term, are generally absent, but it is by no means uncommon to find that peculiar modification of the cast known as the "cylindroid." The frequent association of cylindroids with the lithæmic diathesis has been commented upon by Alfred Stengel.² As suggested by DaCosta, who has recently studied the subject of lithæmic albuminuria, it is highly probable that various forms of albuminuria described as "intermittent," "post-cibal," "albuminuria of adolescents" etc. are in reality dependent upon lithæmia.³

Our knowledge of this entire subject is yet in its infancy, but the existing facts warrant the statement that the condition of the kidney associated with lithæmic albuminuria is not organic and has little tendency to result in structural change.

The DIAGNOSIS of lithæmia is based chiefly upon symptoms of disorder of the nervous system occurring independently of organic disease of the cerebro-spinal axis or of the peripheral nerves and associated with a urine presenting the above-described deviations from the healthy standard. In addition, gastro-intestinal disturbances are frequent, and the pulse is often weak and intermittent.

Notwithstanding the apparent gravity of its symptoms, lithæmia does not tend, *per se*, to a fatal issue. It does, however, lessen the general powers of resistance, and therefore renders the system an easier prey to intercurrent acute disease.

The TREATMENT of lithæmia is for the most part dietetic, and therefore its success depends upon the degree of self-control possessed by the patient. Alcoholic stimulants of every kind are harmful, but especially champagne, Port wine, Burgundy, and Madeira. It is generally conceded that the least injurious form of stimulant is whiskey, and some lithæmic patients can take a moderate amount of whiskey and water at dinner with apparent impunity.

There are different opinions concerning the proper diet for this condition, some recognized authorities recommending a diet largely nitrogenous, composed of every kind of digestible meat with a scanty allowance of carbohydrates, while others, equally experienced, proscribe such meats as beef and

¹ Murchison, *Croonian Lectures*, 1874, p. 66.

² "Cylindroids in the Urine, and their Significance," *Medical News*, July 15, 1893.

³ For a full discussion of this important subject, see "The Albuminuria and the Bright's Disease of Uric Acid and of Oxaluria," by J. M. DaCosta, MD., LL.D., *American Journal of the Medical Sciences*, Jan., 1893.

mutton, and limit the nitrogenous food to fish, the white meat of chicken and game, eggs, and oysters. The latter plan is believed by the writer to be preferable, at least at the beginning of treatment. Later, when the patient is able to take considerable out-door exercise, beef and mutton once a day and in small amount may be permitted. The most important point in the dietetic treatment of lithæmia is *to limit the amount of the food*. The condition is one of *hepatic inadequacy*, precisely analogous to the renal inadequacy described by Sir Andrew Clark. Excess is a relative term, and what seems like privation to the robust may be excess to the lithæmic. The principal meal should be taken early—at one or two o'clock—for in the majority of cases the digestion is at its best at that time. Late dinners and suppers are notoriously injurious. Green vegetables, with the exception of asparagus and rhubarb, may be freely allowed, but the amount of potatoes and bread should be restricted. Sugar should be discarded, with the exception of a small amount in the tea, coffee, or cocoa, which beverages may be permitted in moderation. Fat, except as it exists in good butter and bacon, is generally digested with difficulty. There are idiosyncrasies regarding the use of milk which should always be respected. In most cases milk to the amount of one pint daily is beneficial. The patient should be encouraged to drink abundantly of pure water: the urine is thereby rendered less irritating to kidneys and bladder and regular evacuations of the bowels are promoted. The latter effect is more certain when a glass or two of water is swallowed before breakfast. It is probable that the various mineral waters employed in this condition owe their undoubtedly beneficial effects to the H_2O which they contain.

Daily warm or tepid baths followed by vigorous friction and out-door exercise, of which the best form is riding, are hygienic measures of the utmost importance. In the opinion of the writer, lithæmia would be a comparatively rare affection if every adult of average strength were to exercise daily to the extent of inducing free perspiration.

The drugs employed in the treatment of lithæmia belong chiefly to the class of laxatives. In case of constipation, half an ounce of the Rochelle salt or the sulphate of magnesia or a drachm of the Sprudel salt dissolved in a glass of water should be taken before breakfast. An occasional dose of blue mass (2 or 3 grains) or a grain or two of calomel at bed-time is often of decided benefit. Anæmia is not a prominent symptom of lithæmia, and if present is mostly due to digestive disorder. In such cases it is most successfully treated by the administration of dilute hydrochloric acid—10 to 20 drops in an ounce of water—after each meal.—H.]

Gout.

The disease called gout has been thought to be allied to articular rheumatism, and the two affections have even been considered to be identical. As will be seen, however, they are shown to be essentially distinct forms of disease by points of contrast pertaining to morbid anatomy, clinical history, pathological character, and causation. The name gout or its synonym in different languages is universally applied to the disease to be now considered. The name is derived from *gutta*, a drop, and is supposed to refer to the dropping of some morbid fluid into the joints.

Gout occurs as an acute, a subacute, and a chronic affection. Writers have made other varieties, such as irregular and misplaced gout. As the subacute form is not always chronic, it is convenient to consider this form when of brief duration and the acute form under one head. The term *transient gout* will embrace the acute and subacute form, the latter ending too soon to be

considered as chronic. *Persistent*, or *chronic gout* will embrace all cases in which the disease is protracted.

ANATOMICAL CHARACTERS.—The most distinctive anatomical character of gout consists in the deposit within the tissues of crystalline urates, chiefly urate of sodium. Mingled with the urate of sodium have been found in small quantity other salts, as urate of calcium and of magnesium and carbonate and phosphate of calcium. The urate of sodium is in the form of acicular crystals, with which may be mingled amorphous granular matter. With few exceptions the urates are deposited first in the joints, and in the majority of cases first in the metatarso-phalangeal articulation of one of the great toes. In the course of the disease other joints become affected. At first the disease manifests a preference for the small joints of the foot and hand, but subsequently (and in rare cases primarily) larger joints, as the knee and elbow, may become involved. The urate deposit seems to form a white, chalk-like incrustation upon the free surfaces of the articular cartilages. Careful examination, however, shows that the deposit is in the substance of the cartilage. Usually only the superficial layers of the cartilage contain the deposit. Upon microscopical examination are found acicular crystals arranged in little clusters which radiate from a centre. The centre of a cluster is often a cartilage-cell, but the crystals are deposited in the basement-substance as well. The deposition of urates in the joints may occur either with or without paroxysms of articular gout. Garrod has shown that a single paroxysm of gout suffices to cause a certain amount of the urate deposit in the affected joint.

Urate concretions are often found in the synovial membranes and the articular ligaments. These gouty concretions are called *tophi* or *chalk-stones*. Tophi consist of needle-shaped crystals of urate of sodium, mingled with granular matter and animal substance. Their consistence is usually compared to that of mortar.

Although the urate deposit is often associated with acute transitory inflammation in and about the joints, it is sometimes though less frequently combined with destructive inflammatory and degenerative changes in the joints. The stiffness of the joints observed during life is due more to the affection of the ligaments than to the alterations of the cartilage. Fibrous ankylosis may occur. There may be erosion of the articular cartilages. These changes, combined with tophaceous nodules, and sometimes subluxation of the joints, may give rise in chronic gout to striking deformities, which are observed most frequently in the hands.

The deposits of urates may be found not only in the ligaments and cartilages, but also in various other situations, of which the most frequently affected are the perichondrium, the periosteum, the periarticular connective tissue, the tendons and their sheaths, the bursal sacs, the kidneys, the skin, and the cartilages of the external ear. Tophaceous masses occurring in the external ear, varying in size from that of a pin's head to that of a split pea, are often of great assistance in diagnosis. Among the rare situations for gouty deposits may be mentioned the spongy texture of bone, the small laryngeal cartilages, the tarsal cartilage, and the sclerotic coat of the eye, the outer sheaths of vessels and of nerves, the endocardium, and the dura mater. In general, those tissues are most liable to be affected which are possessed of little vascularity, but the gouty deposit has been found in such vascular structures as the skin and the muscles. Tophi, especially those seated subcutaneously, may lead to the formation of abscesses, which burst and discharge pus mingled with chalky material. In this way or by simple necrosis of the skin over the tophi sluggish ulcers are formed which have little tendency to repair.

The interesting discovery has been made by Ebstein that the tissues which

are the seat of urate deposits in gout are in the condition of coagulation necrosis. According to Eberlein this coagulation necrosis precedes the deposit of urates and is caused by the abnormal chemical constitution of the blood. The deposit of urates in the tissues, according to this view, is due to the presence of urate in excess leading to the formation of the urate crystals out of the normal urates, which are in excess in the circulating blood. An area of reactive inflammation exists around the deposit of urate crystals.

It has not, however, been established the fact that gout is one of the diseases of the kidney. The diseased kidney presents the gross anatomical lesions which have already been described as characteristic of chronic Bright's disease (p. 823). The gouty kidney has some urate deposits, chiefly in the pyramids, where they appear as white streaks and patches. The uric acid deposit is found both within and between the tubules. The diseased kidney may develop without the occurrence of any of the characteristic symptoms, although at the autopsy urates are found in the interstitial cartilages. It is an occasional cause of waxy degeneration. Crystals of urate of sodium have been found in the renal calices and pelvis.

It has been generally claimed that the blood in gout contains an excess of uric acid, which is present in the form of urate of sodium. According to this view the appreciable excess of uric acid is present in the interstices between the early attacks of gout, but in chronic gout the blood is comparatively normal.

The gouty dyscrasia is frequently associated with various anatomical changes in the joints, which have been described. These lesions, however, are generally without special peculiarities by which they can be recognized as gouty in origin.

Patients with gout are especially liable to chronic inflammations, of which the most common are the gastritis, chronic enteritis, chronic bronchitis, and chronic nephritis, nephroma. Fatty liver and, according to some authorities, excess of the liver may be an effect of gout. Various cutaneous lesions, especially of the feet, are ascribed to gout. Cardiac lesions are common in gout. They are most frequently secondary to chronic nephritis, but fatty heart, dilatation and pericarditis and myocarditis may occur in association with this disease. Gouty patients have a tendency to the formation of uric acid calculi and to chronic inflammations of the bladder, urethra and prostate gland. Gout and diabetes mellitus are sometimes combined or may be a sequel of the other.

CLINICAL HISTORY.—Transient gout and persistent gout require separate consideration as regards their clinical history. Having considered these forms of the disease, I shall now discuss the irregular and misplaced gout.

TRANSIENT GOUT.—Under this head are to be embraced all cases in which the disease is of short duration; that is, the duration not sufficiently prolonged for the disease to be regarded as chronic. In this form of the disease the patient is said to have an attack or fit of gout. The disease is generally acute, but sometimes it is subacute.

The seizure is generally sudden, occurring, as a rule, during the night and in the early part of days after midnight. In a certain proportion of cases the seizure occurs without premonitions; and the patient may have entirely bed-riddenness well as usual. In some cases, however, there are prodromic phenomena consisting of arthralgia, gastric flatulency, eructations, and other dyspeptic ailments, together with inability to exert the mental faculties, irritability of mind, and depression of spirits. These phenomena are not sufficiently significant to lead to the expectation of an attack of gout if they

more attacks have not been already experienced, but in persons who are subjects of the disease they may denote an impending seizure. Observations have shown that for several days preceding a gouty paroxysm there is a notable diminution of uric acid in the urine.

The seizure is marked by pain, which in the great majority of cases is seated in the metatarso-phalangeal joint of one of the great toes. The pain soon becomes more or less intense, and frequently it is excruciating, being compared by patients to pain caused by the gnawing of an animal, a dislocation of the bone, a nail driven into the joint, tearing of the parts with pincers, etc. Such comparisons express only intensity of suffering, for it is not to be supposed that patients have actually experienced the pain produced by the various causes mentioned. A sense of throbbing in the part accompanies the pain. More or less pyrexia is developed, preceded by shivering. These symptoms continue for several hours, and then the pain and fever subside. The patient is comparatively comfortable and obtains some sleep. The relief is usually accompanied by slight perspiration. In the mean time, the affected joint becomes swollen, the skin is reddened and shining, the subcutaneous veins are distended, the heat is raised, and there is exquisite tenderness to the touch. These appearances are observed after the severe pain has abated.

In some cases only a single paroxysm of severe pain is experienced, but much oftener the seizure is renewed on the following night, and on successive nights for a variable period. The local affection may remain in the joint affected at the first seizure, or the affection may be transferred from this joint to the corresponding joint of the opposite foot. In some cases the inner side of the foot, the instep, or the heel becomes affected, and the affection may extend to the larger joints and to the small joints of the upper extremities. This extension of the local manifestations of the disease rarely occurs until after several attacks, and it occurs especially in cases of chronic gout. After recovery from transient gout there is often a feeling of better general health than before its occurrence, the patient being relieved of indefinite ailments which previously existed.

During the continuance of transient gout the symptoms other than those referable to the part or parts affected vary considerably in different cases. Pyrexia is more or less marked in proportion to the acuteness of the local manifestations. The fever appears to be symptomatic, and, as a rule, it is less than in cases of acute articular rheumatism. The appetite is frequently impaired or lost, but in some cases it is preserved. Dyspeptic ailments are sometimes present and sometimes absent. The urine is generally scanty, high-colored, and deposits a lateritious sediment on cooling. The excretion of uric acid is lessened. The bowels are generally constipated.

Cases also differ much as regards the local symptoms. The affection may be called acute when the pain is severe, the swelling, redness, etc. are marked, these local symptoms being accompanied by a corresponding amount of fever. On the other hand, the affection is subacute when the pain is notably less severe, the other local symptoms are less marked, and fever is either slight or wanting. As regards the seizures of pain, which occur usually at night, they are in some cases paroxysmal, the pain passing off in the day, but in other cases more or less severity of pain continues during the day as well as at night; in other words, remissions occur instead of intermissions. The local symptoms gradually decline as the fit or attack passes off. Edema of the part or parts is more or less marked at the decline of the local affection, with frequently pruritus, and in the majority of cases furfuraceous desquamation of the epidermis. The local symptoms just named are diagnostic of gout as contrasted with rheumatism. Cramp affecting the muscles of the leg, the

thigh, and other parts of the body is a symptom more or less marked in a considerable number of cases.

The duration of transient gout varies between a few days and several weeks. In the majority of cases the paroxysms recur nightly for at least a week. Generally, the paroxysms or exacerbations are less and less severe in proportion to the duration of the attack. If the disease continue for more than three or four weeks it is to be considered as persistent or chronic. An attack of acute or subacute gout, especially the latter, may eventuate in the persistent or chronic form of the disease, or, having continued for a variable period, the disease for the time ceases, recurring at longer or shorter intervals in the vast majority of cases.

Persistent or Chronic Gout.—Gout, beginning as either an acute or subacute affection, in a certain proportion of cases continues as a chronic affection for many weeks, months, and even years. Generally, this persisting or chronic form of the disease is preceded by the occurrence of many transient attacks recurring after intervals which become shorter and shorter, until at length, as it were, they run together. When the disease is persistent it has not continuously a uniform severity, but remissions occur from time to time, and not infrequently intercurrent acute attacks take place.

In the persistent or chronic form the local symptoms which characterize the acute affection—namely, intense pain, heat, and redness—are either slight or wanting. There is little or no fever. Disorders of the digestive system are often present and the general health is more or less impaired. In this form the joints are liable to become stiffened, ankylosed, and deformed from the abundance of the gouty deposit. Chalk-like concretions may occur within and around the small joints of the hands. In some cases collections of semi-solid matter are felt near the surface, and if they be opened the matter may be pressed out. Sometimes collections of considerable size open spontaneously. The solid concretions, or chalk-stones, sometimes make their appearance through the skin. The gouty matter may be deposited in the bursæ mucosæ in the neighborhood of joints. In a certain proportion of cases—the number, happily, not large—the hands and feet become permanently distorted and crippled, the fingers sometimes presenting an appearance compared by Sydenham to that of a bunch of parsnips. Nodules of the deposit are frequently seen on the helix of the ear, sometimes also on the eyelids, and occasionally on the face.

In chronic as in acute gout the predilection of the disease, as regards the seat of the local manifestation, is for the joints of the great toe. An affection of other joints occurs primarily in a small proportion of cases. After the great toes, the order in which parts are liable to become implicated, according to Garrod, is as follows: The heels and ankles, the knees, the smaller articulations of the hands, the elbows, and lastly the shoulders and hips. There are, however, many exceptions to this order of sequence. A blow, sprain, or other injury may determine the seat of the local affection. A point of difference in different cases pertains to the number of joints which become affected.

In some cases the local manifestations of the disease, however long it may persist or frequently recur, remain concentrated on a few joints; in other cases a large number of joints are implicated; and, again, in some cases different joints are affected in successive attacks. If the same and a few joints be always affected, and if the disease either persist or recur frequently, permanent changes in the affected joints are more likely to occur. Another point of difference in different cases relates to the palpable changes in the affected joints. Some gouty patients escape ankylosis and nodosities, although they suffer from the disease more or less throughout their lives, whereas in other cases

the hands and feet become deformed and crippled after a comparatively short duration of the disease.

Irregular and Misplaced Gout.—It is an old doctrine that local manifestations of gout are liable to be seated in the different visceral organs—namely, the stomach, intestines, lungs, heart, liver, kidneys, and brain. Disorders referable to these viscera preceding the ordinary manifestations of gout have been considered as gouty, and it has been supposed that gouty disorders of viscera may occur without any affections of the joints either accompanying or ensuing. In such cases gout is said to be *irregular* and *misplaced*. *Anomalous* and *latent gout* are other terms applied to these cases. Sometimes during an attack of gout the affection of the joint or joints suddenly disappears, and symptoms denoting an affection of some internal organ supervene. In these cases a transference or metastasis of the gouty manifestations is supposed to take place, and the name *retrocedent gout* is employed to express such an occurrence. These notions are probably, in a measure, well founded, but it is difficult with our present knowledge to say how far they are to be accepted as correct. The difficulty consists in the inability to determine whether antecedent, coexistent, or consecutive affections in certain cases of gout are not associated merely by coincidence. It has doubtless been too much the custom to consider all affections occurring in persons subject to gout as of a gouty character, and the gouty diathesis is often considered to exist on insufficient data. Making, however, due allowance for error, it can scarcely be doubted that the constitutional morbid condition which constitutes the disease in cases of gout may determine disorders, sometimes of a grave character, in organs more important to life than those in which the local manifestations are usually seated. Evidence of a pathological connection of these disorders with gout is afforded by complete relief following the development of a gouty affection of the joints, by their occurrence immediately after a gouty affection of the joints has been apparently suppressed, by the absence of any other appreciable causes explaining their occurrence, and by the indefinite or anomalous character of the disorders.

Disorders of the stomach and intestine attributed to gout are neuralgic pain or spasm, flatulent dyspepsia, and persistent vomiting, accompanied with more or less prostration, diarrhoea, and in some cases symptoms denoting enteritis.

Disturbed action of the heart is not uncommon in gouty patients. It sometimes occurs in an alarming degree, but it may be doubted if a purely functional disturbance occurring in this connection ever prove fatal. Valvular lesions and enlargement of the heart often exist in persons affected with chronic gout, being usually associated with chronic Bright's disease. The want of a tendency to acute endocarditis and pericarditis is one of the points distinguishing gout from rheumatism.

Cough, asthmatic dyspnoea, and bronchitis are attributed to gout. Spasmodic affections of muscles or cramp in various situations, neuralgia affecting the branches of the fifth pair, the sciatic nerve, and other nervous trunks, paroxysmal headache and hysteria, are to be added to the list.

Delirium and fatal coma are among the disorders imputed to gout. These symptoms may be due to uræmia or to meningitis, which may or may not be dependent on gout.

The deposit of the urate of sodium in the uriniferous tubes in cases of gout has been stated under the head of the morbid anatomy. It is not difficult to understand that this deposit may accumulate and form renal calculi. Clinical observation shows that gouty persons are liable to the formation of renal calculi and to paroxysms of pain caused by the passage of the stones along the ureter, or renal colic. It has been established that the contracted kidney may be due to gout. The coexistence of renal disease in certain cases may account for the occurrence of some events which have been heretofore consid-

ered as being specially connected with gout—namely, vomiting and purging, headache, neuralgia in different situations, delirium, convulsions, and coma. The existence of renal disease is to be ascertained by means of the urinary changes which have been already considered. The urine presents the characters distinctive of the small granular kidneys. It usually is clear and abundant, and it deposits but little sediment. The amount of albumen in the urine may be slight, but in some cases it is considerable. Casts are usually not abundant, and they may be absent. Slight albuminuria in the course of gout is not necessarily indicative of Bright's disease.

Cystitis and urethritis have been attributed to gout, but the existence of any special pathological connection may be doubted. Certain affections of the skin, particularly eczema, are common in persons subject to gout. Graves called attention to the habit of grinding the teeth as peculiar to cases of gout. The habit proceeds from an uneasy sensation in the teeth, which is in this way momentarily relieved.

A small amount of sugar may be found occasionally in the urine of gouty patients. The association of gout and of diabetes mellitus in some cases has been already referred to. This association has led to the idea that the vices of nutrition which are the causes of these diseases are in a measure allied, but we are wholly in the dark as to the fundamental disorders of nutrition in both of these diseases.

PATHOLOGICAL CHARACTER.—The researches of Garrod show that the pathology of this disease involves a particular morbid condition of the blood—namely, an abnormal accumulation of uric acid, *uricæmia* (*lithæmia*). The blood in health contains only a trace of uric acid. In 47 cases of gout an analysis of the blood-serum by Garrod showed a notable increase of this constituent. Garrod has also shown that during an attack of acute gout the uric acid in the urine is notably diminished. It is apparently increased, since a deposit of the urates in more or less abundance when the urine cools is common; but the increase is only apparent, the deposit being due to the scanty quantity of urine. In chronic gout the quantity of uric acid excreted by the kidneys is habitually below the average in health. Garrod has found the uric acid in excess in the blood in cases of lead-poisoning.

From the facts just stated, taken in connection with the deposit of the urate of sodium within or around the joints, it is rationally concluded that the local manifestations of gout are effects of the *uricæmia*; but it is evident that the *uricæmia* is itself an effect, and the primary perversions underlie the excess of uric acid in the blood. Either this principle is produced in too great abundance, or, without being unduly produced, it accumulates as a result of insufficient excretion by the kidneys. Probably both explanations are involved. Direct observation, at all events, shows deficient excretion, since the amount in the urine is less than in health. Garrod entertains the opinion that the deposit of uric acid in the form of the urates takes place within and around the joints in consequence of diminished alkalinity of the blood; whereas Ebstein considers the primary effect of the abnormal condition of the blood to be the production of coagulation necrosis, which is followed by the deposit of urates.

In treating of rheumatism it has been stated that an examination of the blood in that disease with reference to the amount of uric acid shows this principle not to be in excess. Here is a capital point of difference between gout and rheumatism as regards pathological character. The clinical history of gout has afforded several striking points of contrast between the two diseases. These points will be reproduced under the head of **Diagnosis**. Other

points of contrast will be presented under the head of Causation. The individuality of each disease is therefore sufficiently established.

CAUSATION.—Gout is a diathetic disease, and the diathesis in a certain proportion of cases is congenital and inherited. It is a matter of common observation that certain families are predisposed to this disease, and it is sometimes transmitted successively through a series of generations. Scudamore's statistics showed that of 523 patients affected with gout, in 309 the disease had existed in either the parents or grandparents. Of 80 cases reported to a commission of the French Academy, in 34 the disease had been transmitted, and Garrod states that in the cases which he has observed an hereditary predisposition existed in 50 per cent. The diathesis, however, is by no means invariably inherited; in a certain proportion of cases it is acquired; and on the other hand the disease is not always transmitted to offspring. There are causes, then, which may produce it in those in whom there is no reason to suppose a congenital predisposition, and in those predisposed by inheritance other causes may be required for its development.

A causative influence relates to age. It occurs very rarely before the age of puberty. Of 515 cases analyzed by Scudamore with reference to age, in only 5 did the disease occur in persons less than eighteen; in 142 cases the ages at the time of the development or first occurrence of the disease were between twenty and thirty years; in 194 cases, between thirty and forty; in 118 cases, between forty and fifty; in 38, between fifty and sixty; and in only 10 cases between sixty and sixty-six years. The liability thus diminishes progressively after fifty, and the development of the disease is as rare, if not more so, after seventy as before puberty. In the cases in which it appears before the age of twenty-five it generally is inherited. In the causative influence relating to age there is a point of contrast to rheumatism, the latter disease affecting by preference young subjects.

A very marked difference exists between the two sexes in the liability to gout. Gout—at least articular gout—is much more common in men than in women. Here is another point of difference from rheumatism, the latter occurring scarcely less frequently in females than in males.

Dietetic and regiminal habits lead to the acquirement of the diathesis, and co-operate with a congenital predisposition in producing the disease. To the habitual use of wine or malt liquors the disease is in many cases chiefly attributable, and, on the other hand, the use of distilled spirits seems to exert no influence in its production. Gout prevails in countries in which wine and malt liquors are largely used, whereas in countries in which the use of spirits predominates the disease is relatively rare. It is comparatively rare in Scotland, Russia, Poland, Denmark, and in this country, probably in a great measure for the reason just stated. It is proverbially prevalent among those of the opulent class of society who are addicted to luxurious habits; but doubtless the habitual indulgence in the pleasures of the table, exclusive of the use of fermented liquors, contributes largely in this class to the production of the disease. Physical indolence also enters into the causation. The agency of malt liquors alone is strikingly shown by the frequent occurrence of the disease among a class of laborers in London employed to raise ballast from the bottom of the Thames, who are accustomed to drink two or three gallons of porter daily. According to Budd, gout is quite common among this class. The lighter wines are less likely to produce the disease than the stronger varieties—namely, sherry, madeira, and port—and this is true of malt liquors. There is little reason to suppose that cider tends to produce it. It is evident from the facts just stated that the causative agent in fermented liquors is not exclusively alcohol. Ascribing

to the use of wine and malt liquors, to high living in other respects, and to indulgence in luxurious ease a due causative influence, the disease is sometimes developed irrespective of these causes. Examples are occasionally met with among laborers accustomed to a plain diet and neither wine-drinkers nor beer-drinkers. My clinical records contain notes of several such cases. Gout developed in individuals of the poorer classes often pursues an atypical course, and the acute paroxysms may be absent.

Various causes may determine the occurrence of an attack of gout; that is, they may act as exciting causes. Attacks are sometimes attributable to prolonged intellectual exertion, anxiety of mind, bodily fatigue, exposure to cold, acts of excessive indulgence in eating or drinking, etc.; but in not a few instances the disease occurs without any appreciable exciting cause. The disease is rarer in tropical than in temperate climates. Attacks are more likely to occur in the spring and autumn than at other seasons of the year. Garrod adduces facts which show that impregnation of the system with lead is among the causative agencies. Of 51 male hospital patients, 16 were either painters, plumbers, or workers in lead. This connection has been noted by other observers. The fact that in cases of lead-poisoning the uric acid is found in excess in the blood has already been stated.

DIAGNOSIS.—The difficulties in the way of the diagnosis of articular gout relate to its discrimination from rheumatism and the affection called rheumatoid arthritis. The distinctive features of the latter will be presented in treating of that affection, and the differential diagnosis of gout and rheumatism only will be here considered. The points involved in this differential diagnosis embrace facts relating to anatomical characters, clinical history, pathological character, and causation which have been presented under these respective heads.

Distinctive Features relating to Anatomical Characters.—Under this head reference is had to the morbid changes within and around the affected joints. A distinctive anatomical change in gout is the deposit of a morbid product abounding in the urate of sodium, the gouty or tophaceous matter, either in collections of a semi-solid consistence or in hard concretions commonly called chalk-stones. These are never present in rheumatism and are pathognomonic of gout. The deposit, however, in a situation and in sufficient quantity to be ascertained during life occurs in only a certain proportion of cases, and chiefly in chronic gout.

Distinctive Features relating to Clinical History.—In the great majority of cases the primary local affection is seated in the metatarso-phalangeal joint of one of the great toes. The larger joints are affected subsequently, if at all. The local manifestations tend to the smaller joints of the toes and hands. In acute cases the pain is more intense than in acute rheumatism, and the tenderness is greater. Pain occurs in paroxysms or in marked exacerbations. Edema, pruritus, desquamation of the cuticle, and enlargement of the veins are distinctive of gout. Febrile movement is less marked than in acute rheumatism, and is apparently symptomatic, whereas in rheumatism the fever is essential as well as symptomatic. Acute endocarditis and pericarditis are very rarely, if ever, developed in the course of the disease. The deposit of small collections of the urate of sodium on the helix of the ear is of frequent occurrence in cases of gout, and serves to establish the diagnosis. They should always be sought for.

Distinctive Features relating to Pathological Character.—The uric acid in the blood is morbidly increased. This may be ascertained by obtaining serum either from a small quantity of blood or by means of a small blister, and resorting to what Garrod calls the "uric-acid thread experiment." The mode

of performing this experiment, as described by Garrod, is as follows: "Take one or two fluidrachms of the serum of the blood and put it into a flat-tened glass dish or capsule. To this add ordinary strong acetic acid in the proportion of six minims to each fluidrachm of serum, which causes the evolution of a few bubbles of gas. When the fluids are well mixed introduce one or two ultimate fibres, about an inch in length, from a piece of unwashed linen fabric, which should be depressed by means of a small rod, as a probe or the point of a pencil. The glass should then be set aside in a cool place until the serum is quite set and almost dry. Should uric acid be present in the serum in more than a small amount, it will crystallize, and during its crystallization will be attracted to the thread and assume forms not unlike those presented by sugar-candy upon a string. To observe this, the glass containing the dried serum should be placed under a linear magnifying power of about fifty or sixty, procured with an inch object-glass and low eye-piece; or a single lens of one-sixth of an inch focus answers perfectly. To ensure perfect success the glasses should be broad and flat; the acetic acid should be neither very strong nor too weak; the glass should not be disturbed during the drying of the serum; the temperature should be that of an ordinary sitting-room; and the glass should be protected from dust."¹

For a diagnosis the thread experiment, according to Garrod, suffices. Crystals of uric acid do not form and adhere to the thread in the blood-serum in health. The uric acid of the blood is not morbidly increased in rheumatism.

Distinctive Features relating to Causation.—Gout occurs very rarely before puberty, and it occurs generally between thirty and fifty years of age. Rheumatism affects especially young subjects. Gout is oftener hereditary than rheumatism. It rarely affects women. The use of fermented liquors and habits of luxury as regards diet and exercise exert an agency in producing gout which is not exerted to the same extent in the causation of rheumatism. The poorer classes are as liable to rheumatism as are the rich, if not more so; the reverse being true of gout.

To determine the existence of the diathesis prior to the arthritic manifestations of the disease, and to recognize the irregular or misplaced manifestations of gout, are objects of diagnosis involving not a little difficulty and doubt. Certain symptoms should excite strong suspicion of the constitutional gouty condition if they occur within the periods of life most favorable for the development of the disease and in a person of a gouty family whose habits of life are such as will co-operate with an innate predisposition. Among the symptoms referred to are those which belong to dyspepsia, with a scanty secretion of urine which deposits the urates, and the liability to gravel or attacks of renal colic. If with these symptoms an examination of the blood-serum show a morbid excess of uric acid, the development of an attack of gout may be predicted with considerable confidence. The diagnosis of disorders of internal organs imputed to gout—or, to use a term which has been applied to these cases, of "visceral gout"—must rest mainly on their occurrence in proximity to attacks of gout, either preceding, accompanying, or following the sudden cessation of well-marked gouty manifestations.

PROGNOSIS.—The immediate danger to life from gout is slight. If it ever, *per se*, prove fatal, it is by its irregular or so-called misplaced manifestations; and in many, if not most, of the cases in which death is imputed to gouty affections of vital organs it is probable, as already intimated, that these affections do not strictly belong to gout, but are to be regarded as coexisting or intercurrent affections. The prognosis becomes grave if the small granular

¹ This account from Garrod's work has been somewhat condensed.

kidney be developed in the course of gout. It is an error to suppose that gout is salutary as regards the duration of life. Frequently-recurring attacks of transient gout and the persistence of the disease in a chronic form impair the constitutional powers, diminish the ability of the system to resist other diseases, and thus shorten life. It is a serious disease in certain chronic cases in which it leads to deformity and rigidity of the affected joints. It has been a favorite notion that the liability to gout lessens the liability to other diseases. There is little foundation for this notion, and, on the contrary, there is ground for the belief that if gout do not tend to produce other diseases it favors their inroads upon the system.

A tendency to recurrence is a law of the disease. It is extremely rare for a single attack only to occur. If life be not cut off by some other disease, frequent attacks are almost invariably experienced, and the disease may become chronic. The diathesis is thus rarely if ever extinguished.

TREATMENT.—Various therapeutical measures heretofore considered as having a curative influence over gout are now rarely employed. Their disuse has resulted from the clinical study of their effects and from improved pathological views. Among the measures referred to are embraced bloodletting, emetics, mercurialization, and continued or often-repeated purgation. These measures are now regarded as contraindicated in both the transient and the persistent form of gout. Other measures, long more or less in vogue, are still prized in the treatment of this disease. In the latter list are colchicum and alkaline remedies. The indications for treatment during attacks of transient gout, during the intervals between these attacks, and in cases of persistent or chronic gout respectively claim separate consideration.

Treatment during Attacks of Transient Gout.—The great Sydenham, himself for more than thirty years a sufferer from this disease, was led to conclude that an attack should not be interfered with. Regarding it as an effort of nature to get rid of a noxious material, he believed it to be undesirable to arrest or abridge it. The propriety of non-interference was also advocated by Trousseau. Few physicians, however, would feel satisfied to fold their hands and await the cessation of the disease, and still fewer patients would be content to forego measures to alleviate their sufferings. Nor is this line of conduct consistent with either reason or experience. Transient gout is a self-limited affection. It is probably rarely, if ever, arrested, and it might not be advisable to arrest it were this practicable. Perhaps its duration is not often abridged by therapeutical interference; but its severity may be lessened and the suffering connected with it may be materially mitigated by measures which, if judiciously employed, will not do harm. This is a mild expression of the resources of medicine in cases of transient gout.

Colchicum is an ancient remedy for gout, assuming the hermodactylus of the Grecian and Arabian physicians to have been this drug. It has been not less prized by the majority of physicians in modern times. Most if not all of the various secret nostrums for gout which have commended themselves to popular favor owe their efficacy chiefly to this remedy. Its special power of controlling the inflammatory phenomena of the disease is undoubted. Our knowledge of the value of this remedy is derived wholly from experience. Its special mode of operation cannot be explained. A rational object of treatment, deduced from the pathological character of gout, so far as it is at present known, is the elimination of uric acid; but the researches of Garrod show that this remedy does not increase the amount of uric acid excreted by the kidneys, nor does it in all cases increase the quantity of urine. It may be here added that other rational objects of treatment are prevention of an undue formation of uric acid or its undue accumulation in

the blood, and neutralization of this acid, or keeping it in a state of solution in the blood until it is eliminated through some of the natural emunctories.

In an acute attack of gout, colchicum may be given at first in a tolerably full dose; that is, half a drachm or a drachm of the wine, or an equivalent dose of the tincture or acetic extract. It should afterward be continued in small doses. It is never judicious to carry its use to the extent of producing vomiting or purging. Carried to this extent, it is objectionable on account of its depressing influence, although relief of the gouty inflammation be procured. Its special influence is independent of its operation as an emetic or a cathartic. An emetic of any kind is not indicated unless the attack occur soon after a full meal and there be reason to suppose that the stomach is overloaded with undigested food. If constipation exist, a free evacuation by means of a saline purgative is desirable. A saline purgative is also appropriate as a depletory measure if the patient be robust or of a full habit and the fever be high. The purgation should be effected by salines rather than by the colchicum. Some physicians regard salicylic acid and salicylate of sodium as beneficial in acute attacks of gout; but the favorable influence of these drugs is far inferior in this disease to that exerted in rheumatism.

Alkaline remedies are rationally indicated with a view of promoting the solubility of uric acid. For this end the salts of potassium and of lithium are to be preferred to those of sodium, the urate of potassium and the urate of lithium being more soluble than the urate of sodium. Moreover, these salts have a diuretic action, and thus contribute to another rational object of treatment—namely, the elimination of uric acid by the kidneys. The bicarbonate of potassa may be selected, and the acetate and the bitartrate are appropriate. The alkaline remedy may be given in conjunction with the colchicum. The phosphate of ammonia was introduced as a remedy in gout some years since by Buckler of Baltimore, its efficacy being supposed to consist in its forming a soluble salt, readily eliminated, by the combination of uric acid and ammonia, the phosphoric acid combining with the soda and forming another soluble salt. Ten grains may be given three or four times daily. This remedy, however, is better suited to the chronic form of the disease or to the intervals between attacks of transient gout. This remark will also apply to the benzoic acid, which is supposed to be useful by converting the uric into hippuric acid.

The carbonate of lithia, introduced as a remedy by Garrod, has proved to be of much value.¹ The urate of lithia is highly soluble, and the remedy in small doses acts efficiently as a diuretic. It is a remedy which produces no unpleasant consequences, although continued for a considerable period. It may be given in five-grain doses three times daily. An efficient and agreeable mode of administration is to give it largely diluted in carbonated water. The citrate of lithia has the advantage of greater solubility in water than the carbonate.

During the paroxysms of pain opiates may be given moderately if they be well borne. If they occasion unpleasant effects, the succedanea of opium must be relied upon—namely, hyoscyamus, belladonna, and aconite. From its action upon the skin the Dover's powder is an eligible form of opiate. The inconveniences of opium given by the mouth may sometimes be avoided by the hypodermic method of administration.

As regards local treatment, the affected joints may be covered with cotton over which oiled silk should be applied. In addition, relief is sometimes afforded by applications containing opium, belladonna, or aconite, singly or

¹ This remedy was suggested as a remedy for gout, on theoretical grounds, by Buckler in 1853.

combined. Chloroform as a local application has been recommended. Trousseau highly recommended tobacco fumigations, not during the paroxysms, but in the intermissions, with a view to diminish the suffering when the pain returns.

The diet for a few days should be considerably restricted, animal food being excluded. Should the attack continue, however, it is important, as in other diseases, to provide against the evils of innutrition. A nutritious but unstimulating diet should be directed, embracing milk, farinaceous articles, eggs, fowl, and fish.

Treatment in the Intervals between Attacks of Transient Gout.—The ends of treatment between the attacks are—the prevention of the recurrence of the disease, the prolongation of the intervals, and the diminution of the severity of attacks. The immediate rational objects are—prevention of the undue production of uric acid, its elimination by the natural excretories, and the promotion of its solubility in the blood. With reference to the latter objects, it is to be borne in mind that the uric acid probably has been accumulating in the blood for some time before gouty manifestations occur, and that probably the deposit of the urates within and around joints precedes, for a greater or less period, the inflammatory phenomena which belong to an attack or fit of the gout.

Removal of the known causes of gout is an essential part of the treatment. Wine and malt liquors, especially the stronger kinds, are to be interdicted. If the use of alcoholics be desirable or allowable, spirits should be substituted. Gin is to be preferred on account of its diuretic tendency. The diet should be plain, wholesome, and restricted to an amount required for nutrition. A certain amount of bodily exercise is an important part of the hygienic management. Travelling, a long sea-voyage, and a sojourn in a tropical climate are in some cases advisable. All exciting causes are, as far as practicable, to be avoided.

If dyspeptic or other symptoms render it probable that an attack is impending, remedies with a view to prophylaxis are indicated. Alkalies should be given in small doses, largely diluted. They should be continued for a short time, then intermitted, and afterward resumed if the indications continue or return. The salts of potassa are to be preferred to those of soda. The carbonate of lithia may also be given. If the near approach of an attack be strongly suspected, colchicum in small doses may be resorted to. There is reason to believe that this remedy sometimes wards off an impending attack.

[Piperazin has been recently highly recommended in the treatment both of acute and persistent gout and as a solvent of uric acid and urates. It should be administered highly diluted with water, and may be given to the extent of 15 grains per diem. Its continued use does not appear to be attended with unpleasant effects.—H.]

These remarks have reference to the treatment directed especially to gout. Disorders of any kind not of a gouty character of course claim appropriate treatment.

Treatment of Persistent or Chronic Gout.—The removal of causes which produce or promote the gouty diathesis, and of exciting causes, ranks first in importance. This is a *sine quâ non* in the treatment. In addition, in obstinate cases, when circumstances permit, travelling, a sea-voyage, and residence in a tropical climate may be recommended as likely to effect a salutary constitutional change. Hygienic is doubtless vastly more important than medicinal treatment, but remedies are undoubtedly of much utility.

Alkalies, the carbonate of lithia, and other diuretics are indicated precisely as in the intervals between attacks of transient gout when the symptoms

denote an impending attack. It is important to bear in mind the injunction to give alkaline remedies in small doses, largely diluted, and to intermit their use after they have been continued for a short time. This injunction is also applicable to the carbonate of lithia and other diuretic remedies. Exacerbations of the disease, which are liable to occur from time to time, may be treated with colchicum in small doses, its effects upon the alimentary canal and circulation being carefully watched. Other remedies, of the value of which in certain cases there is abundance of testimony, are the iodide of potassium, guaiacum, and the phosphate of ammonia. Perhaps the benzoic acid is to be added. *Fraxinus excelsior* (European ash) is said to have efficacy "administered in an infusion with thirty grains of the leaves in half a pint of water, strained and sweetened, and taken twice or thrice daily."¹

The most important point in the treatment of the gouty diathesis is the regulation of the diet. It has been generally held that the diet of gouty individuals should consist largely of farinaceous food. It has been customary to withhold to a great extent animal food, which is rich in nitrogen. This selection of a diet chiefly vegetable is based upon the assumption that the formation of uric acid, which it is desired to restrict, is increased by highly nitrogenous food. Clinical experience, however, has shown, as has been pointed out especially by Draper,² that saccharine and amylaceous articles of food are in general not so well tolerated by gouty patients as is animal food. Draper, therefore, recommends in gout a diet similar to that suitable for diabetes mellitus—namely, one composed mainly of animal food, fatty substances, and vegetables which do not contain much sugar or starch. The experience, however, of many physicians is in favor of a predominantly vegetable diet.

It is important that food should not be taken in excess; and still, it should never be inadequate to nutrition, either as regards quantity, kind, or variety. The articles of food which are to be especially recommended in the treatment of gout are lean meats, fish, soups, eggs, milk, bread, and green and succulent vegetables, such as tomatoes, cauliflower, cabbage, and the different kinds of salads. If well borne, fatty food may be taken. Saccharine substances, especially pastry, starchy vegetables, particularly potatoes, and acid substances are to be avoided. Ripe fruits may be taken in moderate quantity. Alcohols, particularly the heavy wines and malt liquors, are to be interdicted. Pure water should be taken freely, especially whenever there are gouty premonitions, in order to hold in solution in the blood the uric acid and to promote its elimination. The sparkling table-waters are likely to be taken more freely than simple water, and they are therefore useful. Active exercise in the open air is a means only second in importance to the regulation of the diet. The function of the skin should be kept active also by frequent bathing and friction.

To relieve stiffness and soreness of the joints methodic friction or shampooing is highly useful, provided undue violence be not used. Small blisters from time to time are recommended. Collections of soft gouty matter—or "gouty abscesses," as they have been called—if near the surface may be punctured and the creamy matter gently pressed out. Occasionally ulceration follows, which is troublesome, but leads to no evil results. Deformities, nodosities, and ankylosis due to chalk-stones and structural changes are effects of the disease which do not admit of removal.

Different mineral waters have been much resorted to in the treatment of gout, particularly the Vichy water. Of the utility of the latter and of other springs there is much difference of opinion among those who have given more

¹ *National Dispensatory*, 1879.

² Article "Gout" in *System of Practical Medicine*, by American Authors, vol. ii.

or less attention to an investigation of their effects. The Vichy water is alkaline, its alkalinity being due to the bicarbonate of soda. The imported and the artificial water are used to a considerable extent in this country; but springs which owe whatever therapeutical value they possess to other saline ingredients, such as the sulphate of soda or of magnesia, the chloride of sodium or of calcium, the chalybeate and the sulphur springs, are severally advocated as useful in cases of gout. The Carlsbad springs are much resorted to by gouty patients. It is difficult to eliminate the beneficial influence of hygienic circumstances connected with a residence at watering-places, and thus arrive at a fair judgment of the therapeutic value of the water. For the discussion of this question the reader is referred to other works.¹

The treatment of irregular and misplaced gout involves indications derived from the character and seat of the disorders; in other words, from the symptoms in individual cases. If gout have retroceded local measures to solicit its return are indicated. For this end warm and stimulating applications are to be made to the part or parts in which the regular manifestations have been seated.

Rheumatoid Arthritis—Deforming Arthritis.

This disease has received a variety of names, of which may be mentioned *rheumatic gout*, *nodosity of the joints* (Haygarth), *chronic rheumatic arthritis* (Adams), *nodular rheumatism*, *dry arthritis*, *proliferating arthritis*, *chronic osteo-arthritis*, *arthritis pauperum*, and *malum senile articulorum*. When the affection attacks the hip-joint it has been called *malum coxæ senile*. When the vertebral articulations are affected it is called *spondylitis deformans*. The term rheumatic gout is much used by practitioners to designate this disease, but it is objectionable. It implies that the disease is a combination of rheumatism and gout. Rheumatism and gout very rarely occur conjointly. It is quite certain that the disease under consideration has no relation with gout, and it is probable that it differs in its nature from rheumatism. The names which have been placed at the head of this article seem to be the most appropriate of those which have been suggested. Garrod introduced the name rheumatoid arthritis. Arthritis deformans is the name chiefly used by German writers.

Some writers make no distinction between rheumatoid arthritis and chronic rheumatism. It must be admitted that it is impossible to draw a sharp distinction between these affections. Indeed, we have very little positive knowledge concerning the etiology and pathology of many chronic affections of the joints. It is probable that under the names chronic rheumatism and rheumatoid arthritis are embraced a number of essentially distinct diseases, but we have no insight into the real nature of these diseases. Anatomically, those cases are usually designated as chronic rheumatism in which the extensive osseous formations and deformities which characterize rheumatoid arthritis are wanting, but it will not infrequently happen that a case which has been considered as one of chronic rheumatism takes on the characteristics of rheumatoid arthritis.

The ANATOMICAL CHARACTERS of rheumatoid arthritis are as follows: Early in the case there may be an accumulation within the affected joints of clear or slightly turbid fluid which in the progress of the disease is absorbed. Fluid effusion, however, does not necessarily occur at any period of the disease, and as a rule upon post-mortem examination the cavities of the

¹ For a discussion of mineral waters in general in gout, and the relative value of different European springs, vide Garrod, *The Nature and Treatment of Gout and Rheumatic Gout*, London, 1859.

joints are found so dry that the disease has received the name of dry arthritis (*arthritis sicca*). Important changes occur in all the structures which compose the joints. The articular cartilages are absorbed, especially their central parts, where opposing cartilaginous surfaces come into contact. The ends of the bones, being denuded of cartilage, come into contact, and acquire a hard, smooth, polished appearance in consequence of the friction to which they are subjected. This condition of bone is called *eburnation*. Around the margin of the articulation there is a new growth, in nodular masses, of cartilage and of bone. In this way the articular extremities of the bones become enlarged by the formation of a rough, irregular, bony and cartilaginous ring which surrounds the eburnated surfaces. After the disappearance of the cartilage the process of absorption may invade the articular ends of the bones. Thus, when the hip-joint is affected, not only the head, but a considerable portion of the neck, of the femur may be absorbed. In consequence of the thickened condition of the end of the bone from the marginal osseous growths, the appearance is often as if the eroded head of the femur had been pushed down nearer to the shaft. Irregular bony outgrowths or *nodosities* are formed around the sockets. The sockets are sometimes widened and sometimes deepened and contracted. Dislocations may have occurred and new sockets have been formed. The synovial membranes and the ligaments of the joints are also affected. The little polypoid or villous outgrowths which are normally present to a certain extent upon the inner surface of the synovial membrane often become greatly increased in number and size, so that the inner surface of the thickened membrane may acquire a shaggy appearance, especially where it extends for a short distance over the articular extremities. To these hypertrophied synovial villi the name *dendritic vegetations* of the synovial membrane is sometimes applied. Some of these hypertrophied villi may become changed into cartilaginous or even into osseous nodules, which are often connected by narrow pedicles with the inner surface of the synovial membrane. The pedicles sometimes rupture, so that the bony or cartilaginous nodules are detached and exist as foreign bodies in the articular cavity. The ligaments may also become thickened. Plates of cartilage and of bone may develop in these thickened ligaments. An ossifying periostitis exists to some extent around the ends of the bones. Osseous ankylosis is said never to occur in arthritis deformans, but the joints may be rendered immovable by the thickened condition of the ligaments and by the new bony growths. The interarticular cartilages are generally destroyed, and also the round ligament of the hip and the long tendon of the biceps brachii when the joints in which they are situated are affected. The disused muscles are atrophied. The atrophy is said to be sometimes greater than can be accounted for by the disuse of the limbs, so that some writers consider that a neuropathic element is involved.

The microscopical examination of the cartilage in this disease shows a proliferation of the cartilage-cells and a breaking up of the basement-substance into fibrils. The spaces enclosed by the capsules of the cartilage-cells become greatly enlarged, especially in a vertical direction. These enlarged spaces contain proliferating cartilage-cells. The intercellular substance is thus reduced in amount. According to Cornil and Ranvier, the capsules on the surface rupture into the articular cavities, into which the cartilage-cells are discharged. The intercellular substance between the ruptured capsules projects for a time in the form of little villi from the surface of the cartilage, to which they give a filamentous, velvety appearance. In the progress of the disease the filaments are destroyed and the cartilage-spaces are gradually opened until the whole central part of the cartilage is removed. At the periphery the articular cartilage is covered by synovial membrane. Here the cartilage-spaces filled

of this disease are a persistently rapid pulse, pigmentations of the skin sometimes resembling freckles, at others occurring as a more diffuse melasma, and excessive perspiration.—H.]

Different varieties of arthritis deformans can be distinguished. In one group of cases (the polyarticular) the affection begins primarily in the small joints of the hand and foot, where it either remains or extends subsequently to the larger joints, as the knee, elbow, shoulder, and hip. In other cases the large joints are first affected, and here there is often a tendency in the disease to confine itself to a single joint, especially to the hip-joint or the shoulder-joint (monarticular form). In some cases the vertebral column, and often at the same time the pelvic articulations and the hip, are solely involved (spondylitis deformans). Charcot considers that the affection characterized by nodosities of the small joints, particularly the distal phalangeal joints of the hand, should be separated from other forms of deforming arthritis. He proposes for the last variety the name Heberden's rheumatism or nodosities, from the author who first accurately described them. Whether these are to be regarded as varieties of the same morbid process or as different diseases is uncertain; but at present they are most conveniently grouped under the same heading.

The DIAGNOSIS involves discrimination from rheumatism and gout. From chronic rheumatism it is not readily discriminated prior to the occurrence of its deforming effects, especially if the affection have not been preceded by acute rheumatism. These effects constitute the diagnostic criterion. It is distinguished from gout by the larger joints being primarily affected in a certain proportion of cases; by the smaller joints of the hands being affected without a previous affection of the toes; by the absence of the paroxysms or exacerbations which are characteristic of gouty attacks; by the absence of the chalk-like deposit and of an excess of uric acid in the blood; and by its occurrence in a certain proportion of cases in young subjects and especially in women.

Although not involving immediate danger to life, rheumatoid arthritis is a hopeless disease as regards recovery. All that can be hoped for is a certain measure of improvement, non-progression, and indefinite tolerance.

The first object of TREATMENT is the improvement of the general health. Tonic remedies, long continued and varied from time to time, in conjunction with a nutritious diet and other hygienic measures calculated to invigorate the system, are to be employed for this object. Remedies which have a special influence in cases of rheumatism and gout—namely, alkalies, colchicum, and salicin or the salicylic acid—are unavailing in this affection. All depressing remedies are contraindicated. Iodine in the form of either the iodide of iron or the iodide of potassium, guaiacum, and arsenic appear to be useful in certain cases. Cod-liver oil may be given in conjunction with tonics if there be a tendency to waste. Chalybeates are especially indicated if the patient be anæmic. Warm baths are recommended by many writers. The alkaline mineral waters and those which act powerfully upon the bowels or kidneys are hurtful. On the other hand, chalybeate and tonic waters may prove beneficial.

Local measures of treatment are important. Leeching or cupping and severe counter-irritation are not indicated. Small blisters and the application of iodine may be useful if there be effusion within the joints. Rest is indicated while effusion exists or when the symptoms denote inflammation; and afterward passive motion, friction, warm douches, shampooing, and the constant current constitute the most important part of the treatment.

[Rhachitis—Rickets—Morbus Anglicus.]

Rickets is a disease of infancy characterized by imperfect and irregular ossification, and more particularly by excessive and perverted development of the epiphyseal cartilages. It is too much the custom to consider rickets as nothing more than a disease of the osseous system, whereas, as insisted upon by Cheadle,¹ it affects not only bones, but muscles and ligaments, mucous membrane, the skin, blood, and nervous system. The muscles are enfeebled, sometimes to such an extent as to simulate paralysis. The ligaments are relaxed so as to permit of deformities of spinal and other joints. The involvement of the mucous membranes is often indicated by persistent diarrhœa and other signs of gastro-intestinal disturbance; that of the skin by excessive sweating; that of the blood by more or less anæmia; and that of the nervous system by laryngismus stridulus, convulsions, and other manifestations of exaggerated reflex excitability. It appears evident, therefore, that the cause of rickets is general or constitutional, and that the theories which account solely for its most conspicuous manifestations—those of the osseous system—are altogether too narrow.

All authorities are agreed that faulty nutrition is at the root of rickets, but there are different opinions concerning the nature and mode of action of the nutritive defect. For example, some contend that rickets may be produced at will by withholding certain elements from the diet, while others insist that a constitutional predisposition is necessary to the development of the disease. The latter opinion seems to me to be correct. Special defects in the food, to be presently alluded to, are undoubtedly the exciting cause of rickets, but they only become operative in certain constitutions and under certain hygienic conditions.

The view held and ably maintained by Parrot that rickets is only a form of congenital syphilis has been generally abandoned. In the first place, in the majority of cases of rickets there is neither a history of syphilis nor any of its signs or symptoms in child or parent. Again, a large proportion of syphilitic children never show the characteristic signs of rickets. The signs of congenital syphilis are patent at birth or a few weeks thereafter, while those of rickets do not appear, as a rule, until the period of dentition. Notwithstanding these essential differences between syphilis and rickets, there can, I think, be little doubt that the general debility consequent upon congenital syphilis may indirectly favor the development of rickets. Although the two diseases are fundamentally distinct, there is no antagonism between them.

Rickets is not directly transmitted from parent to child. Individuals free from rickets may have rickety children, and, conversely, rickety parents may have healthy children. When both parent and child are rickety, it is because they have been exposed to the same hygienic influences. These generally-admitted facts with reference to heredity furnish additional proof of the distinction between rickets and syphilis. Bad hygienic surroundings, such as want of light, the absence of pure air, deficient clothing, dampness, and insufficient food, have been regarded as the sole causes of rickets. They are undoubtedly powerful predisposing factors, but rickets may develop in children whose hygienic environment leaves nothing to be desired. The weight of evidence is in favor of the view that the principal, if not the sole, cause of rickets is some special defect in the food. As a rule, the disease is limited to "hand-fed" children. Exceptionally, it may occur in children who are at the breast, but under such circumstances the milk will be invariably found to be of poor quality, either because the mother is enfeebled by

¹ *Brit. Med. Journ.*, Nov. 24, 1888.

previous disease or other cause or because the lactation is too prolonged. Cheadle states that he has seen but one instance of rickets in a child suckled by a healthy mother, and on investigation it was found that the woman had continued to nurse her child while pregnant. Admitting the fact of the almost exclusive limitation of rickets to hand-fed children, the question arises as to the nature of the dietetic defect. At one time it was believed to consist in the administration of farinaceous substances. The lactic acid generated in excess by the fermentation of starch was supposed to unite with the lime of the bones and remove it from the system in the form of a soluble salt. This would account for the well-known fragility of the bones of rickety children. There are, however, formative lesions in rickets at the points of junction of epiphysis and diaphysis, and these were supposed to be due to an irritation of the cartilaginous tissue by the lactic acid. This theory seems very plausible, especially as digestive disturbances are exceedingly common in rickets and lactic acid has been found in the urine of rickety children. It is, however, inadequate, because rickets may be cured in children who are kept upon a farinaceous diet, provided other substances, such as milk and cream, are also freely administered. It is evident, therefore, that the effect of a farinaceous diet in producing rickets is negative rather than positive; in other words, a child upon such a diet acquires rickets not because it is given certain articles of food, but because it has been deprived of others.

Rickets has been attributed to want of lime in the food, and the disease is said to have been produced in animals by depriving them of this substance. The bones may certainly be rendered brittle in this manner, but rickets which is chiefly distinguished by *formative* cartilaginous lesions does not arise. Rhachitis is by no means unknown in limestone districts, and Cheadle states that in his native town, where the water is highly charged with lime and goitre is common, the disease is especially rife among the children.

Certain facts with reference to particular animals—bears, lions, and monkeys—in the Zoological Gardens of London tend strongly to support the view that a deficiency of animal fats and earthy salts is the chief dietetic cause of rickets. Up to within a few years it has been found next to impossible to rear young lions in the London Gardens, these animals almost invariably dying with all the symptoms of rickets. More than twenty litters perished from this disease. But one litter was raised during the period referred to, and in this solitary instance the cubs were suckled by the dam. As a rule, the lioness in captivity cannot be trusted to suckle her young, and they have to be fed "by hand." Their food until quite recently consisted of the flesh of old horses, which is almost destitute of fat, and the bones of these animals are said to be proof against the teeth of adult lions. As a consequence the cubs were inadequately supplied with fat and earthy phosphates. A short time ago, at the suggestion of Mr. Bland Sutton, the diet was changed, the meat being continued while the bones were crushed and mingled with cod-liver-oil. In addition, the animals were supplied with milk. The consequence was that a litter of young lions in whom the signs of rickets were well marked recovered entirely from the disease and became in every respect strong and healthy. The raising of this litter is said to be a "unique event in the history of the society," and is undoubtedly to be attributed to the improved diet.

If further proof is needed that a deficiency of fat is an important element in the etiology of rickets, it may be found in the fact that this disease is often preceded by intestinal disturbances which are chiefly manifested by diarrhoea. While this affection lasts the system is inadequately supplied with fat, even though an abundance of the latter be ingested, for it is

hurried through the intestine before it can be prepared for absorption by being emulsified.

SYMPTOMS AND ANATOMICAL CHARACTERS.—A child that has learned to walk ceases to do so or complains of being tired on slight exertion. The teeth fail to appear at the proper time, or, if dentition has begun, the process is interrupted. Coincident with these symptoms there are often well-marked digestive disturbances, manifested by a coated tongue, a distended abdomen, frequent eructations, vomiting, and obstinate diarrhœa. The general nutrition suffers and the subcutaneous fat disappears. The first striking alterations are observed in the skull, which assumes a characteristic square shape known as the *caput quadratum*. The fontanelles remain patulous at a time when they are usually closed (middle of the second year and later), and are much larger than normal; the sutures also remain open, and the edges of the bones which form their boundaries are thickened. The term *craniotabes* is applied to a condition of the bones of the skull sometimes observed in rhachitis. It is most marked in the occipital bone, which becomes thin and yielding in spots and crackles on pressure like parchment.

The jaws undergo changes of shape on account of their yielding too readily to muscular traction. The inferior maxilla is flattened anteriorly, so that the incisor teeth form a straight line instead of a curve, and in consequence the body of the bone acquires a rectangular outline. The upper jaw is narrowed laterally at the point corresponding to the zygomatic process.

The thoracic alterations are highly characteristic. At the junction of the ribs and costal cartilages a series of small nodular tumors (ecchondromata) develop, which in thin infants are plainly visible, and in those with a thicker layer of fat may be distinctly palpable. They form a chain extending in a curved manner from above downward and outward, and constitute what is commonly known as the rickety rosary. In addition, the sides of the thorax are depressed, so that the sternum projects forward like that of a chicken or like the keel of a boat; hence the terms *pectus gallinaceum* and *pectus carinatum* applied to this deformity. The lower ribs are bulged outward, partly by way of compensation for the depression of the lateral portions of the chest and partly because of the pressure exerted upon them by the distended abdomen. On transverse section a rhachitic chest is generally pear-shaped, instead of circular as in health. The vertebral column may be deformed in every possible manner. Kyphosis, lordosis, and scoliosis may coexist in the same case. The pelvis undergoes changes which, in females, may be the cause of serious dystocia in after-life. Under the weight of the body the yielding bones which bound this cavity give way and permit the sacrum to approach abnormally near the symphysis.

In the extremities the epiphyses are seen to be abnormally prominent, especially those at the inferior extremities of the ulna and radius, tibia and fibula. In the lower extremities curvatures in all directions, but usually with the convexity outward, develop. These are most marked in the bones of the leg, but the femur may also be decidedly distorted. Characteristic deformities in infants are produced by strain and pressure on the yielding bones during the act of crawling. It is in this way that the curvatures of the arms are produced, as well as an angular bend above the ankles, to which attention has been called by Fagge, who suggests that it is due to pressure transmitted to the tibiæ from the insteps and feet.

The clavicles and scapulæ are bones in which marked changes are frequently observed, and the former may be fractured by suddenly lifting a rhachitic child.

Pain in the bones, either spontaneous or evoked by handling the little

patient, profuse sweating of the head at night, so that the pillow is drenched in the morning, and a tendency to cast off the bed-clothing, are three symptoms of the disease which, taken together, are regarded by Jenner as highly diagnostic.

Rhachitis pursues a chronic course. An acute variety has been described, but the bony changes which it presents are in the diaphyses instead of the epiphyses of the bone, the joints are implicated, and there is bleeding from the gums. Cases of this sort are probably of a scorbutic nature. Rhachitis may be complicated with *tabes mesenterica*, pulmonary tuberculosis, and laryngismus stridulus. The latter, indeed, is so often seen in rickety children, and so seldom in others, that it is rather a symptom than a complication.

Without entering into minute histological details, it will suffice to state here that the developmental processes in rhachitic bones, and especially in the epiphyseal cartilages, are extensively disorganized. Normally, the epiphyseal cartilage is separated from the shaft of the corresponding bone by two well-defined layers: first, an outer one, one to two millimetres thick, next the epiphyseal cartilage, of a dull-bluish color, and known as the proliferative zone; secondly, an inner, thinner layer, of a yellow hue, called the zone of calcification. In rickets there is excessive formation of cartilage-cells in the proliferative zone, together with diminution of its hyaline matrix and its partial conversion into fibrous tissue. The zone of calcification is abnormally vascular and contains an unusual quantity of marrow. Both zones encroach upon each other by irregular projections of their hyperplastic tissues, so that the boundary between them is very ill defined.

Rhachitic bones are diminished in weight, and the proportion of their organic to their mineral constituents is decidedly increased. They have been shown experimentally to fracture with abnormal readiness.

DIAGNOSIS.—The physiognomy of well-pronounced rickets is unmistakable. The square head and distorted limbs are highly diagnostic, and on closer investigation the epiphyses, especially those of the lower extremities of the ulna and radius, are found protuberant. The chest should be carefully examined for the prominences at the junction of rib and cartilage, as well as for the more conspicuous projection of the sternum, forming the so-called pigeon-breast. It must be borne in mind, however, that the latter is frequently seen in individuals entirely free from rickets, being due in such cases to obstruction to respiration in infancy from enlarged tonsils, bronchitis, or other cause. The more latent forms of the disease may be recognized, or at least suspicions of their existence should be excited, by retarded dentition, profuse sweating of the scalp at night, obstinate diarrhœa, and pain excited by suddenly lifting the child.

PROGNOSIS.—The prognosis of rickets in itself is favorable. Even decided deformities, such as bowing of the legs and enlargement of the epiphyses, may disappear in time. When, however, the disease is not recognized at an early stage, and the child in consequence placed upon proper treatment, it may lead to dwarfing of the body and irretrievable deformities of head, thorax, vertebral column, extremities, and pelvis. The latter, in the case of females, may be, as previously stated, of the gravest import as concerns the act of parturition.

TREATMENT.—In the treatment of rickets diet is of paramount importance. The disease can be prevented with absolute certainty by giving children food which contains an abundance of animal fat, proteids, and salts. The total

quantity of animal fat should amount to at least one-fourth of all the total solids, the proteids to about one-third, the carbohydrates to a little more than one-third, and the salts to about one-tenth.¹ The fat is best administered in the form of cream or rich milk, but if these cannot be obtained the best substitute is cod-liver oil; "but raw meat is better than iron, cream or fresh milk than cod-liver oil." The hygienic environment should be carefully selected, the patient occupying a room in which the sunshine enters freely and spending the greater portion of the day in the open air. A residence at the seashore and warm sea-water baths are highly beneficial. The latter may be administered at home by dissolving sea-salt in the bath-water.

Among drugs, phosphorus is pre-eminent. There is a general consensus of opinion in favor of the view that its administration in rickets exerts a favorable action upon the nutrition of the bones. It may be given in doses of $\frac{1}{150}$ to $\frac{1}{100}$ grain twice or thrice daily.

The following formulas may be employed with advantage:

Thompson's Solution.

R. Phosphori,	gr. j ;
Alcohol. absolut.,	℥ cccl ;
Spt. menth. pip.,	℥ x ;
Glycerinæ,	ʒij.—M.

Of the above mixture, 6 minims may be given thrice daily to a child from two to four years old, increasing the dose by 1 drop every week until 10 drops are given.

Or the following formula of Dembitz may be used:

R. Phosphori,	gr. $\frac{1}{2}$;
Carb. bisulph.,	gtt. vj ;
Aquæ destillat.,	ʒiv.—M.
S. A teaspoonful daily, or half as much twice daily, after eating.	

The phosphorated oil of the U. S. P. is an excellent vehicle for phosphorus, and may be given with cod-liver oil:

R. Olei phosphorati,	℥ xl ;
Olei morrhuæ,	ad. ʒvj.—M.
One teaspoonful for a child one year old, to be given after food.	

Intercurrent maladies such as bronchitis and diarrhœa should receive appropriate treatment. Unless the latter is checked neither medication nor diet will be of any avail.—H.]

¹ Vide Cheadle, *loc. cit.*

CHAPTER XII.

SCORBUTUS.—PURPURA.—HÆMOPHILIA.

Scorbutus, or Scurvy: Anatomical Characters; Clinical History; Pathological Character; Causation; Diagnosis; Prognosis; Prevention; Treatment.—Purpura Simplex, Purpura Rheumatica, and Purpura Hæmorrhagica.—Hæmophilia.

THIS concluding chapter will be devoted to three affections which, as regards symptomatic events, are closely allied to each other—namely, *scorbutus*, or *scurvy*, *purpura*, and *hæmophilia*. The first of these affections is of interest and importance especially in view of the fact that our knowledge of its pathology and causation, although by no means complete, is sufficient to serve as a basis of effective treatment, and has rendered the disease preventable.

Scorbutus, or Scurvy.

This disease appears to have been known to the ancients, but it began to prevail frequently and extensively when, with improvements in navigation, long voyages were undertaken, and hence it was called *sea-scurvy*. During the last five or six centuries it has been pre-eminently the disease destructive to life in armies, navies, and exploring or emigrating expeditions by land and by water. Notwithstanding that it has been rendered preventable by our knowledge of its pathology and causation, it has prevailed largely and proved greatly destructive to life within the present century. Hammond states that at Council Bluffs in 1820 nearly the entire garrison was attacked, and many died; and the efficiency of the United States forces in the Florida and the Mexican Wars was very materially lessened by its occurrence.¹ It prevailed enormously in the English and French armies in the Crimean campaign. It contributed not inconsiderably to the mortality of our armies in the late Civil War. The inconsistency between these facts and the existing state of knowledge is in part to be explained by the inability always to secure the means of prevention in military operations; but it is in a greater measure to be accounted for by a censurable ignorance or neglect of these means.

There has been of late years great success in preventing scurvy in the naval services of the chief nations of the world. According to Wales,² in 1881, out of 82,629 cases of disease in the chief naval services of the world, there were only 34 cases of scurvy. The statistics of the mercantile marine are less favorable.

ANATOMICAL CHARACTERS.—It is probable that the primary and essential morbid changes relate to the blood. Our present knowledge, however, does not enable us to state in what consist the changes peculiar to the disease. Observers differ as regards the appearances as well as the results of chemical and microscopical examinations. The color has been found sometimes darker and sometimes lighter than that of normal blood. The blood in the heart-cavities and vessels has been in some instances fluid and in other instances

¹ "Report on Scurvy," *United States Sanitary Commission*, by William A. Hammond, M. D., 1862.

² Article "Scurvy," in *A System of Practical Medicine*, by American Authors, vol. ii. p. 168.

coagulated. The blood-corpuscles have been considered by some observers diminished in number, and by others unaffected in this regard. [In eight cases in which the blood-corpuscles were counted by the writer,¹ the highest number per cubic millimetre was 5,320,000; the lowest 1,980,000. These wide differences are due to the varying severity of the disease. Examinations of the blood, so far as the enumeration of its corpuscles is concerned, possess no absolute significance, but are of great practical interest in individual cases.—H.] No uniform changes in the form or constituents have been determined. It is not established that a deficiency of potassa is a constant feature. Contradictory results have been obtained respecting the white corpuscles, the quantity of fibrin, and the proportion of albumen. In short, quoting Immerman, "If we take a general survey of the total analyses made of the blood of scurvy patients up to this time, we can hardly avoid a feeling of dissatisfaction. From the various and contradictory statements by different authors, we obtain but *one*, and that a decidedly *negative* result—namely, that the condition of the blood of scurvy patients, so far as we understand it at the present time, shows no peculiarities which might not occur as well in other pathological processes."

Extravasations of blood are found within and beneath the skin, where they are apparent before death, and between the fibres of muscles. The gums are swollen, ulcerated, and sometimes sloughing. A bloody serum is often found in the joints, associated sometimes with intra-articular ulcerations. A sero-sanguinolent liquid, often in considerable or large quantity, together with inflammatory products in a certain proportion of cases, is contained in the pericardial and pleural cavities. The spleen is often enlarged and softened. Parenchymatous and fatty degenerations of the heart, muscles, liver, and kidneys have been found. The kidneys may be infiltrated with blood and inflamed. Ecchymoses are observed in many internal situations—namely, on the serous membranes, the bronchial mucous membrane, within the whole tract of the alimentary canal, and in the urinary passages. The extravasations are evidently secondary to, and dependent upon, the morbid blood-changes. The mode, however, in which the latter give rise to the former is not clearly understood. Either the blood is so altered that it escapes from the vessels, or the nutrition of the walls of the vessels is impaired, so that they do not offer adequate resistance to the pressure of the blood, or, again, paralysis affecting the vaso-motor nerves may be a pathological element. It is not impossible that each of these conditions enters into the mechanism.

CLINICAL HISTORY.—The symptomatic events which are characteristic of the disease are preceded by general weakness and lassitude. Patients are listless, apathetic, and indisposed to either mental or physical exertion. The appetite fails and pallor of the surface is marked. These symptoms progressively increase. The more characteristic events are swelling and sponginess of the gums, which bleed either spontaneously or on slight pressure, hemorrhage from the mucous surfaces in other situations, and extravasation of blood within and beneath the skin. The fungous appearance of the gums is chiefly marked around the teeth. It is less marked in situations where the teeth are wanting. The teeth may become loose, and they sometimes either fall out or can be easily removed. The prolabia are notably pale, presenting a striking contrast to the redness of the gums. Hemorrhages are frequent from the different outlets—namely, the nostrils, mouth, vagina, and intestinal canal. It is rare from the bronchial tubes. The ecchymoses apparent on the cutaneous surface are either in the form of petechiæ or of patches of variable size; and generally these forms are conjoined. They are either limited

¹ *Philadelphia Hospital Reports*, vol. i., 1890.

to or most abundant on the trunk and lower extremities. The ecchymoses undergo the same successive alterations in color as when due to contusions. A slight bruise suffices to produce them in any part of the surface of the body. They occur sometimes beneath the conjunctiva and within the globe of the eyes; into the joints, between the muscles, in the serous cavities, occasionally between the meninges of the brain, and beneath the periosteum. Fetor of the breath is usually a marked symptom.

The skin is dry and rough, compared by Larrey to that of a plucked fowl. The ankles are often œdematous, and some œdema of the face is not infrequent. The patient complains of pain in the loins and in the extremities, especially the lower limbs. The muscles of the lower limbs are swollen and hard. Palpitation and dyspnoea are excited by slight exertion. Hæmic murmurs are heard over the heart. Pain referred to the chest is not uncommon. The bowels are in some cases constipated, in other cases loose, or looseness may succeed constipation in the progress of the disease in the same case. The urine is diminished in quantity. The excretion of urea and of chlorides is diminished. The excretion of potash, either absolutely or relatively to that of soda, is increased. The phosphates are also increased in quantity. The specific gravity is usually higher than normal, and the color is more intense. The urine often is albuminous. There is absence of pyrexia except as symptomatic of an inflammatory complication. The pulse is sometimes slower than in health, but it becomes rapid on any exertion. It is always soft and compressible. The temperature of the body is somewhat lowered. The spirits are depressed. The patient frequently longs for fresh vegetables and fruit.

These symptoms are more or less marked. In extreme cases or in an advanced stage of the disease the prostration is great. Slight exertion occasions syncope. The patient may fall into a state of collapse. This is likely to follow abundant hemorrhage. Old ulcers and cicatrices sometimes reopen, and bones which had been fractured and united may become separated. Ulcerations occur within the mouth and over the ecchymoses on the skin. Weakness of vision, day-blindness, and night-blindness are not uncommon. Inability to sleep is common, but generally the mental faculties, although weakened, remain intact. In cases which are comparatively mild general debility, mental depression, pain in the back and lower limbs, together with the other symptoms, are more or less marked, but not excessive; and associated with these symptoms are spongy swelling of the gums and ecchymoses beneath the skin.

Scorbutus may exist as the sole affection, but it is frequently combined with other diseases. It may be combined with dysentery, and the latter affection is then called *scorbutic dysentery*. It may coexist with typhus and with typhoid fever. It may be accidentally associated with a variety of diseases which are liable to mask the scorbutic affection. The recognition of its coexistence with other diseases is of great importance with reference to appropriate treatment.

Secondary affections or true complications which are likely to occur are lobar pneumonia, pulmonary hemorrhagic infarctions, pulmonary gangrene, pericarditis and pleuritis with bloody effusion, and acute diffuse nephritis.

PATHOLOGICAL CHARACTER.—The essential characteristic blood-change in this affection is not as yet determined. There is doubtless a deficiency as regards certain of the constituents of the blood, but the particular deficiency which belongs specially to the affection is a matter of question. Garrod considers that the special deficiency relates to the salts of potassa. That this deficiency enters into the pathological condition is probable, but that it con-

disease caused by a specific micro-organism received any substantial support from the sc-

CAUSATION.—Scurvy is a dietetic disease, and of the causation to say that the disease is caused by a deficiency of elementary supplies. A less comprehensively correct view is to say that the disease is caused by an insufficient supply of vitamin C obtained in vegetable food. For a long time it was thought to be caused by free use of salted meat. It is, however, now known to be produced by this diet, except in so far as it is due to a deficiency of the principles necessary for the normal development of the morbid process has repeatedly been developed when the diet is changed to fresh meat. Garrod's theory of the disease involves the conclusion that it is caused by a deficiency of the quantity of the salts of potassa. Admitting a deficient supply of vitamin C as the cause of the disease, admitting in the causation, other causes, such as the deficiency of which causes the disease, and the deficiency of food distinguished as antiscorbutics, which prevent the development of the disease.

Although causes relating to the disease, other causes act preventively, such as exposure to cold and dry weather, and acting moral influences. The disease is often produced during the summer. It is often to be produced by a deficiency of this instance, from an excessive use of the disease. The disease is often caused by a deficiency of the cause of the disease. The disease has been implicated in the excesses of any kind of the blood which falling short of the

The morbid condition of the blood peculiar to scurvy may exist to a greater or less extent when the most striking symptomatic features of the disease are not present—namely, the subcutaneous ecchymoses and hemorrhages from mucous outlets. Under these circumstances the disease may be overlooked. Thus, Hammond, Woodward, and others state that in cases called in army sick-reports cases of *general debility* the disease is not infrequently incipient or not fully-developed scorbutus. The pain in the back and muscles of the lower limbs may lead the practitioner for a time to consider the disease as muscular rheumatism or myalgia. When associated with other diseases, such as dysentery and the essential fevers, it is liable to be overlooked. The appearance of the gums is highly important with reference to the diagnosis in the cases in which petechiæ or vibices are wanting; and when, from the appearance of the gums and other symptoms, the scorbutic condition is suspected, an investigation of the diet may lead to the knowledge of facts which will tend to settle the diagnosis. This investigation is important, not only in army or naval practice and in public institutions, but in private cases in which the symptoms point to scurvy. It is to be added that in children before dentition and in aged persons who have lost their teeth the characteristic appearances of the gums may be wanting. They are also wanting in rare instances irrespective of these circumstances.

PROGNOSIS.—In cases of scurvy in which the ecchymoses are many and large, or in which hemorrhage from the mucous outlets is profuse, the danger to life is great. Life may be destroyed by rapid hemorrhagic effusion into the pleural or pericardial cavities. Meningeal hemorrhage is sometimes the immediate cause of death. Sudden death sometimes occurs from syncope induced by muscular exertion. If the causes which have produced the disease continue in operation, it proves fatal in a large proportion of cases. Before the pathology and causation were as well understood as now the mortality from this disease among soldiers and seamen was often very large. Associated with other diseases, it contributes indirectly to their fatal termination, and it stands in the way of recovery from wounds and surgical operations which otherwise would not prove serious.

Promptly recognized and judiciously treated, the disease may be expected to end in recovery in a large proportion of cases. It has no definite duration. It continues for a longer or shorter period, according to the extent to which it has advanced, the amount and situations of hemorrhagic extravasation, the previous condition of the patient, etc. The recovery is usually gradual, not infrequently tedious, and the system is likely to remain debilitated for a long time.

PREVENTION.—The disease may be prevented by a diet embracing the requisite variety of alimentary principles, and this is secured by a proper variety of animal and vegetable food. With the knowledge of this fact, and with due attention to its practical application, scurvy should never occur except under circumstances which render the means of its prevention unavailable. Its occurrence is always an occasion for reproach when articles of food containing adequate supplies for the healthful constitution of the blood can be obtained. It is chiefly in military campaigns and long sea-voyages that there are difficulties in the way of prevention. These difficulties, however, may generally be met by providing antiscorbutic articles of diet; and with reference to these difficulties the knowledge of the various articles which may furnish the needed alimentary principles is of vast importance. The prevention of this disease has been made practicable under all circumstances by the preservation of meats, vegetables, and fruits in hermetically-sealed cans.

Lemon-juice or lime-juice has long been known as antiscorbutic. Experience has abundantly shown that one of the fresh juice will prove an effectual preventive on long voyages without fresh provisions. For convenience the juice can be reduced in bulk by evaporation and is an effectual antiscorbutic. Pure citric acid, although not a substitute for the fresh juice of the fruit. One antiscorbutic vegetable is the potato. It is most useful. Pickles, onions, raw cabbage or sauerkraut, the *Cruciferae*, are to be reckoned among the valuable antiscorbutics. Green corn, green apples, and most of the esculent vegetables are more so unripe than ripe. Spruce and juniper are antiscorbutics. Many vegetables which do not enter the diet may often be used as antiscorbutics in medicinal articles which have been named are not to be obtained. The vegetables now referred to which experience has shown to be effectual in the prevention of scurvy are the sorrel (*Rumex acetosella*), the bulb of the wild artichoke, (*Helianthus tuberosus*), as the *Agave Americana* or *maguey*, indigenous to Mexico, the prickly pear (*Cactus opuntia*), and the *taraxacum*.

Wales suggests that "in the event of the occasional exhaustion of the fresh-vegetable stores, various quantities of such as mustard, radishes, turnips, and cresses, could be used on board if seeds are provided."¹

That the antiscorbutic virtue of certain vegetables depends to a greater or less extent, on the presence of the salts, is probable. These salts, isolated, are useful in the treatment, but experience has shown that they cannot be used as antiscorbutic articles of diet.

Finally, in addition to dietetic means, attention to the general health, avoidance of unnecessary exposure and physical exertion, of a nature to produce cheerfulness, constitute the prophylaxis.

TREATMENT.—The dietetic means of prevention are the basis of the treatment. The juice of lemons, oranges, or limes, taken freely, but of course not to such an extent as to irritate the stomach. The antiscorbutic vegetables and fruits should be taken as abundantly as the digestive powers permit, with a diet of starchy and farinaceous food. Remedies to improve the process of digestion are indicated—namely, quinia, salicylic acid, the mineral acids, and chalybeate preparations are useful. The bitartrate or the citrate of iron, with cider in small quantities, if an agreeable beverage, is useful. In short, the chief objects of treatment are the elementary principles needed for the healthy invigoration of the system.

Particular symptoms or disorders claim attention in addition to those having reference to the objects of the treatment. Those relieved by mild laxatives or simple enemata are to be controlled by anodyne and astringent. Itching of the skin indicates sponging with tepid water. Swelling of the joints and limbs may be alleviated by friction.

¹ *Lancet*.

liniments. Stiffness of the joints, which sometimes occurs, is to be prevented or removed by passive movements. The condition of the mouth calls for astringent collutories. Ulcerations in the mouth or on the skin are to be treated locally on general principles. Hemorrhage from the different outlets is to be restrained by hæmostatic remedies.

It is hardly necessary to add that the scorbutic condition, when associated with dysentery, typhus or typhoid fever, or with any disease, claims the same dietetic and other measures of treatment as does scorbutus existing alone.

Purpura Simplex, Purpura Rheumatica, and Purpura Hæmorrhagica (Morbus Maculosus Werlhofii).

The term *purpura* is applied to circumscribed extravasations of blood into the skin. Purpuric spots are bright-red, livid, or dark purplish-red in color, do not disappear on pressure, and are unattended by itching or other signs of local irritation. Small extravasations of blood, from the size of a pin-point to that of a finger-nail, are called petechiæ. Larger extravasations are called ecchymoses. If the hemorrhages take the form of lines or broad stripes, they are called vibices. The purpuric spots generally are not elevated, but they sometimes appear as small papules around the hair-follicles (*purpura papulosa*, lichen lividus), or as wheal-like nodules (*purpura urticans*), or rarely there are formed bullæ containing blood (*purpura bullosa*). The extravasated blood undergoes the usual changes of color, becoming brown, green, and yellow.

Purpura may be due to a great variety of causes. It is customary to distinguish between *secondary* or *symptomatic* purpura and *primary* or *idiopathic* purpura; but it is probable that in many cases so-called idiopathic purpura is really symptomatic of some underlying morbid condition.

The following may be mentioned as the leading causes of secondary purpura: injury, including the bites of insects; passive congestion; various drugs, such as iodide of potassium, phosphorus, copaiba balsam, ergot, chloral hydrate, and mercury; snake-bites; embolism or thrombosis of cutaneous vessels; cachexiæ, as tuberculosis, cancer, Bright's disease, and cirrhosis of the liver; profound anæmia, as pernicious anæmia and leucocythæmia; diseases of the nervous system; infectious diseases, as smallpox, typhus fever, and typhoid fever; acute ulcerative endocarditis, measles, scarlet fever, acute articular rheumatism, malaria, cholera, yellow fever, cerebro-spinal meningitis, and icterus gravis; and, finally, scorbutus. Purpura may be accidentally present in the course of any disease.

Purpura is distinguished as primary or idiopathic when it is not dependent upon any other disease. As has already been mentioned, there is some doubt whether even in these cases the purpura be not symptomatic, but with our present knowledge it is convenient to treat of purpura as sometimes an idiopathic disease.

Idiopathic or primary purpura is usually subdivided into three varieties—namely, purpura simplex, purpura rheumatica, and purpura hæmorrhagica, or morbus maculosus Werlhofii. No sharp lines of distinction can be drawn between these varieties. They merge into each other by every grade of transition, so that it is often difficult to classify cases according to these subdivisions.

Purpura simplex is the mildest form of idiopathic purpura. Hemorrhage occurs only in the skin, and not from mucous membranes. Purpura simplex occurs both in the robust and in the debilitated. The purpura may be preceded or accompanied by languor, loss of appetite, aching of the limbs, and

slight fever, or there may be no constitutional disturbance whatever. Purpuric spots occupy chiefly the lower extremities, or they may extend to the trunk and upper extremities, and in rare instances to the face. Only a single crop of purpuric patches may develop, in which case recovery takes place in between ten and fourteen days, or the disease may be prolonged for several weeks by the appearance of successive crops. Even in mild cases of purpura, hemorrhages from mucous surfaces; particularly hæmaturia, may occur, thus showing the close relationship which exists between the different varieties of the disease. Purpura simplex is not uncommon in elderly persons. It is then called *purpura senilis*.

Purpura rheumatica—or, as it is also called, *peliosis rheumatica*—is characterized by the combination with purpura of rheumatic pains in the joints, and sometimes with actual inflammation of the joints. There are often moderate fever, debility, and gastric disturbances. The joint affection may precede or accompany the purpura, or it may disappear when the purpuric eruption occurs. The duration is generally between ten days and three weeks, but relapses are common, especially when the patient walks too soon. Rheumatic purpura is most common in males between twenty and thirty years of age. The affection of the joints is etiologically distinct from acute articular rheumatism. Joint affections are common in all forms of primary purpura, and in general in diseases characterized by a hemorrhagic diathesis. The propriety, therefore, of distinguishing rheumatic purpura as a separate variety of the disease is questionable. The occurrence of hemorrhages from mucous membranes in some cases which have been classified as rheumatic purpura shows the relationship of this to the following variety of idiopathic purpura.

Purpura hæmorrhagica is not an appropriate name for the variety of purpura now to be described, as every kind of purpura is hemorrhagic. The name *morbus maculosus Werlhofii*, or Werlhof's disease, is the one adopted by German and many English writers. This variety of purpura is characterized especially by the occurrence of hemorrhages, often profuse, from mucous surfaces. The hemorrhages in the skin usually are larger and greater in number than in purpura simplex. Constitutional symptoms are more marked and the prognosis is graver. The disease is somewhat more frequent in females than in males. It develops oftenest between fifteen and thirty years of age. It may occur in previously healthy individuals, but it is more common in those whose constitution is enfeebled by disease or bad hygienic surroundings. Pregnancy and the puerperal state have been thought to aid in the causation.

The first manifestation of *morbus maculosus Werlhofii* may be the appearance of purpuric spots in the skin, or, less frequently, hemorrhage from some mucous surface. Often, however, there are vague premonitory symptoms, such as malaise, anorexia, vomiting, pains in the muscles, and even slight fever. Pain and swelling of the joints may occur as an early symptom. Hemorrhages occur from the nose, mouth, throat, stomach, intestine, and urinary organs. Bronchial and pulmonary hemorrhages are rare. In severe cases hemorrhages take place into serous cavities, and even into the substance of internal organs. Petechiæ and ecchymoses can be detected in the visible mucous membranes. As in all forms of purpura, hemorrhages are liable to occur in parts of the skin subjected to pressure or injury. In distinction from scurvy, the gums are not swollen and inflamed. Constitutional disturbance may be slight or even wanting, but often it is marked. There may be fever, which is usually moderate, but is sometimes high. The patient sometimes sinks into a typhoid state. There may be diarrhœa, colicky pains, and other severe gastric and intestinal symptoms. Endocarditis and acute hemorrhagic nephritis are occasional complications. There sometimes is acute splenic tumor. Perforative peritonitis has been known to occur. Symp-

toms of anæmia, such as vertigo, weakness, functional cardiac disorders, and œdema, develop in proportion to the loss of blood. Hemorrhage may occur into the brain or its meninges. Death may result from loss of blood or from grave constitutional disorder, marked especially by typhoid symptoms or from some complication.

The duration of the disease is usually between two and four weeks, but it may be protracted for many months. The prognosis in general is favorable, but it is necessary to be cautious in expressing a positive opinion on this point, as even in apparently mild cases grave symptoms may develop. As has already been remarked, there are cases representing every grade of transition from the mildest purpura simplex to the most severe purpura hæmorrhagica.

The DIAGNOSIS from scorbutus is based especially upon the absence of swelling of the gums and of ulcerative inflammations elsewhere, by the lack of the cachexia which antedates and accompanies scurvy, by the absence of the dietetic causation of scurvy, and by the comparative inefficacy of the dietetic regimen, which, as a rule, promptly relieves the symptoms of scurvy. According full force to these points of difference, it must be admitted that they do not establish conclusively the non-identity of purpura hæmorrhagica and scorbutus, nor do they always suffice to enable the practitioner to make with positiveness the differential diagnosis.

Nothing is known as to the essential cause of purpura hæmorrhagica. Changes have been surmised to exist in the walls of the blood-vessels, in the composition of the blood, and in the nervous system, but none have been demonstrated which can fairly be considered causative. Infection has also been suggested as a cause.

The objects of TREATMENT in cases of purpura hæmorrhagica are—the restoration of the normal constitution of the blood, increase of the vital powers, and arrest or restraint of hemorrhage. With reference to these objects the diet should be nutritious and varied, and digestion is to be aided by tonic remedies, together with wine or spirits in small quantity if the immediate effect be good. In view of the difficulty in always discriminating purpura from scorbutus, and of there being ground for supposing that the same morbid condition of the blood exists in both affections, the treatment should embrace the dietetic and other measures which experience has shown to be useful in cases of scorbutus. Of tonic remedies, the dilute sulphuric acid is especially recommended. This remedy has the advantage of being agreeable to the taste if added to a proper quantity of water and syrup. It may be given in doses of from five to fifteen drops every two hours. Quinia is often combined with the sulphuric acid. Hæmostatics are to be given with reference to the hemorrhage. Ergot or ergotin has been highly recommended. The gallic acid, the muriated tincture of iron, and the acetate of lead are remedies which may be employed. The oil of turpentine has been recommended as a valuable remedy in this affection. It is important that the patient should preserve the recumbent posture in bed, avoiding all unnecessary exertion.

Hæmophilia.

Hæmophilia, or hæmatophilia, is a congenital and usually an hereditary affection, characterized by a tendency to immoderate bleeding, traumatic or spontaneous, and often associated with swelling of the joints. Persons with this diathesis are called “bleeders.” No other disease illustrates in so striking a manner transmission by inheritance. The diathesis has been traced through successive generations of the same family for more than two hundred years. Males are far more liable to the disease than females, the

ratio being as 11 of the former to 1 one of the latter.¹ The diathesis is transmitted, however, far more frequently through the female members of bleeder families than through the male members. The daughters of a bleeder family, even when not themselves bleeders, transmit the diathesis to their sons. A son of a bleeder family, if himself a bleeder, should he live to beget children more frequently transmits the disease to his grandsons, through his daughters, than directly to his own children. The male members of a bleeder family, if not themselves bleeders, rarely transmit the disease to their descendants. It rarely happens that all of the members of a family are bleeders. It is uncertain whether the diathesis ever dies out in a family, although it may pass over one or more generations. It has been noted that the females of bleeder families are very fertile. In 12 such families there were 120 children (Wachsmuth).

Hæmophilia may develop, as it were spontaneously, in individuals coming from a healthy family stock. Such persons may become the starting-points of new bleeder families. Even in these spontaneous cases the diathesis seems to be congenital. Probably in a considerable number of the apparently spontaneous cases a full knowledge of the ancestral history would reveal transmission by heredity.

A larger number of instances of hæmophilia have been reported among the Anglo-Germanic nations than among other races.² The affection has been repeatedly observed in Jews. It seems to be more common in cold, moist climates than in warm climates. Although a large proportion of bleeders have been blondes, with fair, delicate skin and prominent superficial veins, it is not likely that any such constitutional peculiarity is involved in the etiology of hæmophilia.

The essential causes of hæmophilia are wholly unknown. It is reasonable to suppose that abnormal constitution of the vascular walls and deficient coagulability of the blood are involved in the causation, but we have no positive data upon which to base these suppositions. No morbid changes have been found, with any uniformity, after death from hæmophilia. An abnormal thinness of the arterial walls has been noted in several cases. It is possible that there are defects pertaining to the fibrin-factors or to the blood-plates, but these have not been ascertained.

There is usually nothing indicative of either this diathesis or aught abnormal prior to the occurrence of a hemorrhage, which is with difficulty, if at all, controlled. The diathesis is sometimes manifested immediately after birth by profuse and sometimes uncontrollable bleeding from the umbilicus. More frequently, the affection is made apparent at a later date, but during the first few years of life. It is exceptional for the diathesis not to be discovered until after the second dentition. Persons having this diathesis continue to lose blood from an insignificant wound, such as that produced by a puncture, a slight cut, a leech-bite, or the extraction of a tooth, all efforts to arrest the hemorrhage proving ineffectual until syncope occurs, which may prove fatal, and if not fatal the loss of blood induces a notable degree of anæmia. The hemorrhagic diathesis also leads to extravasation of blood, often extensive, within and beneath the integument, resulting from slight contusions. Hemorrhage is also likely to occur from the nose and the gums, and less frequently the stomach, the intestine, and the urinary passages. Hemorrhages into internal organs which are removed from any external mechanical influences are very

¹ Of 780 cases collected by Dunn, 717 were males and 63 females (*American Jour. of Med. Sciences*, Jan., 1883).

² A full account of the American literature on this subject will be found in the article by Dunn above cited, and in the article on "Hæmophilia," by Osler, in *A System of Practical Medicine, by American Authors*, Philadelphia, 1885, vol. iii.

rare, if indeed they occur at all. In females, in whom the diathesis is generally less marked than in males, the menstrual flow usually is profuse and post-partum hemorrhage is abundant.

As in other diseases with a hemorrhagic diathesis, there is a tendency to swelling of the joints, most frequently the knee-joint, particularly after some injury. The swelling seems to be due to hemorrhage into the joint. Neuralgia, especially of the trigeminus, is not infrequent.

All degrees of the hæmophilic diathesis may exist, from the rudimentary form, in which there is simply a tendency to excessive but not dangerous hemorrhage after a wound, to the fully-developed form which has been described. Children affected in a marked degree with this diathesis rarely live to adult age, but in some instances the diathesis diminishes or ceases after childhood; and if it continue in a moderate or slight degree it may not interfere with longevity.

The prophylactic treatment is the most important in the management of hæmophilia. Wounds are of course to be avoided as far as possible. The diathesis constitutes an insuperable objection to all surgical operations which are not unavoidable. Teeth should never be extracted. The operation of circumcision should not be permitted. Vaccination should be performed with great care. Leeches should never be applied to "bleeders." Measures should be employed to invigorate the system, such as a nutritious diet, out-of-door life, frequent bathing, and tonic remedies. The marriage of female members of bleeder families and that of male members who are bleeders should be prohibited. When hemorrhage occurs, either from wounds or spontaneously, local measures to arrest the flow of blood are to be resorted to if practicable, and hæmostatic remedies are to be given internally. [The fluid extract of *Hydrastis canadensis* has been used successfully in hæmophilia by Fürth, the dose being 30 drops daily. Hayem believes the best hæmostatic in this affection to be the transfusion of *entire* blood, of which but a small quantity will sometimes put an end to an otherwise uncontrollable hemorrhage. He believes that it acts by supplying to the blood the elements—the hæmatoblasts or blood-plaques—which are so active in the formation of thrombi.—H.]

[SECTION. EIGHTH.]

THE ZOÖNOSES, OR DISEASES TRANSMITTED FROM ANIMALS TO MAN.

CHAPTER I.

ACTINOMYCOSIS.—ANTHRAX.—GLANDERS.—RABIES.

Actinomycosis: Diagnosis; Prognosis; Treatment.—Anthrax: Diagnosis; Prognosis; Treatment.—Glanders: Symptoms; Diagnosis; Prognosis; Treatment.—Rabies.

Actinomycosis.

ACTINOMYCOSIS is an affection which prevails extensively in cattle and is occasionally observed in horses, swine, and dogs. Its constant association with a parasite belonging to the species *Cladothrix* and commonly known as the ray-fungus was first demonstrated by Bollinger in 1876. In cattle the disease manifests itself, for the most part, as a tumor of the jaw which involves both the bone and the soft parts investing it. The skin covering the tumor is for a time intact, but eventually ulcerates and gives exit to a purulent material in which are suspended numbers of yellowish granules which, when examined under the microscope, are found to be composed of the specific fungus of the disease. Besides the jaw, the neck and tongue of the animal are frequently involved in the morbid process, and the disease may have its primary seat in the stomach, lungs, or integument. The predilection of the affection for the maxillary bones is attested by the term "big-jaw" popularly applied to it. In this situation it bears a close resemblance to osteo-sarcoma.

Infection in man may occur directly by inoculation with the discharges of animals suffering from the disease or by eating their flesh. A not uncommon mode of infection is perforation of the mucous membrane of the mouth or other parts with vegetable substances to which the ray-fungi are adherent. A number of cases are on record in which the disease had its starting-point in an abrasion of the buccal mucous membrane caused by chewing ears of wheat, barley, or rye, and it is undoubtedly in this manner that cattle are, as a rule, infected.

In actinomycosis of the lung the disease has been traced to a bristle of barley imbedded in the parenchyma of the organ, and in abdominal actinomycosis the morbid process has had its origin in a bristle of grain lodged in the vermiform appendix. A relation has been supposed by some observers to exist between dental caries and actinomycosis. Doubtless, infection through the mouth might more readily occur in cases in which the gums are loosened around one or more carious teeth, but, in view of the frequency of decayed teeth and the great rarity of actinomycosis, the relation between them must be regarded as accidental.

Four avenues of infection are generally recognized: (1) The mouth and

throat; (2) the respiratory tract; (3) the utestinal canal; (4) the integument.

Secondary infection may occur through the medium of the blood, the fungus being swept along by the current, either free or in the interior of leucocytes. Secondary infection *via* the lymph-vessels is rare: as a rule, therefore, the lymphatic glands do not participate in the morbid process.

Actinomycosis in man is distinguished from actinomycosis in animals by the much slighter tendency in the former to the formation of a circumscribed tumor and the much greater tendency to extension by fistulous burrowing in all directions. From the throat, for example, the process may extend beneath the skin of the neck externally and downward along the spinal column to the thorax, involving the lungs; it may perforate the diaphragm and invade the abdominal organs; in a word, by continued extension in the manner just mentioned and by secondary embolic deposits all the organs of the body may be ultimately involved in the morbid process.

On the other hand, exceptionally, the disease may, as in animals, remain more or less circumscribed, without presenting the abscess-like characters above described. This is more frequently the case, however, with the secondary embolic deposits.

The seat of the primary manifestations of actinomycosis depends upon the point of infection, the disease in the great majority of cases developing at or in the neighborhood of the latter. Among 421 cases analyzed by Illich, the disease was seated in the head and neck 218 times; in the tongue, 16; in the lungs, 58; in the abdominal region, 89; in the stomach, 11. In 29 cases the point of infection could not be determined.

The COURSE of actinomycosis is, as a rule, chronic. In exceptional cases, in which it seems to be acute, it is probable that the affection has been latent for some time before the advent of symptoms. This statement is particularly applicable to intestinal actinomycosis, in which the first overt manifestation of the disease may be caused by a perforative peritonitis the result of a long-standing invasion of the intestine.

The SYMPTOMS of actinomycosis depend largely upon its seat. In the head and neck it appears as a hard, indistinctly circumscribed, painless swelling of the soft parts, the bones in man being seldom involved. Softening gradually takes place in one or more portions of the growth, and pus is eventually discharged, in the absence of surgical interference, either externally through the integument or into the mouth alongside of a carious tooth.

When seated in the lungs the disease runs a course very similar to that of chronic tuberculosis, being attended with cough and expectoration, often copious, and sometimes fetid or hemorrhagic. There are also pains in the chest and back, irregular fever, and progressive emaciation. Pulmonary actinomycosis may last many years, its course being diversified by marked remissions. The physical signs are those of consolidation and cavity-formation. In one important particular the course of pulmonary actinomycosis differs from tuberculosis—namely, in its tendency to perforate the chest-wall and form a fistulous communication with the exterior.

The intestinal form of actinomycosis may begin as a pseudo-membranous inflammation of the intestinal mucosa, but, as a rule, is not recognizable clinically until it has involved the abdominal walls, the tissues around the anus (*periproctitis actinomycotica*), or the lumbar region. It may also extend to the bladder, and lead to perforation of that viscus, or, as above stated, its first manifestation may be an acute perforative peritonitis. Metastatic deposits

in the liver with consecutive abscess are liable to occur in this variety of the disease.

When seated in the integument actinomycosis may assume the form of a fungous ulceration, or it may consist of nodules which cicatrize in the centre and invade the integument in all directions. The latter variety may be mistaken for lupus on superficial examination.

The DIAGNOSIS is made by microscopic examination, although suspicions of the disease should be excited by the characteristic grayish or yellowish granulations contained in the purulent discharge of the open ulcers or fistulous tracts. When these are examined microscopically, they are found to be composed, for the most part, of the pathognomonic organism of the disease, the so-called ray-fungus. This term is derived from the peculiar arrangement of the fungus, which is in the form of rods or rays with rounded or club-chaped extremities converging to a common centre.

The PROGNOSIS is most favorable when the disease is seated in the head and neck, doubtless because in this situation it is more amenable to surgical treatment. Of 100 cases in this situation, 13 were fatal,¹ whereas of 34 cases of pulmonary actinomycosis analyzed by Hodenpyl, 32 died. The prognosis of intestinal actinomycosis is undoubtedly more favorable than that of the pulmonary form of the disease, although, as remarked by Illich in his valuable monograph, it is a disease of the gravest significance.²

The TREATMENT of actinomycosis is altogether surgical, and consists of incision, curetting, drainage, and injections of solutions of corrosive sublimate, boric acid, tincture of iodine, and other antiseptic substances. When superficially situated the disease is quite amenable to the treatment just outlined. In fact, the process has been cured by simple incision. It is an interesting fact that several cases treated with hypodermic injections of Koch's tuberculin have reacted in the same manner as cases of tuberculosis.—H.]

[Anthrax (Malignant Pustule; Charbon; Splenic Fever; Wool-sorters' Disease).

Anthrax attacks by preference the herbivora, especially cows, sheep, and horses, and is usually transmitted to man by inoculation—i. e. by the secretions of the diseased animal coming in contact with an abraded or wounded surface. It may, however, be conveyed in other ways: by the bites of insects, by inhalation, and by eating the flesh of infected animals.

The SYMPTOMS vary in accordance with the mode of infection. When acquired by inoculation, they are at first exclusively local. At the point of inoculation, in which a burning pain is felt, a papule speedily develops. This soon becomes vesicular at the summit, the contents of the vesicle being either serous or bloody. The neighboring parts become extensively indurated and oedematous and assume a red or purple tint. The vesicle rapidly enlarges and ruptures, leaving behind a dark-brown scab which conceals a gangrenous base. Streaks of redness indicative of lymphangitis may be traced from the primary lesion to the nearest lymphatic glands, which are enlarged and tender.

On the second or third day constitutional symptoms set in. These consist of severe pyrexia, rapid pulse and dry tongue, great prostration, delirium,

¹ Birch-Hirschfeld, *Real-Encyclopädie*, vol. i., 1894.

² "Eine höchst gefährdende Krankheit."

diarrhœa, cyanosis, dyspnœa, and collapse. Enlargement of spleen and liver is distinctly manifest. In fatal cases death may occur in from five to eight days after the first signs of inflammation.

In favorable cases both the local and general symptoms are milder; the gangrenous patch sloughs out, and the ulcer gradually heals.

Instead of proceeding to the formation of a distinct papule and vesicle, the local lesion may be limited to an œdematous infiltration of the affected part. This *anthrax œdema*, to which attention was called by Bollinger, is most apt to be seated in the eyelid, but may occur in other parts.

Two other forms of anthrax are recognized—the *gastro-intestinal* and the *thoracic*. In the former the infection has its starting-point in the gastro-intestinal tract. In this variety the constitutional symptoms are the first to attract attention, doubtless because the local process is concealed from view. They may be ushered in with a chill, but this is not constant. The leading characters of this form of infection are—great prostration; headache; nausea and vomiting; diarrhœa, the evacuations generally containing blood; colicky pains; and tenderness over the liver. Dyspnœa is often prominent. The patient rapidly falls into a state of collapse, the surface becomes cyanotic, and death is the inevitable result in the course of from two to seven days. Phlegmonous areas may appear on the surface, but the papule, vesicle, and eschar above described are not seen.

The thoracic variety of anthrax has received the name of wool-sorters' disease because of its prevalence among those whose business it is to handle wool. Previous to its recognition and description by Dr. Bell of Bradford, England, fatal cases of this disease were habitually registered as pneumonia, congestion of the lungs, and bronchitis. A chill or slight chilly sensations followed by great prostration, dyspnœa, rapid pulse, and vomiting are the earliest symptoms. The face becomes congested or cyanotic and the extremities cold or livid. There may be a copious hemorrhagic sputum, but expectoration is sometimes wanting. Mucous râles are often heard on auscultation, but the signs of pulmonary consolidation are wanting. The latter fact, taken in connection with the gravity of the general symptoms, should excite suspicions of the true nature of the disease. The thermometer in the axilla may register a normal or subnormal temperature, but placed in the rectum it will show the existence of decided fever—102° to 103°. The mind may remain clear to the last, or death may be preceded by delirium, coma, and convulsions.

The external *post-mortem appearances* consist of the above-described cutaneous lesions and of swelling and hemorrhagic infiltration of lymph-glands. The blood remains fluid and contains an abnormal number of white cells—leucocytosis. In addition, there are sub-serous ecchymoses, cloudy swelling of the cells of the liver and kidney, granular degeneration of the muscular fibres of the heart, swelling and softening of the spleen, intumescence of the intestinal follicles and of the mesenteric and retro-peritoneal glands, and localized œdema, ecchymosis, and loss of substance of the intestinal mucosa. The last-mentioned signs are the analogues of the cutaneous lesions, and may indicate the point of infection in cases of the gastro-intestinal variety.

The bacillus anthracis is found in the smaller blood-vessels throughout the body.

DIAGNOSIS.—The diagnosis is based upon known exposure to contagion, the detection of the anthrax bacillus in the contents of the pustule and in the œdema of infiltrated parts, and upon the results of inoculations in the lower animals—rabbits, guinea-pigs, and mice.

The PROGNOSIS, always grave, is most favorable when the point of inoculation is accessible to surgical treatment.

TREATMENT.—The treatment of anthrax is mostly surgical. A crucial incision should be made in the pustule and pure carbolic acid applied to the wounded surface; or carbolic acid in solution (50 centigrammes of the acid to 10 grammes of glycerin and water) may be injected around the point of inoculation. The actual cautery is preferred by others. Out of 40 cases treated in Buenos Ayres with the cautery, only 1 died.¹ Internally, carbolic acid, quinine, calomel, sodium salicylate, and other antiseptic drugs have been administered, and, it is claimed, with benefit.

Prophylaxis is of the utmost importance. The sad death of Hoffmann, pathologist to the General Hospital of Vienna, should serve as a warning to those engaged in experiments with the anthrax bacillus. "After using a hypodermic syringe for an experiment on animals, he sterilized it through a spirit flame and administered to himself an injection of morphia. Blood-poisoning followed, and numerous gangrenous spots developed over his body."—H.]

[Glanders (Farcy).

Glanders is a contagious and inoculable disease which prevails among the equidæ—horses, asses, and mules—but may be transmitted accidentally to other animals, excepting the hovidæ, and to man. Clinically, it presents itself under two forms, according to whether or not it attacks the nasal cavities. When the latter are involved the affection is known as glanders, whereas when the lesions are chiefly cutaneous it is called "farcy." It is an interesting fact that the contagiousness of this disease, which at the present day appears so manifest and so pronounced, has been contested from the beginning of the eighteenth century up to a comparatively recent period. Elliotson of England (1833) and Rayer of France (1837) were probably most instrumental in determining its contagious character.

The specific infectious agent of glanders is a bacillus which was isolated and cultivated at about the same time by Bouchard, Capitan, and Charrin in France and by Löffler and Schütz in Germany. It is from 2 to 5 μ long by from 0.5 μ to 1.4 μ in width, and is readily stained by aniline dyes in alkaline solution. It is destroyed in two minutes by a temperature of 100° C., and in fifteen minutes by a solution of corrosive sublimate of the strength of 1:1000. In a word, it offers little resistance to the ordinary microbicides, such as aëration, insolation, heat, and putrefaction. It invades by preference the lymphatic system, being present in very scanty numbers, and therefore found with great difficulty, in the blood, saliva, and urine. It has never been found in either the bile or the milk.

Man is generally infected by the horse, and therefore those most frequently attacked with glanders are grooms, coachmen, farmers, veterinary surgeons, cavalry soldiers, and others whose occupation brings them in close contact with this animal. Glanders has been communicated by the bite of an animal suffering from the disease, but infection does not invariably occur after such an injury. As is well known, Claude Bernard escaped the disease after being bitten by a glandered horse. As a general rule, infection occurs through inoculation of a wound or minute abrasion of the integument or mucous membrane, although an experiment of Babès tends to prove that the virus may penetrate the sound skin. This well-known bacteriologist induced glanders in guinea-pigs by rubbing their skins with a pomade containing the specific organism of the disease. Glanders has been acquired by drinking

¹ *Annual of the Universal Medical Sciences*, vol. iii., 1890.

water from the bucket used by a diseased horse and by blowing the nose with the cloth used to clean the animal's nostrils. The disease may be caused by the ingestion of meat contaminated with the secretions of an infected animal; this has been established experimentally, and is not refuted by the fact that such meat has been eaten with impunity. Experiments are opposed to the view that glanders may be acquired by inhalation of the infectious agent. As already stated, in the great majority of cases the disease is acquired by man from the horse, but a number of instances of its transmission from man to man are recorded.

SYMPTOMS.—When acquired by inoculation, the incubation stage lasts, as a rule, from three to five days; when acquired by infection—as, for example, by the ingestion of contaminated meat or water—this stage is longer, lasting, according to Roger,¹ from fourteen to twenty-five days. The disease may assume the form of glanders or farcy, and may be either acute or chronic.

Acute Glanders.—This variety may begin acutely, or the acute symptoms may be engrafted upon a chronic process. Profound prostration, chilly sensations or well-marked chills, headache, and anorexia are the first general symptoms. To them may soon be added pains in the limbs and joints, either vague and ill-defined or so localized as to resemble the pains of articular rheumatism. Before the onset of the above-mentioned symptoms the wound of inoculation may have cicatrized, or, on the other hand, it may be in an ulcerated condition. The face, hands, and feet are swollen, and often streaked with lines of redness corresponding to inflamed lymphatic vessels (lymphangitis), while the glands to which they lead are swollen and painful. The face is sometimes the seat of an erysipelatous inflammation which may extend to the scalp. The nose and cheeks are swollen, and from between the closed eyelids there exudes a puriform fluid. About the sixth day a purulent eruption generally appears. It is seated in the integument of the face and extremities and in the mucous membranes of the eyelids, nose, tongue, and fauces. The pustules are acuminate, surrounded by a red areola, and often rest upon an indurated base. They may be the starting-points of more or less extensive patches of gangrene.

Simultaneously with the eruption the characteristic symptoms of glanders make their appearance. They are chiefly referable to the nasal cavity, and consist of a sense of obstruction in this region accompanied with a mucopurulent discharge, generally blood-streaked, which, by contact with the nostrils and lips, gives rise to excoriations of these parts. When examined with the nasal speculum the mucous membrane of the nares is seen to be reddened, swollen, excoriated, and ulcerated. The ulcerations may involve the perichondrium, attack the bone, and lead to perforation of the nasal septum. The gums are swollen and ulcerated. The salivary glands and the lymphatic ganglia of the neck are tumefied and tender, and the latter may suppurate. The patient is annoyed with a frequent cough attended with a mucopurulent, fetid secretion, and signs of broncho-pneumonia may be detected in the bases of the lungs. The fever, at first slight, now rises to 104° or even higher, and its type is continuous. The pulse is small, weak, and frequent—from 100 to 150—and may be irregular. Nervous symptoms are now prominent; there are great restlessness and insomnia, and delirium, previously nocturnal, is now continuous. The urine is albuminous and contains leucine and tyrosine. Diarrhoea and vomiting are often prominent symptoms at this stage.

The duration of acute glanders depends upon whether the disease begins

¹ *Traité de Médecine publié sous la direction de MM. Charcot, Bouchard et Brissaud*, vol. i.

as such or is engrafted upon the chronic last for three or four weeks; in the latter

Chronic Glanders.—The symptoms are but are less intense and are subject to relapse. The symptoms are limited for the most part to the pharynx, and larynx, in which, or in the trachea, are first detected. There runs from the nose a discharge which dries in blackish crusts and obstructs, and the voice in consequence is rendered faint and hoarse or becomes a stridulous larynx. Cough is a frequent accompaniment, or to broncho-pneumonia.

The disease has succeeded to far advanced stages. The general symptoms are not so marked. The duration of chronic glanders is reported in which it has been known to recover ever takes place.

Acute Farcy.—The disease is characterized by those of acute pharyngitis and cutaneous abscesses, but the latter are more than purulent. The disease is characterized by redness and other symptoms.

The disease is characterized by the development of the most prominent feature is laryngeal spasm, which prevents the patient from swallowing water. The patient has a dread of swallowing it occasion violent paroxysms of suffocation, which are relieved by the use of opium. The association with these paroxysms gives rise to hydrophobia. After they have repeatedly been provoked the sight of water may be sufficient to provoke them; and in some cases the sound of water may be sufficient to provoke them. In the cases which I observed the patients were sometimes able to swallow other liquids. In one of the cases the patient was able to swallow spirit was taken without much inconvenience. The chief complaint was that water was taken from a teaspoon without excitement. The patient was able to take ice were taken without any inconvenience. The patient was able to attempt to swallow water are extremely violent. The patient is determined to drink precipitantly, and instantly the whole frame is agitated, terror and distress are manifested. The patient is unable to maintain the water is forcibly ejected from the mouth. In some cases paroxysms of laryngismus occur spontaneously. In some cases which I have noted they were repeated forty or fifty times in succession. The patient suddenly and quickly raising himself in bed, the spasm of the larynx is relieved, and in the intervals the respiration was hurried and the patient is free from paroxysms if he do not swallow liquids. A current of air may excite laryngeal spasm. The patient complains that it takes away his breath. A bright light, the sound of a mirror or any polished surface, and any mental excitement may excite the disease. The countenance expresses excitement, anxiety, and

parent cases. In one of the cases it lasted seven weeks, and in some cases it is cured. There is ground for believing that the disease is a case in which the disease is also when several years have elapsed. The first of these cases probably co-existed with the disease. The utmost possible duration of the disease is not known; and this is a point in the natural history of the disease which requires further reference to the anxiety of the patient. The disease is very rarely if ever less than eight or ten years. The disease is a gradual. It is stated that certain morbid symptoms precede other symptoms; but this is not so of all cases. There were no premonitions in the cases which I have observed. The premonitions of the disease are change of disposition, restlessness, mental depression, sleep, cephalalgia, chilly sensations, loss of appetite, and sometimes nausea. The disease is characterized by the distinctive characters of the disease. The disease is characterized by the development of the most prominent feature is laryngeal spasm, which prevents the patient from swallowing water. The patient has a dread of swallowing it occasion violent paroxysms of suffocation, which are relieved by the use of opium. The association with these paroxysms gives rise to hydrophobia. After they have repeatedly been provoked the sight of water may be sufficient to provoke them; and in some cases the sound of water may be sufficient to provoke them. In the cases which I observed the patients were sometimes able to swallow other liquids. In one of the cases the patient was able to swallow spirit was taken without much inconvenience. The chief complaint was that water was taken from a teaspoon without excitement. The patient was able to take ice were taken without any inconvenience. The patient was able to attempt to swallow water are extremely violent. The patient is determined to drink precipitantly, and instantly the whole frame is agitated, terror and distress are manifested. The patient is unable to maintain the water is forcibly ejected from the mouth. In some cases paroxysms of laryngismus occur spontaneously. In some cases which I have noted they were repeated forty or fifty times in succession. The patient suddenly and quickly raising himself in bed, the spasm of the larynx is relieved, and in the intervals the respiration was hurried and the patient is free from paroxysms if he do not swallow liquids. A current of air may excite laryngeal spasm. The patient complains that it takes away his breath. A bright light, the sound of a mirror or any polished surface, and any mental excitement may excite the disease. The countenance expresses excitement, anxiety, and

secretion of tenacious mucus from the fauces, together with a profuse flow of saliva, leading to frequent and sometimes almost constant expectoration. An examination of the throat shows the pharynx more or less reddened. At first, the mind is simply excited, but as the disease progresses delirium becomes developed. The patient is incoherently. Sometimes the delirium assumes the form of a mania. The mind acts under the influence of hallucinations, and forcible

DIAGNOSIS.—The occupation of the patient and known exposure to contagion are important factors in the diagnosis. Cases, however, are occasionally encountered in which a history of contact with infected animals is wanting.¹ The cutaneous lesions, as well as those of the nasal cavities, may be mistaken for manifestations of syphilis. In doubtful cases the secretions from the diseased parts should be tested by inoculation in rabbits or guinea-pigs, and should be examined both microscopically and by culture methods.

PROGNOSIS.—The prognosis varies in accordance with the course of the affection. Acute glanders is almost inevitably fatal. Chronic farcy is the most favorable form that the disease can assume, one-fourth, or, it is said, even one-third, of the cases recovering under proper treatment.

TREATMENT.—In case of direct contagion by inoculation, the wounded part should be excised or cauterized. For the latter purpose the actual cautery or the galvano-cautery is preferable to the mineral caustics. When the disease is fully developed, precautions should be taken to prevent the infection of others. Linen soiled with the secretions or discharges of the patient should be burned, and those in attendance upon the sick should make sure that there are no abrasions upon their skin through which the system might be infected. Abscesses and ulcers are to be treated upon general surgical principles, with the addition of measures to destroy the germs *in situ*. For example, after the opening of an abscess the resulting cavity should be thoroughly mopped with cotton saturated with creosote, iodine, or a strong solution of carbolic acid. Obstinate ulcers may be lightly touched with the actual cautery. The nasal cavities and the fauces should be sprayed with weak solutions of carbolic acid, sulphocarbonate of zinc, or nitrate of silver. Internally, phosphorus, arsenic, mercury, sulphur, and iodine have been administered with a view to a specific action upon the morbid process. Good results are claimed from the employment internally of the binarseniate of strychnia. In the chronic forms of the disease the strength is to be maintained by nutritious food, tonics, and stimulants.]

Rabies.

The affection called *rabies canina*, and more commonly known as *hydrophobia*, is due to the action of a special poison, a virus derived from the mouth of some animal of the canine or feline race—namely, the dog, wolf, fox, or cat. The virus is communicated by inoculation; that is, by the bite of an animal affected with the disease. An animal affected with the disease in this way communicates it to other animals, herbivorous as well as carnivorous. The former rarely communicate it, because they rarely bite other animals or man. That it may be communicated by herbivorous to carnivorous animals appears to be proven. The virus is contained in the fluids of the mouth, in the central nervous system, perhaps in the blood, and in other organs. It appears that the virus enters the body only by inoculation. It is not absorbed from the healthy cutaneous or mucous surface. It has been communicated from man to inferior animals by inoculation. The disease in man is much oftener derived from the dog than from any other animal; and hence the name *rabies canina*. Owing to the pains taken to confine or to destroy animals suspected of having the disease it is rarely seen in man. A few cases have come under my observation.

The disease does not make its appearance for some time after the bite. The usual period of incubation is stated to be from thirty to forty days.

¹ As in a case reported by Pepper, *Trans. Association American Physicians*, vol. vii.

There is considerable variation in this period in different cases. In one of the cases which I have observed the patient was bitten seven weeks, and in another case eight weeks, before the disease appeared. There is ground for distrusting the accuracy of statements as regards cases in which the disease is said to follow very quickly after the bite, and also when several years have been supposed to elapse. The error in the first of these cases probably consists in confounding the disease with tetanus. The utmost possible duration of the period of incubation cannot be stated; and this is a point in the natural history of the disease of no little consequence with reference to the anxiety of persons after having been bitten by an animal known or suspected to be rabid. It is probable that the period is very rarely if ever less than eight or ten days, and that it very rarely exceeds a year.

The development of the disease is gradual. It is stated that certain morbid sensations emanating from the cicatrized wound precede other symptoms; but if this be true of some it is certainly not so of all cases. There were no such premonitions in the cases which I have observed. The premonitions are—noticeable depression of spirits, so that this premonitory period has been called the *studium melancholicum*; change of disposition, restlessness, mental agitation, vigilance or disturbed sleep, cephalalgia, chilly sensations, loss of appetite, a sense of distress referred to the epigastrium, and sometimes nausea and vomiting. Two or three days elapse before the distinctive characters of the disease are fully declared.

When the disease is developed the most prominent feature is laryngeal spasm excited by the effort to swallow water. The patient has a dread of water because efforts to swallow it occasion violent paroxysms of suffocation, and are generally unsuccessful. The association with these paroxysms gives rise to the fear of water, or hydrophobia. After they have repeatedly been thus produced the mere sight of water may be sufficient to provoke them, but this is not always the case. In the cases which I observed the patients did not suffer any inconvenience from seeing water or hearing the sound of water. Patients are sometimes able to swallow other liquids. In one of the cases which I have noted spirit was taken without much inconvenience, and in another case at times water was taken from a teaspoon without exciting spasm. Pieces of ice were taken without any inconvenience. The paroxysms excited by attempting to swallow water are extremely violent. The patient with a nervous determination drinks precipitantly, and instantly respiration is arrested, the whole frame is agitated, terror and distress are depicted on the countenance, and the water is forcibly ejected from the mouth and nostrils. In some cases paroxysms of laryngismus occur spontaneously. In one of the cases which I have noted they were repeated forty or fifty times in an hour, the patient silently and quickly raising himself in bed, the spasm lasting a few seconds, and in the intervals the respiration was hurried and panting. In other cases the patient is free from paroxysms if he do not attempt to swallow liquids. A current of air may excite laryngeal spasm, and the patient complains that it takes away his breath. A bright light, the reflection from a mirror, many polished surfaces, and any mental excitement have the same effect. The countenance expresses excitement, anxiety, and terror.

A loud hoarse scream is sometimes heard from the fauces, together with a diminished flow of saliva, and at the throat and sometimes almost constant expectoration of frothy mucus. An examination of the throat shows the tonsils to be enlarged and inflamed. At first the mind is simply excited, but as the disease advances it becomes delirious. Delirium is developed. The patient loses consciousness, and the equilibrium assumes the form of a delirium tremens, with much tremor, and sometimes hallucinations, and forcible

restraint in some cases becomes necessary. There is no foundation for the vulgar notion that patients assume the character of the animal from which the virus was received and attempt to bite persons around them. In some cases delirium is manifested by excessive tenderness and affection. Satyriasis has been observed in males, and nymphomania in females.

Convulsions occur in a large proportion of cases. These are sometimes clonic, extending more or less over the voluntary muscular system, and they are sometimes tonic, as in tetanus. The pulse becomes frequent and small. Febrile movement does not belong to the history of the disease; the temperature of the body being increased but little or not at all. The surface presents capillary congestion, and is sometimes covered with clammy perspiration. The vital forces progressively fail: the patient is worn out with continued vigilance, the paroxysms of laryngismus, the convulsions, and innutrition; and the mode of dying is by asthenia.

Of all the diseases in the nosology, there is no one in which the intrinsic tendency to death is greater than in this. The disease runs a brief career, death usually taking place on the second or third day, and always within five days, after it has become fully developed.

Small hemorrhages are often found in the central nervous system after death from hydrophobia, but these are probably secondary. Of more importance, however, is the accumulation of small round cells, especially about the blood-vessels. These accumulations have been found with considerable constancy in the posterior half of the medulla oblongata, particularly at or near the deep origin of the nerves in this situation. Similar but less marked changes have been found in the cerebral cortex and elsewhere in the central nervous system. Hyaline metamorphosis of the vascular walls in the nervous centres has also been observed.

The diagnostic features of rabies are highly distinctive. It is distinguished from tetanus by the absence of trismus and the occurrence of delirium. In some cases of tetanus the deglutition of liquids is impossible; but the difficulty arises from spasm of the pharyngeal, not involving the laryngeal, muscles, the latter being affected in rabies. Moreover, convulsions occur at a late period in rabies, and the convulsions are tetanoid only in a certain proportion of cases. The only difficulty of diagnosis relates to the discrimination of cases of true rabies from those in which, to a greater or less extent, hydrophobic phenomena are simulated. Notable repugnance to liquids, susceptibility to currents of air and to light reflected from a mirror or some polished surface, frequent sputation, together with delirium and convulsions, are occasionally incident to various acute diseases; but the hydrophobic phenomena are especially simulated under intense apprehension of rabies after a bite has been inflicted by an animal suspected of being rabid. Excessive fear leads to the belief in the mind of the patient that the disease exists, and this belief leads to the production of certain of the phenomena, especially horror of liquids, delirium, and sometimes a fancied disposition to bite others. Among the points to be considered in this discrimination is the time which has elapsed after the bite. If the morbid phenomena occur immediately or quickly afterward, or, on the other hand, after a very long period, the reality of the disease is very doubtful. If it be evident that the horror of liquids is purely mental or dependent entirely on spasm of the pharynx, as in some cases of hysteria—in other words, if laryngeal spasm be excluded—the affection is not true rabies. The continuance of the hydrophobic phenomena is another point. If they continue for many days or weeks, the affection is not true rabies, for the latter affection ends fatally within five days. The opinion which some have entertained that rabies may be developed in man spontaneously probably has no foundation

other than the cases in which hydrophobic phenomena have been incidental to other diseases.

Of the great number and variety of remedies which have been tried for the cure of rabies, one only at the present time claims consideration. This remedy is curare. A few cases have been reported of the successful employment of this remedy administered by subcutaneous injection. There is room for doubt in these cases concerning the diagnosis, and hence other cases must be observed before it can be asserted positively that the remedy has proved in any instance successful. One of the cases reported as cured by this remedy came under my observation. The patient had been bitten by a dog undoubtedly rabid. A servant in the family was bitten by the same dog, and died with rabies. Many of the symptoms in the case which ended in recovery pointed to rabies, but hydrophobia was wanting.¹ In a case reported by Dr. Offenbergh of Wickrath (Rhein-Preussen) all the diagnostic symptoms, inclusive of hydrophobia, were apparently well marked. The patient, a maid-servant, had been bitten by a dog evidently rabid, and a member of the family in which she lived, having been bitten by the same dog, died with rabies. The curare was given in successive doses, as follows: two doses of 0.02 gramme (gr. $\frac{1}{8}$) after an interval of fifteen minutes; an hour after the last dose 0.03 gramme (gr. $\frac{1}{8}$), the latter repeated twice after an hour's interval, once after an interval of two hours and thirty minutes, and again after two hours and twenty minutes. Temporary general paresis was produced by the remedy.² This drug is of uncertain strength, and it must therefore be used with caution. Curare has repeatedly failed to exert any curative influence in hydrophobia.

There is no prophylactic treatment to be relied upon save excision or effectual cauterization of the wound as quickly as possible after it has been inflicted. Amputation of fingers or toes, and even of larger members, is advisable if the extent or character of the wound be such that the excision and cauterization cannot be effectually employed.

It is desirable, of course, to know whether an animal which has inflicted a wound be really rabid. Dogs and cats are often supposed to be rabid when they are affected with epilepsy or some disease other than rabies. It is a popular error that dogs are especially liable to become rabid during the so-called dog-days; that is, the hot months of summer. Cases are quite as likely to occur at other periods of the year. When rabies is suspected the animal should be confined, and not killed until the character of the disease is fully declared. Rabies in the dog is to be suspected when the animal manifests a notable change of habits, becoming shy and irritable, eating straw, bits of paper, etc., and refusing food. When the disease becomes developed the appearance is much changed. The look is depressed and haggard, the ears and tail droop, the quality of the bark is altered, the eyes are watery, the fauces are reddened, saliva flows from the mouth, and there is febrile movement. Dread of water is no test of the malady in the dog and other animals. They frequently lap water without difficulty. Delirium supervenes, and then the dog snaps at his master as well as others, and at any animal which comes in his way. He seldom becomes ferocious, but bites and runs away. He appears sometimes to have hallucinations and snaps at invisible objects. Convulsions may or may not occur. Death takes place usually within five days.

Persons bitten by an animal known to be rabid are by no means invariably

¹ Vide report of this case by Dr. B. A. Watson in *Am. Journ. of Med. Sciences*, July, 1876.

² For a translation of the history of this case, by Dr. S. W. Williams, with full details, vide *New York Med. Record*, Aug. 9, 1879.

affected with rabies, even if no preventive measures be resorted to. The chances of escape are a little more than three to one. The exemption may proceed from an insusceptibility to the poisonous action of the virus, but probably often, in those who escape, the inoculation does not take place. If the bite be inflicted through clothing, the virus will be likely to be wiped away from the teeth before they penetrate the skin. The inoculation is more likely to take place from the bite of the wolf than from that of the dog. Of 250 cases collected by Renault of persons bitten by the wolf, 164, about two-thirds, became affected by rabies.¹

At the present time (1886) great interest is aroused in a method of inoculation which is claimed by its discoverer, Pasteur, to be preventive of hydrophobia, and which was reported by him to the French Academy of Sciences in October, 1885. Pasteur was led to the adoption of this method by the following series of experiments on dogs and rabbits: If a portion of the brain-substance of a mad dog be injected beneath the dura mater of a rabbit, the latter animal is affected with a disease supposed to be hydrophobia after a period of incubation of fifteen days. Successive inoculations in a series of rabbits of portions of the spinal cord from rabbits dead of experimental hydrophobia cause a gradual diminution of the period of incubation, which after forty to fifty inoculations becomes only seven days, where it seems to remain without much further diminution. The spinal cord of these rabbits contains the hydrophobic virus. Preservation of these cords in dry, warm air leads to a gradual deterioration of the poison, which is finally extinguished. If dogs be subcutaneously inoculated, first with the weak virus (that is, with cords preserved for twelve or fifteen days), and then daily with progressively stronger virus, it is found that they acquire immunity against the strongest virus (that is, fresh cords from hydrophobic rabbits). Pasteur has had the opportunity of applying this method of preventive inoculation to a large number of human beings who have been bitten by animals supposed to be rabid. Up to the present time (June, 1886) of nearly 1000 persons thus inoculated, 8 have died of hydrophobia. Of the fatal cases, 5 were from hydrophobia following wolf-bites (out of 38 wolf-bitten persons treated by Pasteur).

The following considerations make it impossible at the present time to judge of the value of Pasteur's inoculations in human beings: It is not known what proportion of the patients treated by Pasteur were bitten by actually rabid animals, and it is probable that the proportion is not large. Of those bitten by rabid animals, in a considerable number of cases the wound soon after its reception was treated by excision and by cauterization and disinfection, and there is reason to believe that these measures are sometimes protective. Furthermore, it is established that of those bitten by rabid dogs a large number, probably at least two-thirds, never develop hydrophobia, even when no preventive treatment has been adopted. At the present writing the period of time allowed for incubation has not elapsed.²

[From 1886 to 1891, 9465 persons were inoculated at Pasteur's laboratory, of whom 90 died of hydrophobia, making a mortality of 0.95 per cent. These figures include all the deaths after the inoculation treatment. If from them there be subtracted the cases which died a few days after treatment—i. e. before the inoculations could have taken effect—the mortality amounts to

¹ Jaccoud, *op. cit.*

² There is not a strict analogy between Pasteur's experiments on dogs and his inoculations of human beings, as in the former the inoculations are made before, and in the latter after, the reception of the strong hydrophobic virus. (For a full description of Pasteur's methods, vide article by H. M. Biggs in the *N. Y. Med. Journ.*, March 27, 1886, and for a critical analysis of these methods and results, the remarks of A. Flint, Jr., in the same number of the *Journal*.)

only 0.61 per cent. A still further proof of the efficacy of these inoculations is afforded by the following facts: It is well known that the bite of a rabid dog is most serious when the head is the part injured. Of persons thus wounded, 80 per cent. perish, whereas of 710 such cases treated at the Pasteur Institute only 24 died, making a mortality of 3.38 per cent. In this estimate are included all the cases of head-wounds treated, not excepting those in which the symptoms broke out immediately after inoculation.¹

An extraordinary case has been recently reported by Murri of Bologna. The patient, a man æt. 22, developed well-marked symptoms of paralytic rabies while undergoing the usual inoculation treatment. Murri, finding this ineffectual, adopted the heroic expedient of injecting the emulsified nerve-tissue directly into the veins, the result being that the paralysis gradually disappeared and the patient recovered after a protracted convalescence.

Tizzoni has isolated from the blood of animals rendered immune from hydrophobia an antitoxin which appears to possess the protective properties of Pasteur's inoculation fluid, and which may be kept indefinitely so as to be available for immediate use. If Tizzoni's experiments are confirmed, the importance of his discovery can scarcely be over-estimated.—H.]
